Psychosocial Effects on Humoral Immunity: Neural and Neuroendocrine Mechanisms

VIRGINIA M. SANDERS, NICHOLAS KIN, AND GEORG PONGRATZ

A major goal over the past 30 years has been to establish not only the mechanisms by which immunophysiology is affected by the host response to psychosocial factors, but also the mechanisms by which *Psychophysiology* is affected by the host response to antigen. In this chapter, we will discuss the evidence that indicates a role for psychosocial factors in modulating the level of humoral-mediated defense mechanisms in the body and vice versa, as well as technical approaches used in experimental designs to measure the status of humoral immunity.

1. HISTORICAL CONTEXT

Our ability to combat the many microorganisms that gain entry into our bodies depends on an intact immune system that functions to recognize and eliminate the invading microorganisms to maintain homeostasis. It was first discovered that the immune mechanisms for defense included those that were not specific for any particular microorganism and those that were exquisitely specific for one microorganism over another. The most well-recognized non-specific mechanism involves the process of phagocytosis by macrophages, which prevents the spread of microorganisms from their point of entry into the host. However, a number of deadly organisms such as encapsulated pneumococci do not adhere well to phagocytic cells. It is thought that humoral immune mechanisms evolved to provide a soluble antibody molecule that specifically recognizes and binds to a particular bacteria to help it adhere more readily to phagocytic cells for more efficient phagocytosis and destruction. Likewise, for intracellular microorganisms such as viruses and parasites, specific humoral immune mechanisms evolved to neutralize the activity of these microorganisms before they entered cells. These humoral immune mechanisms are mediated by T and B lymphocytes that are able to use cell surface receptors to recognize invading microorganisms specifically, and with high affinity. A B cell that receives cell contact and cytokine help from a T cell will produce an antibody to either neutralize or destroy a low number of invading pathogens.

One of the earliest studies to suggest that a relationship existed between the immune status and mental state of an individual was a study in 1919, which showed that psychosocial factors imposed upon a host with pulmonary tuberculosis decreased the phagocytic capacity of cells within the blood to eliminate the pathogen (Ishigami, 1919). The findings from this study suggested that the high rate of death from tuberculosis in the Japanese young might be related to the depression that ensued from “over-taxation of the mind” by a school system that dictated severe entrance examinations and had overcrowded learning conditions. Although the finding from this study was pioneering, it was ignored by the scientific community for a number of years, but is now considered by some to be the first documented venture into the area of psychoneuroimmunology.

Other studies soon followed that showed a similar relationship between an individual's mental state and immune status. The high incidence of industrial workers succumbing to the common cold and pneumonia in the 1920s was the impetus for the design of studies to determine if a relationship existed between a worker's perception of fatigue and their susceptibility to infection. This possibility was first tested with rabbits, in which a state of fatigue increased disease susceptibility to, and mortality from, *Streptococcus pneumoniae* (Bailey, 1925). What was most interesting about this study was that the rabbits were made less susceptible to infection if they were routinely exercised before inducing a state of fatigue, a topic that will be discussed later in this chapter.

In 1936, Selye (Selye, 1936; 1946) introduced the concepts of stress and stressor. Stress was defined as a biological response to a noxious stimulus, such as heat or cold, that induced activation of the hypothalamic-pituitary-adrenal axis (HPA). Stressor was defined as the noxious stimulus itself. Selye described a myriad of structural changes that occurred during the biological response to stress, including the appearance of lymphoid organ atrophy. This finding was the first to relate a stress-induced change in HPA activity to a change in immune system architecture. Today, the list of stressors has expanded

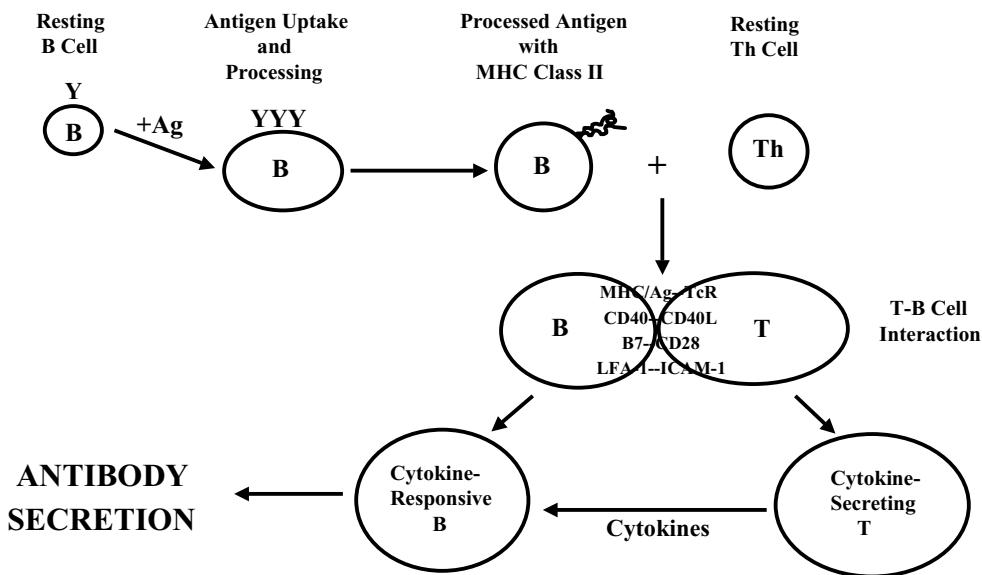

Figure 16.1. Diagram of the stages of T cell and B cell participation in the production of cytokines and antibodies. In this model the B cell binds, processes, and re-expresses antigen on the cell surface in association with MHC Class II molecules. The complex of MHC Class II and antigen is recognized by the T cell receptor associated with a resting Th cell. The presentation and recognition of MHC/antigen in conjunction with other T cell- and B cell-associated adhesion and costimulatory molecules allows a physical interaction to occur which is essential for the activation of both cells. The activation of these cells renders the Th cell capable of producing and secreting cytokines and the B cell capable of responding to the cytokines. As a result of cytokine stimulation of the activated B cell, the B cell is able to further differentiate into an antibody-secreting cell. In addition, the intracellular messengers generated as a consequence of cell activation are shown, as are the adhesion and costimulatory molecules that induce and strengthen the interaction between the T cell and B cell.

to include non-noxious stimuli, such as psychological stress.

By the 1960s, studies by Solomon and Moos showed that a relationship existed between psychological and immunological profiles of individuals afflicted with the immune-mediated disease rheumatoid arthritis (Solomon & Moos, 1964; Solomon & Moos, 1965). These studies introduced the concept that emotions could influence disease, introduced the area of psychoimmunology to the health science field, and, more importantly, emphasized the need for interdisciplinary approaches to (understanding the relationship between psychological factors and immunity). Some fifteen years later, a series of experiments were performed to show that humoral immune suppression could be conditioned (Ader & Cohen, 1975; Cohen et al., 1979). The latter studies are considered the cornerstone for the area of psychoneuroimmunology, providing the first experimental evidence to show that a link existed between a psychological process and immune system function.

The cellular, biochemical, and molecular mechanisms by which psychosocial factors affect humoral immune status is an area of active research. The endogenous molecules that most likely mediate effects on humoral immunity include neuroendocrine hormones, opioid peptides, neuropeptides, and sympathetic neurotransmitters. An understanding of the mechanisms by which these molecules modulate the level of humoral immunity and vice versa,

coupled with an increased availability of sensitive and reliable techniques to evaluate humoral immune status, will help us to define the relationship that exists between psychological and immunological states. Furthermore, any drug, disease, or psychosocial factor that either stimulates or inhibits hormone, neurotransmitter, or neuropeptide production and/or release might likewise be expected to alter the level of humoral immunity.

2. PHYSICAL CONTEXT

2.1. The T-helper cell-dependent antibody response

Figure 16.1 outlines the sequence of events leading to antibody production by a B cell, and these events are reviewed in detail elsewhere (Parker, 1993; Vitetta et al., 1989). This figure is presented not only to emphasize the complexity of the antibody response to antigen, but also to make clear that neuroendocrine hormones, opioid peptides, and neurotransmitters can regulate any cellular activity along this pathway, if the receptors for these modulators are expressed on the cells participating in the response. Initially, antigen is introduced into the immune system. The immunoglobulin (Ig) receptor expressed on the surface of the B cell, together with associated signaling molecules, is known as the B cell receptor (BCR). The Ig receptor binds

antigen, whereas the BCR complex transmits signals to the B cell interior. The capping of the antigen/BCR complex also triggers receptor endocytosis into endosomal compartments where antigen dissociates from the Ig molecule. Further processing of the antigen occurs in the lysosomal compartment to form small peptide fragments. These peptide fragments encounter Major Histocompatibility Complex Class II (MHCII) molecules as vesicles containing the peptides fuse with vesicles containing newly synthesized MHCII. The peptide/MHCII complex is then expressed on the B cell surface for presentation of the peptide antigen to the CD4⁺ T cell receptor (TCR), which is restricted to the recognition of that specific peptide in association with MHCII.

During the cell-cell interaction between the CD4⁺ T cell and B cell, the T cell not only activates the B cell, but also provides the cytokines necessary for B cell growth and differentiation into an antibody-secreting cell. Two CD4⁺ T cell subsets have been identified and are characterized by the cytokines they secrete following cellular activation. These cells are collectively referred to as T-helper (Th) cells. Th1 cells secrete interferon (IFN)-gamma and IL-2, whereas Th2 cells secrete IL-4, IL-5, IL-6, IL-10, and transforming growth factor (TGF)-beta. The cytokines are involved in determining the antibody isotype produced by B cells, that is, IFN-gamma-producing Th1 cells induce mouse B cells to produce IgG_{2a}, IL-4-producing Th2 cells induce mouse B cells to produce IgG₁ and IgE, and TGF-beta-producing Th2 cells induce B cells to produce IgA.

In addition to the TCR interaction with peptide/MHCII, the binding of CD86 (also known as B7-2) on the B cell to CD28 on the T cell is also important. CD28 is constitutively expressed on the Th cell. In contrast, CD86 is expressed at low levels on splenic B cells, but is upregulated following B cell activation. In addition, the interaction between CD40L on the T cell and constitutively expressed CD40 on the B cell plays an important role in regulating the process of antibody production by the B cell. In summary, the initial interaction between the B cell and Th cell is a critical event that determines if the B cell will differentiate into an antibody-secreting cell. Therefore, any factor that alters antigen recognition, binding, processing, or presentation by a B cell to a T cell, cell surface molecule expression on a Th cell/B cell, or cytokine production by a Th cell, will consequently result in a change in the level of antibody produced by a B cell.

2.2. Neuroendocrine hormones and immunity

Activation of the HPA is induced by physical stressor, as first suggested by Selye (Selye, 1936; Selye, 1946), and by psychological stressors, such as academic stress (Malarkey et al., 1995). An understanding of the mechanisms by which the HPA axis is activated to release various biological mediators, and the mechanisms by which these mediators influence immune responsiveness, is an area under

much investigation. The reader is referred to the following reviews for a more detailed discussion of the role of the HPA in immunity (Harbuz, 2003; Harbuz et al., 2003; Jessop, 2002; Webster & Sternberg, 2004; Webster et al., 2002) and to recent articles suggesting a role for the HPA axis in mood disorders (Muller et al., 2004) and depression/anxiety (Strohle & Holsboer, 2003).

Interleukin-1 (IL-1) is a biological molecule that is released by an activated immune cell. Interleukin-1 also increases the production of corticotrophin releasing hormone (CRH) by neurons located in the paraventricular nucleus of the hypothalamus. These neurons project through the median eminence and terminate on the hypophyseal portal vessels that transport CRH to the anterior pituitary to act as a potent secretagogue for adrenocorticotropin (ACTH). The adrenal cortex, in turn, responds to the ACTH by increasing the rate of secretion of glucocorticoids that exert a suppressive effect on humoral immunity, except for IgE. In addition, because the hypothalamus is an area within the CNS that controls efferent sympathetic nerve activity, an IL-1 β -induced increase in hypothalamic nerve activity and the level of CRH secretion from the hypothalamus (Akiyoshi et al., 1990; Chuluyan et al., 1992; Fleshner et al., 1995; Sapolsky et al., 1987) may also enhance the level of efferent sympathetic nerve activity and the rate of norepinephrine release in the periphery. For example, peripheral IL-1 β administration induced c-fos expression in CRH-producing cells in the paraventricular nucleus of the hypothalamus, suggesting that IL-1 β increased hypothalamic neuronal activity, which translated into an increase in efferent sympathetic nerve activity (Ericsson et al., 1994). The role played by the SNS in regulating humoral immunity will be discussed in the next section of this chapter.

Both T and B lymphocytes have been reported to release CRH protein and express CRH mRNA (Karakis et al., 1997). However, another finding suggested that the proposed CRH made by lymphocytes may actually be urocortin, which is a new member of the CRH family and which uses the same receptor as CRH to mediate an effect on cell activity (Bamberger et al., 1998). But in 2003, another group reported that immunoreactive CRH is produced within human T and B cells, and that this peptide was not urocortin (Baker et al., 2003), indicating that lymphocytes indeed produce CRH. Specific receptors for CRH are expressed on immune cells (Audhya et al., 1991; Smith et al., 1986; Webster et al., 1990). The effects of CRH on T cell function appear to be suppressive on cytokine production and cytokine receptor expression. (Singh, 1989; Singh & Leu, 1990). CRH exerts a suppressive effect on B cell proliferation (McGillis et al., 1989; Venihaki et al., 2003), and inhibits antibody production (Aebischer et al., 1994; Leu & Singh, 1993), possibly via an effect of CRH on accessory cells, as opposed to a direct effect on B cells themselves (Aebischer et al., 1994). When CRH is injected into the brain, IgG production in response

to a T cell-dependent antigen is suppressed (Friedman & Irwin, 2001; Irwin, 1993), reportedly through a mechanism that involves activation of the sympathetic nervous system (SNS) and stimulation of the beta-adrenergic receptor on B cells, as opposed to a direct effect of CRH. If CRH is over-expressed in mice, chronic activation of the HPA occurs, accompanied by a loss of B cells, decreased IgG production, and impaired isotype switching (Murray et al., 2001). In addition, CRH transgenic mice fail to form germinal centers that are critical for B cell antibody production, via a mechanism that appears to involve an effect on follicular dendritic cell function (Murray et al., 2004). Thus, the actions of CRH within the brain or in the periphery appear to suppress peripheral T and B cell functions that are important for the ultimate production of antibody by a B cell, either via a direct effect or via activation of the SNS.

Glucocorticoids inhibit antigen-specific antibody production after a primary immunization, but not after a secondary response (Wallgren et al., 1994). Also, various stressors, such as acute alcohol exposure (Han & Pruet, 1995) and inescapable shock (Fleshner et al., 1996) inhibit both cytokine and antibody production via a mechanism that partially involves an elevated level of glucocorticoids. However, it is interesting to note that glucocorticoids are not associated exclusively with immune suppression. Glucocorticoids appear to cause a shift to a Th2-slanted immune response, also as discussed in detail in recent reviews (Franchimont, 2004; Riccardi et al., 2002). This shift to a Th2 cytokine profile may be partially responsible for the enhancing effect of glucocorticoids on the level of IgE in individuals with asthma and atopy (Akdis et al., 1997; Kimata et al., 1995). For example, more Th2 cells making more IL-4 may induce more B cells to switch to the production of IgE. In addition, glucocorticoids may synergize with Th2 cell-derived IL-4 to increase the level of B cell isotype switching to IgE by a B cell (Jabara et al., 1991; Jabara et al., 1993; Wu et al., 1991), via a mechanism that involves an upregulation of CD40L on the Th2 cell to deliver a more intense activation/switching signal to the B cell via CD40 (Jabara et al., 2001). These findings suggest that the concentration of glucocorticoids at the site of action may be important. For example, the level of stress, an activity that induces glucocorticoid release, is an important factor that determines the effect that stress will induce on immunocompetence, with moderate stress increasing the level of immune responsiveness and intense stress decreasing it (Dhabhar, 2002; Weiss et al., 1989). On the other hand, a low level of glucocorticoid signaling, because of a decreased level of either the hormone, level or sensitivity of the receptor, or both, may also be detrimental during a stress-related circumstance, as has been discussed recently (Raison & Miller, 2003). Thus, any drug, disease, or psychosocial factor that either stimulates or inhibits CRH or glucocorticoid production/release might likewise be expected to alter the level of antibody-mediated immunity.

2.3. The sympathetic neurotransmitter norepinephrine and immunity

Over the years, four key discoveries documented that a link exists between the immune system and the SNS: (1) The discovery that the parenchyma of primary lymphoid organs, such as bone marrow and thymus (Bulloch & Pomerantz, 1984; Calvo, 1968; Felten et al., 1985; Williams & Felten, 1981) and secondary lymphoid organs, such as spleen, lymph nodes, gut-associated lymphoid tissue, and bronchiolar-associated lymphoid tissue (Butter et al., 1988; Reilly et al., 1976; Riegele, 1929; Williams & Felten, 1981; Williams et al., 1981) was innervated. These findings indicate that the anatomy existed for the neurotransmitter to be released within close proximity to the immune cells that were primarily responsible for generating an immune response against antigens; (2) The discovery that the sympathetic neurotransmitter norepinephrine was released from the sympathetic nerve terminals in the spleen upon the administration of either antigen or cytokine (Del Rey et al., 1981; Felten et al., 1987; Fuchs et al., 1988; Lorton et al., 1990; Shimizu et al., 1994); (3) The discovery that lymphoid cells expressed the beta-2-adrenergic receptor (β_2 AR) that could bind norepinephrine (Sanders et al., 2001), indicating that the machinery for transducing a norepinephrine signal directly to the immune cell was available; and 4) The discovery that norepinephrine regulated the level of T and B lymphocyte activity via a cAMP- and PKA-mediated mechanism (Madden et al., 1995), indicating a mechanism by which the brain was able to communicate with peripheral immune cells. These findings suggest that a mechanism exists to explain the antibody changes that occur when an individual is exposed to a psychosocial stressor that affects some component of SNS activation and/or beta-2-adrenergic receptor (β_2 AR) expression/function. This area of research has become quite exciting in recent years because of the data obtained using molecular tools to study cytokine and antibody immunobiology, techniques which will be discussed later in this chapter.

In vivo, norepinephrine depletion or administration of a non-selective β AR antagonist in adult animals either increases (Kruszewska et al., 1995) or decreases the T cell-dependent antibody response (Alaniz et al., 1999; Hall et al., 1982; Kasahara et al., 1977; Kohm & Sanders, 1999; Livnat et al., 1985), with the latter finding suggesting that norepinephrine enhances baseline immune cell activity and is necessary for maintaining an optimal level of antibody production *in vivo*. Likewise, results obtained *in vitro* support the finding that norepinephrine induces an enhancing effect on the level of antibody normally produced by a B cell *in vivo* (Burchiel & Melmon, 1979; Roper et al., 1990; Sanders & Munson, 1984a; Sanders & Munson, 1984b; Sanders & Powell-Oliver, 1992; Teh & Paetkau, 1976; Watson et al., 1973). To study this effect on a more mechanistic level *in vivo*, IgG₁ production and germinal center formation were found to decrease in *scid*

mice depleted of norepinephrine prior to reconstitution with Ag-specific Th2 cells and B cells, an effect that was reversed by the administration of a β_2 AR agonist (Kohm & Sanders, 1999).

In general, naive T cells and Th1 cells, but not Th2 cells, express the β_2 AR as determined by radioligand binding, immunofluorescence, mRNA analysis, and cell function analysis (Ramer-Quinn et al., 1997; Sanders et al., 1997; Swanson et al., 2001). Resting B lymphocytes preferentially express the β_2 AR, also {#3958; #1066; #1013; #8; #2649}. For a more detailed review of β_2 AR expression by immune cell subsets, the reader is referred to the following comprehensive review article (Sanders et al., 2001). Classically, stimulation of the β_2 AR initiates an intracellular signaling cascade leading to adenylyl cyclase activation, cAMP accumulation, and PKA activation. An increased level of intracellular cAMP decreased the level of IFN- γ production by an unfractionated population of CD4+ T cells (Betz & Fox, 1991; Borger et al., 1998; Paul-Eugene et al., 1992; Snijdewint et al., 1993; Van der Pouw-Kraan et al., 1992) and the β_2 AR-selective agonist terbutaline decreased the level of IFN- γ by resting and activated Th1 cells (Ramer-Quinn et al., 1997; Sanders et al., 1997). In contrast, when naive CD4+ T cells were exposed to norepinephrine at the time of naïve T cell activation under conditions that promoted the development of Th1 cells, the progeny Th1 cells produced higher levels of IFN- γ upon restimulation with antigen in comparison to progeny Th1 cells generated in the absence of norepinephrine (Swanson et al., 2001). The β_2 AR-selective agonist terbutaline failed to affect the level of IL-4 production by either unsorted CD4+ T cells or Th2 cell clones, likely because Th2 cells do not express the β_2 AR (Sanders et al., 1997). Therefore, norepinephrine may selectively influence naive and Th1 cell cytokine production, but not that by Th2 cells.

β_2 AR stimulation on a CD40L/IL-4-activated B cell *in vitro* was found to increase the rate of mature IgG1 transcription, without affecting class switch recombination to IgG1 or mature IgG1 transcript stability (Podojil & Sanders, 2003). This result was supported *in vivo* when norepinephrine depletion or administration of an antagonist decreased the serum level of Th2-dependent IgG1, disrupted formation of germinal centers in the spleen, and decreased the level of antigen-induced CD86 expression on B cells (Kohm & Sanders, 1999). Because the Th2 cell does not appear to express the β_2 AR (Sanders et al., 1997), the effect of norepinephrine on the level of IgG1 produced by a B cell *in vivo* appears to be a direct one.

CD86 is a costimulatory molecule on the B cell, which appears to serve two functions. First, CD86-mediated stimulation of CD28 expressed on the surface of T cells exerts a critical regulatory influence on T cell cytokine production and surface molecule expression, thus indirectly influencing B cell function by modulating the level of "help" that the B cell receives from a T cell. Second, stimulation of

CD86 sends a signal directly into the B cell to regulate the level of antibody production (Kasprowicz et al., 2000). β_2 AR stimulation on a B cell was reported to increase the level of CD86 expressed on, and IgG1 produced by, a B cell (Kasprowicz et al., 2000), and the β_2 AR-induced upregulation of CD86 is dependent on the activation of NF- κ B (Kohm et al., 2002). The mechanism by which this effect occurs appears to involve a CD86- and β_2 AR-induced increase in B cell expression of the transcription factor Oct-2 and its coactivator OCA-B, respectively, as well as the binding of each protein to the 3'-IgH enhancer region (Podojil et al., 2004), a region of the genome that regulates the rate at which IgG1 is produced. Taken together, these findings suggest that an immune receptor-induced signaling pathway induced by CD86 may cooperate with a nervous system receptor-induced signaling pathway induced by the β_2 AR to regulate the rate of mature IgG1 transcription.

Taken together, psychological responses that involve activation of components of the CNS, such as the HPA, or the SNS, may affect immune cell activity via endogenous molecules released by these organ systems and, thus, induce the immune changes that are often associated with individuals experiencing various psychological responses to a variety of psychological factors.

3. SOCIAL CONTEXT

3.1. Psychological factors: Association with changes in parameters of humoral immunity

A number of studies have shown that a correlation exists between factors that alter psychophysiological states, such as mood alterations, depression, and acute/chronic stress with changes in the humoral arm of the immune system. It is important to note that most of these studies have measured the level of antibody produced against the endogenous latent herpesvirus, Epstein-Barr virus (EBV), or the exogenous influenza virus. Epstein-Barr virus is a latent virus that requires an intact cell-mediated immune response to maintain control over its expression, although, a rise in anti-herpesvirus antibody is often measured as an indicator that a cell-mediated immune response may be compromised in an infected individual. Nonetheless, for both EBV and influenza virus, the antibody response that develops is used to reflect the ability of B cells to produce antibody against the viruses, with the help of CD4+ T cells. Thus, an assessment of humoral immune status can be used as an indicator of the status of both Th and B lymphocyte immunity at a given time point in time during the response to a stressor. Although some limitations exist with these studies, a review of their findings is necessary in order to formulate educated hypotheses about the impact that psychophysiological factors may have on immune interactions that must occur for the generation of a humoral immune response against antigen.

3.1.1. Stress

A number of excellent review articles have summarized the findings indicating that a connection exists between stress and immunity (Black, 2002; Marsland et al., 2002; Padgett & Glaser, 2003; Segerstrom & Miller, 2004; Yang & Glaser, 2002). A particularly enlightening meta-analytic study of 30 years of inquiry summarizes how the degree of stress – subacute, acute, and chronic – differentially affected different aspects of cellular and humoral immunity, and that age and disease played a role in modulating the effect induced (Segerstrom & Miller, 2004). The following summary focuses on the key findings with regard to the effect of stress on humoral immunity.

A number of studies indicated that psychological and physical stress increases the susceptibility of animals and humans to microbial and viral pathogens (Sanders, 2000). In animals, a number of stress paradigms were used to study the relationship between stress and humoral immunity. For example, the stress of crowding and heat (Beard & Mitchell, 1987; Edwards & Dean, 1977; Mashaly et al., 2004), restraint stress (Feng et al., 1991; Yorty & Bonneau, 2003; Yorty & Bonneau, 2004), forced exercise (Reyes & Lerner, 1976), and electric shock (Cao et al., 2004; Kusnecov et al., 1992) significantly delayed the development of antibody production. In contrast, a few studies using a stress and viral infection model system showed either no change or an increase in anti-viral antibody responses (Beard & Mitchell, 1987; Chang & Rasmussen, 1965; Yamada et al., 1964). However, as suggested by two other studies (Feng et al., 1991; McLean, 1982), stress may delay anti-viral antibody production and, hence, the effect of stress on humoral immune status could be misinterpreted if the antibody production is measured at only one point in time. Thus, although the cumulative antibody level generated against a pathogen may be unchanged in stressed individuals, the rate at which these antibodies are made may be the difference between an individual's ability to mount an early antibody response against a viral infection.

In humans, the majority of studies on the effects of stress on the humoral immune response have used natural stress paradigms, such as academic examinations stress, bereavement, stress associated with HIV-1 infection, and stress due to caring for a patient with progressive dementia. The majority of results obtained in these paradigms suggest that stress reduces humoral immunity; however, a few contradictory results have been obtained. The secretory immune system and, in particular secretory IgA (sIgA) that is present in mucosal membranes, provides the body with a first line of defense against invading pathogens. In a pioneering 1983 study, the effect of academic stress was examined in 64-first year dental students (Jemmott et al., 1983). The results showed that sIgA secretion rates were diminished from baseline during high-stress periods as compared to low-stress periods. In addition, the inter-individual responses revealed secretion of IgA was elevated at all time points in subjects who showed a great need to

establish and maintain warm personal relationships. In contrast to all other subjects, in those students who exhibited an inhibited need for power, the IgA secretion did not return to baseline and continued to decline through the final low-stress period.

However, the type of academic stressor may have been the important factor that determined whether a change in salivary sIgA occurred during a given test period. Recent studies using a variety of acute academic stressors showed that significant increases (Ring et al., 2000; Willemse et al., 1998; Willemse et al., 2000) and decreases (Deinzer et al., 2000) occurred in the level of sIgA before and after a stressful academic activity. For example, one study showed that no significant change occurred in the sIgA levels of students before and after a *written* examination, but that a significant increase occurred after an *oral* presentation (Lowe et al., 2000). Another study recently confirmed that a written exam did not increase sIgA levels, and extended this finding to show that no change occurred in sIgA before the exam when perceived stress and cortisol levels were high (Ng et al., 2003). More recent results show that salivary samples from female students experiencing stress during exams had higher levels of EBV-specific IgG and IgA (Sarid et al., 2004) and that students with positive personality traits, with or without hypnosis, exhibited greater immune competence as indicated by T and B cell counts (Gruzelier et al., 2001). These findings suggest that the type of a specific academic stressor may induce changes in sIgA levels that are not necessarily reflected by the level of perceived stress or the stress-related changes in cortisol.

In addition to a change in salivary IgA levels, the effect of academic stress on the ability to mount an immune response to a hepatitis B vaccination was studied in 48 medical students (Glaser et al., 1992). In this study, students were administered a series of three hepatitis B vaccinations over an extended period of examinations. To assess the levels of perceived psychological stress, the students filled out a Profile of Mood States (POMS), Perceived Stress Scale (PSS), and an Interpersonal Support Evaluation List (ISEL). Results of this study revealed that although all of the students had seroconverted at the six-month interval, only 25% of the students had seroconverted at the one-month interval. Further analysis of the perceived psychological stress data revealed that the students who seroconverted at one month were significantly less anxious than those who seroconverted later. Thus, stress may delay the production of antibody in response to viral antigen challenge, suggesting that it may be important to monitor seroconversion in individuals who are experiencing stress, such as healthcare workers starting a new job, military personnel who are being transferred overseas, or elderly people who are moving to group care facilities, before exposing them to situations that increase their exposure to potential pathogens.

Consistent with the above study, a recombinant DNA hepatitis vaccine was utilized to assess the effects of perceived psychological stress on vaccination efficacy in

medical students (Jabaaij et al., 1993). The effects of stress on both the initiation phase and the boost phase were examined. Results of this study also showed that stress reported at month 2 during the initiation phase of the immune response had a negative influence on antibody production. Another study indicated that the perception of mild, intermittent stress affected long-term maintenance of an antibody response against influenza virus in healthy adults (Burns et al., 2003). However, a more recent study showed that perceived stress either a few days before, or at the time of, influenza virus vaccination were not associated with a change in the antibody response, but that perceived stress 10 days after vaccination appeared to associate with a change in the antibody response, independently of other variables such as cortisol levels (Miller et al., 2004). Thus, perceived stress may play a role in the development and/or maintenance of an anti-viral antibody response.

Another recent study (Burns et al., 2002b) using undergraduate students who had received a series of EBV vaccinations showed that, in students performing an arithmetic task, salivary cortisol levels were higher in those students with high serum EBV antibody titers when compared to those with low titers. In contrast, using cardiac reactions as an indicator of SNS activation, reactions were greater in those students with low antibody titers. Taken together, this pattern of results suggested that both the HPA axis and the SNS are involved in regulating immune status following EBV vaccination, although the exact mechanism responsible for mediating the observed effects remain unclear. These findings lend some support to results from a subsequent study indicating that participants with above normal stress exposures were at a greater risk of having a low antibody titer against EBV (Burns et al., 2002a).

The effects of chronic stress associated with caregiving have also been studied. Caregivers of a relative with a progressive dementia experience high levels of distress and produce high levels of antibody against the endogenous latent herpesvirus (Kiecolt-Glaser et al., 1991; Kiecolt-Glaser et al., 1987). On the other hand, if exposed to an exogenous virus, such as influenza, the caregiver tends to produce less antibody than sex-, age-, and socioeconomically matched controls (Kiecolt-Glaser et al., 1996). Likewise, elderly caregivers of spouses with dementia showed an increase level of HPA activation, as indicated by salivary cortisol levels, and a decreased anti-HBV IgG response to influenza vaccine (Vedhara et al., 1999). However, when elderly caregivers received cognitive-behavioral stress management intervention, an increase in anti-influenza IgG was noted when compared to caregivers without intervention and non-caregivers (Vedhara et al., 2003). In contrast, young caregivers of spouses with multiple sclerosis showed no signs of immune suppression or enhancement, as measured by anti-influenza antibody titers and IFN-gamma/IL-4 levels (Vedhara et al., 2002). However, one study reported that no change occurred between young and elderly adults in their ability to develop increased levels of anti-influenza antibody (Brydak et al.,

2003). In response to a pneumococcal bacterial vaccine, the IgG antibody response in spousal caregivers is also decreased when compared to controls (Glaser et al., 2000). Thus, these findings suggest that differences may exist between caregivers due to age and/or the psychological burden associated with caring for spouses with different diseases.

In a study to examine the effects of stress on the ability to develop an immune response to a novel antigen (Snyder et al., 1990), women were immunized with the novel antigen keyhole limpet hemocyanin (KLH) and serum IgG was measured before immunization, 3 weeks following immunization, and at 8 weeks following immunization. Although the correlations were not significant, specific trends for antibody production were noted. First, more stressful events, either good or bad, were correlated with lower antigen-specific IgG at 3 weeks. Second, more good stressful events correlated with higher levels of IgG at 8 weeks. And third, women who reported more bad stressful events exhibited lower IgG at 8 weeks.

One commonly occurring stressful event is conjugal bereavement. Results of one study revealed that although there were no differences in T and B cell counts at one or two months after the spouse's death, cell proliferation in response to mitogens was significantly decreased (Schleifer et al., 1983). The results from this study suggested that suppression of mitogen-induced lymphocyte proliferation was a direct consequence of bereavement and not a consequence of major changes in diet, activity levels, alcohol, tobacco, drug use, or weight changes following death of a spouse. Although serum Ig levels were not reported in this study, the decreased proliferation to PWM, a mitogen that stimulates both B and T cells, suggests that the stress of bereavement may decrease both T and B cell function.

In a pilot study of 11 asymptomatic HIV-1 seropositive men, the effect of life stressors and coping style on CD4⁺ T cell numbers was assessed (Goodkin et al., 1992). Results of this study indicated that a significant correlation existed between the occurrence of a major life stressor over the previous year and total lymphocyte count. In addition, the low stress groups had higher CD4⁺ T cell counts than did high stress groups. Thus, the stress associated with HIV-1 infection may alter an individual's CD4⁺ Th cell population, which, in turn, could eventually lead to a decreased level of antibody production from the B cells that rely on CD4⁺ Th cells for "help." A more recent study showed that cognitive-behavioral stress management in HIV-infected men produced short-term increases in anti-herpesvirus IgG that were accompanied by a decrease in urinary cortisol and norepinephrine levels, as well as a reduction in the symptoms of depression (Antoni, 2003b). More details on this specific area of research can be found in the following comprehensive review (Antoni, 2003a).

In conclusion, the majority of studies presented above indicate that stress has a dampening effect on the humoral immune response in humans, but that the type of stress,

the level of stress perception, age, and the inclusion of intervention therapy, may profoundly affect the response. At present, the mechanisms whereby stress leads to either a delay in the mounting of an antibody response or a decrease in the levels of antibody produced overall are unclear. This is where translational studies that are designed to relate basic science findings from mice and humans into one study will move the field forward, as suggested in one review on norepinephrine, beta-adrenergic receptors, and immunity (Sanders & Straub, 2002).

3.1.2. Mood

On a daily basis, humans are subjected to a variety of positive and negative experiences that have mood altering consequences, such as accomplishing a task, getting a promotion at work, losing keys, or having an argument with a loved one. A tight relationship between stress and the regulation of immune function has been documented in many studies (see [previous section](#) on stress) but less is known about the influence of the hedonic tone on immune function. Hedonic tone or mood states affect our daily lives and can be manipulated easily by conscious recall of emotional situations (Futterman et al., 1992). A within-subject analysis strategy was utilized to assess the effect that daily mood changes have on sIgA production to a novel antigen (Stone et al., 1987). Subjects in the study were orally administered a novel protein antigen and were asked to keep a daily diary. For a period of 8 weeks, sIgA that was specific for the novel antigen was measured 3 times a week from parotid saliva. The results of this study indicated that the level of sIgA directed against a novel antigen was lower on days in which daily diaries reported a high negative mood as compared to higher levels on days in which diaries reported a high positive mood. These studies were further confirmed in 1994 with a larger sample size ($n = 96$) over a 12-week sampling period (Stone et al., 1994). In 2004, a study reported that depressed and non-depressed female Japanese undergraduates, who were required to either write about unpleasant experiences or suppress their emotional response about them, showed differential regulation of sIgA levels in saliva (Takagi & Ohira, 2004). For example, writing about negative experiences was positively correlated to improved mood states in both depressed and non-depressed subjects. However, writing about negative emotions increased sIgA selectively in the depressed group only. Also, in a study undertaken with 105 students from Florida, who lived in neighborhoods more or less damaged by hurricane Andrew, the severity of disaster the subject has gone through was found to inversely correlate with sIgA levels (Rotton & Dubitsky, 2002).

A second strategy to assess the possibility that daily mood changes influence humoral immune status involved a process that "artificially" induces alterations in mood state in a laboratory setting. Results show that sIgA in saliva increases following the viewing of humorous videotape. In addition, female viewers who watched non-humorous videotape, and then wept openly, showed a

significant decrease in sIgA when compared to subjects who did not weep openly (Labott et al., 1990). Another study was done to investigate whether negative or positive mood induction has a short-term influence on the rate of sIgA secretion (Hucklebridge et al., 2000). Surprisingly, both negative and positive mood states were correlated with an increase in sIgA concentration as well as sIgA secretion rate. In this study, the change in sIgA secretion rate and concentration were observed within minutes of mood manipulation, suggesting that the effect was on the transepithelial secretory process rather than an effect on B-cell function directly. Interpreting these data can be difficult as many parameters are able to influence sIgA levels. For example, the activation state of the autonomic nervous system has been shown to directly control transepithelial sIgA transport in the submandibular salivary gland of the rat (Carpenter et al., 1998) and sIgA concentration and rate of secretion parallels the diurnal pattern of cortisol with a declining phase in the morning (Hucklebridge et al., 1998; Zeier et al., 1996).

Interestingly, mood changes provoked by watching a humorous video (laughter) compared to watching a non-humorous video about weather information were found to differentially affect immunoglobulin isotype pattern generated in patients with atopic keratoconjunctivitis (Kimata, 2004). After watching the humorous video, cedar pollen-specific IgE, as well as IgG4, was decreased, whereas cedar pollen-specific IgA levels were increased in the tears. This group was also able to show that the decrease in allergen specific IgE measured whereas watching humorous films improved bronchial hyperresponsiveness in patients with allergic asthma. Pathophysiological relevance was demonstrated in a study investigating the role of emotional style on susceptibility to two strains of rhinoviruses that cause the common cold (Cohen et al., 2003). The data showed that an increased tendency to experience positive emotions was associated with a decreased susceptibility to both strains of virus, but not vice versa (Cohen et al., 2003). In addition to providing new information about a relationship between psychological factors and the level of humoral immunity, these types of studies may be very important therapeutically. For example, if creating a positive mood change with either a humorous video or through recall of positive events either enhances sIgA or decreases allergen-specific IgE production, then these types of mood altering strategies may be useful in obtaining an increased level of protection against viral and bacterial pathogens, as well as a decrease in the severity of allergic symptoms.

3.1.3. Depression

Results from previous studies designed to examine immune parameters in depression are somewhat conflicting (Stein et al., 1991). Much of this conflict may be due to an inadequate number of controls. Therefore, for ease of presentation, a series of well controlled studies will be presented, starting with those showing a correlation with immune suppression. A 1984 study examined

eighteen patients hospitalized for major depressive disorder (Schleifer et al., 1984). Blood samples were taken from patients and controls and the absolute number of B and T cells, the percentage of B and T cells, and the ability of PBMC to proliferate in response to three mitogens was assessed. Results of this study showed that depressed patients exhibited decreases in all parameters measured. Thus, this early study indicated that the level of depression correlated with immune suppression.

When the Flinders sensitive line (FSL) rat, which is used as a genetic animal model of depression, was compared to the Flinders resistant line (FRL) rat used as controls depressive rats showed no change in the Th2 cell-dependent IgG1 response to KLH, but a decrease in the Th1 cell-dependent IgG2a (Friedman et al., 2002). In addition, IFN-gamma production was decreased in splenocytes obtained from immunized FLS rats compared to FRL rats after restimulation with KLH in vitro. In mice, chronic sequential exposure to a mild stressor can mimic symptoms of depression and was used to investigate the role of depression in T-cell independent versus T-cell dependent antibody responses (Silberman et al., 2004). After 6 weeks, stressor-exposed mice showed a significant decrease in T cell-dependent antibody production compared to non-exposed mice. Further, the authors were able to show that T cells obtained from stressor-treated animals were more sensitive to inhibitory signals delivered by corticosterone. Another study demonstrated that a direct link existed between major depression in humans and the level of cellular immunity against varicella-zoster-virus. The VZV-specific responder cell frequency in major depressed patients ($n = 11$) was significantly reduced compared to healthy controls ($n = 11$) of same age and sex implicating reduced VZV-specific cellular immunity in depressed individuals (Irwin et al., 1998). Thus, the majority of findings suggested that a state of immunosuppression exists in depressed individuals.

In contrast, another study showed that minor and major depressed patients have significantly higher serum antibody titers to the autoantigens phosphatidylserine and thromboplastin, as compared to non-depressed controls (Maes et al., 1993). To clearly address the possible correlation between depression and humoral immunity, further experimentation is necessary. To obtain a clearer picture, these experimental designs should include an analysis of complete antibody isotype profiles, a measurement of T cell cytokine profiles, and flow cytometric analysis of all CD4+ and B lymphocyte subsets. It is important that all of these parameters be measured in the same patient, and that repeated measures be taken over time to examine the possibility that the immune changes measured may be due to other psychological variables, such as daily mood changes. It will also be important to measure neuroendocrine parameters in parallel with measurements of immune parameters. Previous studies indicated that a number of neuroendocrine changes are present in some depressed patients, including alterations in CNS

neurotransmitter function, as measured by alterations in metabolites of both norepinephrine and serotonin in blood, CSF, and urine (Zis & Goodwin, 1982), abnormalities in the HPA axis, as measured by blunted ACTH responses to CRH (Gold et al., 1984; Gold et al., 1988; Sachar, 1982), and abnormalities in autonomic nervous system function, as measured by changes in plasma catecholamine levels (Potter, 1984; Rudorfer et al., 1985). In a recent study, the humoral response and the role of catecholamines and corticosterone were analyzed in a chronic mild stress model of depression in mice (Silberman et al., 2004). Although the T cell-dependent antibody response was decreased, the change did not appear to correlate with any changes induced in norepinephrine or glucocorticoids, but did appear to correlate with the sensitivity of receptors on T cells for the neurotransmitter and hormone. It is also important that age-matched controls be utilized in all analyses. As discussed earlier, some of the conflicts in the interpretation of the data collected thus far may be due to the different methods used to categorize depressed patients. Thus, a study that utilizes different depression categorization methods may provide useful information. Although many previous studies have not included patients with unipolar and bipolar depression because studies would provide a better understanding of the effects of depression on humoral immunity. Finally, depression and humoral immunity should be evaluated in patients involved in drug and behavior therapy programs to determine if treatments that decrease depressive symptoms concomitantly change neuroendocrine and humoral immune parameters.

Two scenarios emerge upon review of previous studies that were designed to examine if a correlation existed between depression and the level of humoral immunity. Studies revealed that the level of depression correlated with either immune suppression or enhancement. Although these two scenarios are somewhat opposite to each other, both scenarios indicate that changes occur in immune status when an individual becomes depressed. It is possible that some of the differences between the two scenarios are due to the methods utilized to classify depressed patients, especially because those who showed immunosuppression were categorized for depression based on Research Diagnostic Criteria (RDC), whereas the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) rating system was used to categorize patients who showed immunoenhancement. In addition, the studies that suggest the level of depression correlated with immune enhancement utilized two-color flow cytometric analysis, a technique that may be more sensitive than the rosette formation technique utilized in the other studies that reported immune suppression.

3.2. Psychological intervention

Psychological factors, such as mood, depression, and stress, may have a negative impact on the humoral immune system. This suggests that psychological intervention may

have beneficial effects on humoral immunity. A few intervention strategies that are commonly used in the area of psychotherapy include relaxation techniques, exercise, classical conditioning, and self-disclosure. In addition, the degree of social support and personal coping styles are often important factors in effective psychotherapy. Although the effects that these types of psychotherapies have on humoral immunity have not been examined mechanistically, the studies conducted thus far suggest that psychological intervention therapies may provide beneficial effects, particularly in individuals who have dampened humoral immune responses due to age or HIV-1 infection.

3.2.1. Relaxation

Two studies indicated that relaxation has a positive effect on the humoral immune system in humans. In the first study, salivary sIgA and serum antibody levels were examined in either control subjects or in subjects that practiced a daily relaxation technique (Green et al., 1988a). Results of this study indicated that following the first relaxation session, sIgA was significantly higher in the relaxation group than in controls. In addition to sIgA, serum IgA, IgG, and IgM levels also increased during the relaxation-training period in the relaxation subjects. In a second study, the effect of relaxation on changes in T helper cell percentages during examination stress was examined (Kiecolt-Glaser et al., 1986). Results of this study indicated that the percentage of T helper cells decreased during examination periods in both the relaxation group and controls. However, further analysis revealed that not all students practiced the relaxation technique with the same frequency (range 5 to 50 times). Thus, a regression analysis revealed that an increased frequency of relaxation practice was associated with a higher percentage of T helper cells in the blood during examinations. A more recent study showed that daily relaxation increased salivary IgA secretion rate after 20 min of relaxation, and was higher in individuals who practiced relaxation for a few weeks prior to saliva sampling (Green et al., 1988b). Serum IgA, IgG, and IgM also increased over the relaxation practice period. Likewise, in newspaper room workers supplied with soothing music during stressful periods, salivary IgA was increased as the level of stress decreased (Brennan & Charnetski, 2000). In addition, the effect of a 10-week cognitive-behavioral stress management intervention on the level of anti-HSV-2 IgG titers in a group of mildly symptomatic HIV-infected gay men showed that the level of cortisol and IgG were reduced in the stress management group, and that home relaxation practice in the stress management group reduced the cortisol and IgG titers even more (Cruess et al., 2000).

3.2.2. Exercise

Previous studies indicate that exercise has a beneficial effect on psychophysiological well-being (Callaghan, 2004; Guszkowska, 2004). Acute or moderate exercise is associated with a decrease in anxiety state and mood alterations.

Studies that examined the effects of long-term exercise programs showed positive effects of exercise in healthy people and in clinical populations, regardless of gender or age (Guszkowska, 2004). The beneficial effects of long-term exercise programs include a reduction in anxiety, depression, and negative mood, accompanied by improvements in self-esteem and cognitive functioning (Callaghan, 2004).

Findings from studies on psychoneuroimmune interactions suggested that stress, mood, anxiety, and depression altered the level of humoral immunity. For example, indicators of negative affective style, including differences in brain electrical measures of activation asymmetry and magnitude of emotion-modulated startle, were found to predict when a weak antibody response to influenza vaccination would occur (Rosenkranz et al., 2003), suggesting that a relationship existed between negative affective style and the ability to produce antibody in vivo. Thus, therapies such as exercise, which reduce the severity of these affective states, may also alter the level of humoral immunity. Other examples include studies showing that regular physical activity in older men was associated with a more robust primary immune response (Smith et al., 2004) and that a regular routine of moderate, physical activity may prevent detrimental stress-induced neuroendocrine and immunological effects (Fleshner, 2000).

One review of previous studies suggested that either brief graded-maximal or short-term submaximal exercise was associated with increases in serum antibody (Nieman, 1991). For example, two studies utilizing moderate exercise training showed that moderate exercise – walking for 45 minutes at 60% VO₂ max – was associated with increases in serum IgM, IgG, and IgA (Nehlsen-Cannarella et al., 1991a; Nehlsen-Cannarella et al., 1991b). In addition, one study reported that individuals who participated in a 10-week aerobic exercise training program exhibited an increase in the number of circulating CD4⁺ T cells and B cells (LaPerriere et al., 1994a), whereas another study using physically active versus sedentary rats reported an increase in B-1 cells and natural IgM (Elphick et al., 2003a; Elphick et al., 2003b).

Although the exact mechanisms by which exercise alters humoral immunity are unknown. One possible mechanism may involve activation of the SNS and HPA, as well as the release of endogenous opiates. One study found that beta-adrenergic blockade suppressed the exercise-induced changes in antibody, IL-2, IFN-gamma, and mitogen-induced proliferation (Kohut et al., 2004). In addition, data showed that an increased clearance of tumor cells from the lung occurred in physically active rats versus sedentary controls (Jonsdottir & Hoffmann, 2000), suggesting that exercise may enhance lung immunity preferentially.

If it is true that psychological states suppress humoral immunity, then the possibility exists that exercise might be a good intervention therapy for individuals infected with HIV-1, who have both decreased immunity and increased depression/anxiety. A few studies have been conducted to

examine this possibility (Dudgeon et al., 2004; LaPerriere et al., 1994b) and suggested that exercise has beneficial effects for HIV-1 infected individuals because it reduced anxiety, fatigue, anger, and depression (Florijin & Geiger, 1991; LaPerriere et al., 1991; Rigsby et al., 1992; Schlenzig et al., 1989), increased (LaPerriere et al., 1991; Rigsby et al., 1992; Schlenzig et al., 1989) or stabilized the CD4⁺ T cell count (Dudgeon et al., 2004; Florijin & Geiger, 1991), and decreased viral load (Dudgeon et al., 2004).

The effect of exercise on the primary and secondary antibody response, especially the response after vaccination, is only beginning to be investigated. One study reported a positive relationship between habitual physical activity and baseline antibody concentration that remained elevated 12 months post-vaccination (Whitham & Blannin, 2003). In addition, another study reported that 2 weeks of physical activity was sufficient to increase the level of a secondary antibody response and, thus, may provide a useful strategy to enhance the antibody response to vaccination in humans (Kapasi et al., 2003).

3.2.3. Conditioning

One type of behavioral conditioning involves the illness-induced taste aversion paradigm. To condition a taste aversion response, a test animal is given a distinctly flavored solution, such as a dilute saccharin solution or chocolate milk, which serves as the conditioned-stimulus (CS). This exposure is followed by an intraperitoneal injection of a toxic agent that causes gastrointestinal distress, such as cyclophosphamide or lithium chloride, which serves as the unconditioned-stimulus (UCS). Since the mid 1970s, a number of studies have been conducted by Ader, Cohen, and others to investigate the effects of behavioral conditioning on both humoral and cell-mediated immune responsiveness (reviewed by Ader & Cohen, 1993; Cohen et al., 1994).

In an initial study (Ader & Cohen, 1975), the effects of taste aversion conditioning on humoral immune responsiveness was assessed by conditioning rats with saccharin solution (CS) and an intraperitoneal injection of cyclophosphamide (UCS), which induced nausea and, more importantly, immune suppression. Three days after conditioning, the rats were injected with sheep erythrocytes (SRBC), a T cell-dependent antigen, and were then allowed to drink the saccharin solution (CS) again. Six days later, serum antibody titers were measured. The results of this study showed that the conditioned rats receiving saccharin (CS) at the time of SRBC injection had lower antibody titers when compared to conditioned rats that had not received saccharin at the time of sRBC injection. Thus, a conditioned suppression of the antibody response had occurred. This experiment was repeated with similar findings by a second group (Rogers et al., 1976), with the exception that this group found it necessary to have two re-exposures to the CS in order to see a significant decrease in antibody titer. In addition, a 1988 study showed that the timing of re-exposure to the CS has a pro-

found effect on the ability of the CS to induce humoral immune suppression (Kusnecov et al., 1988).

Although the above studies showed that immunosuppression was linked to a conditioned stimulus, it was unclear as to whether B cells and/or T cells were affected. In an attempt to clarify which population of cells was altered, a conditioning protocol similar to the protocol described above was utilized in concert with either the T cell-dependent antigen SRBC or the T cell-independent antigen *Brucella abortus* (Wayner et al., 1978). The results of this study indicated that the T cell-independent antigen induced no change in antibody titers in the conditioned versus non-conditioned control rats, in contrast to the decrease measured when the T cell-dependent antigen was used. Thus, T cells may be the target cell of the conditioned taste aversion. However, in contrast to the results obtained in rats, a study conducted in mice reported that a conditioned antibody response could be induced with a T-independent antigen (Cohen et al., 1979), suggesting that B cells are the target cell of the conditioned taste aversion. Taken together, the data suggested that the cell populations responding to the conditioned response might differ depending on the species being studied.

The data obtained from animal conditioned immunosuppression studies suggested the possibility of using an alternative therapy for patients with autoimmune diseases, especially those who are currently treated with large doses of immunosuppressive agents that possess toxic side effects. Because the reported data implicate both B and T cells as targets of the conditioned response, conditioned immunosuppressive therapy may be particularly beneficial in diseases, such as Alzheimer's disease, multiple sclerosis, and systemic lupus erythematosus, all of which are diseases in which both B and T cells contribute to pathogenesis. However, it is clear from animal models that further experimentation is necessary with regard to the number of training sessions for conditioning necessary for beneficial effects, as well as the optimal time of exposure to the CS.

Although some studies have shown that an unconditioned stimulus, such as cyclophosphamide appears to condition immune suppression, other studies showed that when antigen was used as the unconditioned stimulus, immune enhancement could be conditioned. In 1993, a study was conducted in mice to determine if antigen could be used as the unconditioned stimulus (UCS) to enhance humoral responsiveness (Ader et al., 1993). In this study, intraperitoneal injections of the antigen key-hole limpet hemocyanin (KLH), the unconditioned stimulus, were paired with a chocolate milk drinking solution, the conditioned stimulus. Mice were given either three CS-UCS pairings at three week intervals, each consisting of intraperitoneal injection of a very low dose of KLH + the chocolate milk drink, or just the chocolate milk drink. Results of this study showed that there was an enhancement of the anti-KLH antibody response when conditioned mice were re-exposed to both the CS and a minimally

immunogenic dose of KLH. Other studies showed that a single exposure to a conditioned stimulus, when associated with exposure to the unconditioned stimulus of antigen, could induce immune enhancement of the antigen-specific IgG response upon re-exposure to the conditioned stimulus (Madden et al., 2001; Ramirez-Amaya & Bermudez-Rattoni, 1999). In contrast, a more recent study challenges these findings to show that one-trial conditioned immune enhancement of an antibody response was found to not occur with all protein antigens tested as the unconditioned stimulus (Espinosa et al., 2004). The idea that conditioning may enhance antibody production to low doses of antigen suggests some exciting possibilities for future use in vaccination protocols in which the antigen used for vaccination is difficult to obtain because of limited quantities or limited financial resources. Thus, it appears that a humoral immune response can be conditioned for either suppression or enhancement.

3.2.4. Social support and coping styles

A 1992 study suggests that social support may play an important role in an individual's response to a vaccination (Glaser et al., 1992). In this study, which was designed to determine the effects of examination stress on the ability to generate an immune response to hepatitis B antigen, medical students were given a series of three hepatitis vaccinations on days when they had examinations. Results of this study showed that students who reported greater social support also produced higher antibody titers to hepatitis B surface antigen (HbBsAg) at the time of the third booster inoculation. A study was also designed to examine the relationship between stress, social support, coping, and immune function in elderly women, revealed that women experiencing high-stress exhibited lower CD4⁺/CD8⁺ T cell ratios than women experiencing low stress (McNaughton et al., 1990). The lower CD4⁺/CD8⁺ T cell ratios were partly due to increases in the number of CD8⁺ T cells in women experiencing either high stress or less satisfaction with emotional social support. Thus, it appears that not only the quantity of social support, but also the quality of social support may be important. In addition, the results of this study showed that CD4⁺ T cell number was significantly related to the endorsement of a greater percentage of problem-focused coping. Social support may also be beneficial for HIV-1-infected individuals. A previous study of 49 HIV-1-positive male hemophiliacs revealed that a low availability of attachment (AVAT) score was associated with a significant decline in CD4⁺ T cell count over a five-year period (Theorell et al., 1995). Two previous studies have also indicated that coping styles may alter immunity in HIV-1-infected individuals (Goodkin et al., 1992; Mulder et al., 1995). A study of 11 asymptomatic HIV-1-positive males showed that passive coping style and high stress were associated with a decline in total lymphocyte number over a one-year period (Goodkin et al., 1992). In addition, in both low stress and high stress individuals who were active copers, there was a trend, although

not significant, toward an increased number of CD4⁺ T cells, when compared to low and high stress individuals who utilized a passive coping style. A second study of 51 HIV-1-infected men, which included a one-year follow-up, showed that active coping strategy was also associated with a decrease in clinical progression (Mulder et al., 1995).

Depression has been associated with an increase in the level of IFN-gamma produced by T cells (Seidel et al., 1995; Seidel et al., 1996). For example, a decrease in IFN-gamma production was found to occur in individuals with multiple sclerosis who had a reduction in depression (Mohr et al., 2001). In contrast, IFN-gamma production appeared to be more readily reduced in patients with poor social support, as opposed to those with good support (Mohr & Genain, 2004). In another study, social support was found to buffer the effects of stress on the level of sIgA produced such that support lowered the amount secreted after the stressful task was completed (Ohira, 2004). Interestingly, it was reported that acute stress paradigms that had distinct effects on autonomic nervous system activity were coupled to distinct changes in the amount of salivary IgA secreted (Bosch et al., 2001), namely that a memory task increased IgA, whereas a surgical video decreased IgA, most notably IgA1.

In conclusion, although the mechanisms by which intervention strategies, such as relaxation, exercise, conditioning, coping, and self-disclosure, enhance humoral immunity are not fully understood, the studies presented above suggest that these intervention strategies have beneficial effects on the level of humoral immunity. Furthermore, although the benefits of these therapies may be minor for young, non-stressed, and healthy individuals, they seem to provide the most beneficial effects for individuals who are experiencing either increased levels of stress and/or who are somewhat immunocompromised, such as the elderly and HIV-1-infected individuals. Taken together, these studies suggest that the most beneficial strategies to ward off a pathogen need to include approaches that ensure both a healthy mind and a healthy body.

4. INFERENTIAL CONTEXT

4.1. Experimental design for PNI studies involving humoral immunity

Although the study of psychoneuroimmunology (PNI) has been ongoing for the past 100 years (Biondi & Zannino, 1997), many of the earliest studies in this field merely reported observations that immune function appeared to be modulated by physiological stressors. The general hypothesis was that stress leads to an increased incidence of disease by either prolonging disease symptoms, increasing susceptibility to infection, weakening protective immune mechanisms, or decreasing vaccination efficiency [reviewed by (Biondi & Zannino, 1997; Cohen & Herbert, 1996)].

4.1.1. Selection of study groups/controls

The initial phase of all scientific studies is to establish the study objectives and a hypothesis so that a proper study group can be generated. In regards to a PNI study, it is very important that the initial hypothesis encompass psychological/behavioral, neuroendocrine and immune parameters. For example, various psychosocial disorders and interventions have been, and are continuing to be, studied for psychoneuroimmunomodulation. One of the most important criteria for a well-designed PNI study is the selection of a proper or comparable control group. Without a well-designated control group, it is difficult to interpret data that are obtained. In addition, study subjects should be grouped based on one, several, or many of the following parameters, depending on the objectives of the study. These parameters include age, gender, disease history and drugs used, lifestyle, such as diet, alcohol and caffeine consumption, and smoking, sleep pattern, personality, and social status (Biondi & Zannino, 1997; Cohen & Herbert, 1996). The importance of each of these parameters must be defined before the study begins. In most cases, one parameter will be more important than another. For example, immunological status/competency – the ability to mount an immune response/antibody response – has been linked to exercise. With this information a study designed to determine the ability of an individual to mount an immune response during and/or following a specific stress response, has to be controlled for exercising subjects. For example if the control group contains individuals who frequently exercise, whereas the experimental group contains subjects who rarely exercise, then the results of an immunological analysis of these subjects may be skewed by factors not properly controlled for in this study. In any scientific study, especially those performed *in vivo*, it is important to remember that many systems in the body are connected and one system may be influencing other systems. To properly control for such events, it is important to set rigid criteria for test subject selection. It is difficult to draw clear conclusions from many previous studies in the PNI area due to the lack of proper age, gender, and lifestyle-matched controls.

4.1.2. Define background levels

Prior to the initiation of a PNI study, it is necessary to obtain a background profile for each of the test subjects (Kiecolt-Glaser & Glaser, 1992), in order to be able to conclude if changes occurred during the experimental testing period. Depending on the specific psychological, neurological, and immunological parameters that will be examined, a variety of tests must be performed to determine each individual's background resting levels. To rule out effects of diurnal variation, samples utilized to assess background levels should be collected at the same time of day as the test samples. In addition, for studies, which examine the effects of stress, it may be important to gather two separate background samples, one prior to the first day of study and

one on the first day of the study, prior to the application of the stressor.

4.1.3. Sample collection and analysis

As reviewed in this chapter, the cellular and humoral immune systems and the CNS, HPA, and SNS are connected in many intricate ways with regulatory mechanisms occurring within the individual systems, as well as between the systems. Therefore, in order to link immunological changes to psychological and neurophysiological changes, it is important that PNI studies include simultaneous analysis of physical, psychological, immune, and neuroendocrine parameters. As discussed above, a few important physical characteristics, which should be recorded for the study group, include age, gender, weight, height, diet, drugs, lifestyle, and social status. Additional physical parameters that may be important to monitor include nutritional status, vaccine history, disease history, allergic status, number of subjects housed together, and the infectious state of subjects sharing the same house. In addition to physical factors, a number of psychological factors (reviewed above in section 3.0) can alter humoral and cellular immunity including mood changes, depression, stress, degree of social support, and personal motivation. Thus, it is particularly important that these psychological states be monitored with questionnaires either throughout the study, or on the days when samples are collected for analysis of immune and neuroendocrine parameters.

Previous PNI studies suggested that changes in psychological and neuroendocrine factors alter both the humoral and cellular immune systems. In addition, soluble factors produced during humoral and cellular immune responses may regulate each other. Thus, it is important for initial studies to include measurements of both humoral and cellular immune parameters. Initial analysis of immunity should include: (1) immunofluorescence staining of peripheral blood samples to determine the percentages of B cells, T cells (CD4⁺ and CD8⁺), NK cells, and macrophages; (2) measurement of both serum and salivary IgA levels by ELISA; (3) measurement of the capacity of peripheral blood T cells to secrete cytokines following anti-CD3 stimulation; (4) measurement of the ability of T and B cells to proliferate in response to mitogens; and (5) measurement of the ability of NK cells to lyse target cells. To obtain a better understanding of which neuroendocrine factor(s) may be altering the immune response, it is important to measure the levels of ACTH, cortisol, epinephrine, and norepinephrine that are present in the blood and saliva.

4.2. Analysis of humoral immunity

The earlier sections of this chapter discuss the process of antibody production in an immune response, as well as the other organ systems that influence this humoral immune response. Understanding the mechanism(s) by which antibody is produced and the non-immune factors that can

enhance or inhibit antibody production are important. However, it is also necessary to understand the techniques that are used to measure the level of antibody produced and to determine specific features about the antibody produced, including antigenic specificity, antibody isotype or class, and affinity of the antibody for its antigen.

The following section focuses on techniques that are used to examine antibody production in animal and human systems. In some cases, such as the diagnosis of viral or bacterial infections, human serum can be tested directly for the presence of antibodies to these different antigens. However, if the goal is to define the mechanism by which a disease develops, it may be difficult to study a human model due to the limited reagents and limited sample material available for analysis. To circumvent these limitations, many scientists use mouse models because the mouse mimics many human diseases, and the assay reagents are easily accessible. Additional animal model systems utilized in psychoneuroimmunology research include rat, rabbit, and goat (Lingrel et al., 1985; Miyoshi et al., 1985; Peters & Theofilopoulos, 1977; Silagi & Schaefer, 1986; Talmadge, 1985).

4.2.1. Detection of antibody production in animals and humans

The techniques that will be described below are used to analyze the humoral (antibody) response in both the human and mouse systems. The limitations in human studies stem from the limited study material, usually only serum, versus multiple organs that can be examined in the mouse, such as the spleen and lymph nodes, in addition to serum. Over the past few decades, assay systems have been refined and are now able to detect nanogram to picogram quantities of antibody per milliliter of sample tested, as compared to sensitivity levels of microgram quantities detected in the earlier assay systems. Although a variety of techniques have been used to measure antibody levels and antibody parameters, the authors of this chapter recommend the techniques described below. To aid in the design of future PNI studies we have included the mechanism of detection, sensitivity of the assay, and the advantages and disadvantages for each technique.

4.2.2. Mechanism, sensitivity, advantages/disadvantages

Enzyme-linked immunosorbent assay (ELISA). The design and sensitivity of the ELISA are similar to the RIA (Engvall & Perlman, 1971; Macy et al., 1988). The ELISA can be used to test antiserum or purified antibody for its antigenic specificity, isotype, and quantity. A solid surface (96-well plate) is coated with an antigen or capture antibody. The antiserum sample is then added and allowed to bind to the coated plate. The plate is washed to remove unbound antibody and an enzyme-conjugated (alkaline phosphatase, horseradish peroxidase) detecting antibody is added. The

detecting antibody will bind to specific antibody that has bound to the capture antigen or antibody, and a soluble substrate is added to the plate. If the enzyme-conjugated detecting antibody is present, it will convert the substrate and result in a colorimetric reaction. The degree of substrate conversion can be measured using an ELISA reader, which determines the optical density of each well. To determine the antibody concentration in each sample well, the optical density readings of the sample wells are compared to the optical density readings of a standard curve. Both the capture antigen/antibody and detecting antibody can help to define the antigenic specificity and isotype of the bound antibody present in the antiserum. The sensitivity of the ELISA assay ranges from 0.0001–0.001 micrograms per milliliter (100 pg –1 ng/ml) of sample. The disadvantage of this system is that it requires purified antigens and antibodies for capturing and detecting antibody. The advantages include the ability to determine antigen concentration, isotype and specificity, its high sensitivity, good reproducibility, and the requirement for small amounts of sample antiserum (Adamkiewicz et al., 1984; Li, 1985).

ELISPOT. The ELISPOT assay is a modification of the ELISA that uses cells instead of cell supernatants or antiserum to assay for antibody production (Czerniksky et al., 1983; Sedgwick & Holt, 1983). This system allows for the determination of the number of cells in a population that are producing antibody, as well as, the level of antibody produced by the cells in the sample population. As in the ELISA, wells are coated with a capture antigen or antibody. Instead of adding antiserum or cell supernatants to the wells, activated cells are added to the wells. The cells are allowed to secrete antibody for a limited period of time. Because the wells are coated with a capture antibody/antigen, antibody secreted by the cells that is specific for the capture antigen/antibody will bind to the plate and remain there when the cells are lysed and the plates are washed. After the plates are washed, an enzyme-linked detecting antibody is added. If antibody from the antiserum has bound to the wells, then the detecting antibody will bind to the captured antibody. An insoluble substrate is added to the wells that can be converted by the enzyme conjugated to the detecting antibody. In contrast to the ELISA assay, which employs a soluble substrate to determine antibody concentration using optical density readings, the ELISPOT assay uses an insoluble substrate that will generate “spots” where antibody has been secreted from cells. These spots can then be counted to determine the number of cells from the starting population that are secreting antibody. One disadvantage to this system is that there is no standard curve to quantify antibody levels. Therefore, samples must be compared to each other instead of a known standard. The ELISPOT is more practical than the Jerne plaque assay because sample wells can be stored before counting, and therefore do not require

immediate analysis (Czerninsky et al., 1983; Sedgwick & Holt, 1983).

Immunofluorescence. The surface or intracellular expression of certain proteins can increase or decrease following the activation of immune cells. Immunofluorescence analysis with fluorescently tagged antibodies or probes can help to identify whether the immune cell expresses the protein of interest. Although immunofluorescence is most commonly used in conjunction with flow cytometric analysis to examine protein expression on either the surface or inside of individual immune cells, when tissue samples are available, immunofluorescence can also be used in combination with histochemical techniques to localize protein expression within a particular tissue. It is now possible to sort specific populations of cells using a Fluorescence Activated Cell Sorter (FACS). The principle is the same as the flow cytometric analysis, however the labeled cells can be collected and placed into culture where functional readouts can be measured.

Quantitative real-time PCR. In the course of immune cell activation, the expression of a variety of genes is altered. Quantitative real-time PCR is a powerful tool to monitor the differential expression of genes on the mRNA level. The technique was first described by Higuchi (Higuchi et al., 1993) and the principle behind it has not changed since. In an ideal PCR reaction the amplified product doubles every cycle. The formation of those products can be detected by either unspecific intercalating dyes, such as SYBR Green I (Schmittgen & Zakrajsek, 2000; Schmittgen et al., 2000), specific probes against the PCR product, such as TaqMan probes (Gibson et al., 1996; Heid et al., 1996), or molecular beacons (Tyagi & Kramer, 1996). By using specific fluorescence-based detection systems, this technique allows the “real-time” monitoring of the accumulation of the PCR product, which is directly correlated to the intensity of the fluorescence signal. Ideally this signal follows an exponential curve (2^{cycle}) due to the *Nature* of the PCR reaction itself. Thereby, the Ct value of a specific sample is defined as that cycle (fractions of cycles are allowed) of the PCR reaction where the fluorescence signal of this specific sample can be detected, that is, is significantly higher than the background fluorescence and follows the exponential curve. Samples containing higher amounts of template will reach this detectable level of fluorescence (also called the threshold level) in an earlier cycle compared to samples with less template. By comparison of the Ct values of different samples, the relative expression of the template can be determined (Livak & Schmittgen, 2001; Meijerink et al., 2001; Pfaffl, 2001). For example, samples containing a high amount of mRNA will have a lower Ct value than one containing a lower amount.

Due to its very high sensitivity, real-time PCR is the method of choice to determine the relative expression of genes that are expressed at a very low level, such as

cytokine genes (Overbergh et al., 1999), Ig heavy chain genes (Podojil & Sanders, 2003), or genes from samples containing limited numbers of cells, including flow sorted cells or laser capture microdissection samples (Glockner et al., 2000; Matsuzaki et al., 2004). Because of this high sensitivity it is important to control for differences in Ct values that may be due to sample processing by normalizing the results obtained for a particular gene of interest to the results for a gene that is constantly expressed in a cell – the so-called housekeeping gene, β -actin. The choice of the right housekeeping gene is a critical parameter and must follow certain procedures. Quantitative real-time PCR is the gold standard in evaluating and confirming results obtained from high-throughput technologies to study gene expression, such as microarray expression analysis (Rajeevan et al., 2001).

Microarray expression analysis. A first approach to determine if a given transcriptional alteration occurred in immune cells due to a certain treatment or stimulus is to use microarray expression analysis. The principle behind this technique involves the hybridization of fluorescently tagged cDNA to oligonucleotide- or cDNA-probes on a solid surface. To obtain the labeled cDNA, RNA is isolated from cell samples and is reverse transcribed in the presence of fluorescently labeled nucleotides. After the hybridization process, the fluorescence signal of each spot can be digitally processed and directly correlated with the amount of specific mRNA that is present in the cell sample. Relative expression patterns of up to $>40,000$ genes can be measured in one sample simultaneously and are calculated by sophisticated algorithms. By comparison of the expression patterns obtained from different samples, genes that are regulated differentially can be identified. The characteristic pattern of expression is then used as “sigNature” of the cell to determine various cellular parameters, such as the state of cell activation or lineage commitment (Alizadeh & Staudt, 2000; Zan et al., 2001). The characteristic pattern of expression also suggests the involvement of certain intracellular signaling pathways, which can be confirmed subsequently by using standard protein identification techniques, such as western blot analysis. The vast amount of data that can be obtained from one single microarray analysis is certainly the advantage of this technique, but this vast amount of data also contributes to certain disadvantages, such as a high number of false positive results and relative low sensitivity when compared to real-time PCR (Hatfield et al., 2003). Thus, it is absolutely necessary to confirm results obtained with microarray analysis by another quantitative method, such as real-time PCR (Rajeevan et al., 2001). Successful application of the microarray technique is dependent on good coordination and planning of the physiological experiment, including selection of proper time points and positive controls, microarray technique, including use of custom arrays vs. commercial arrays, and bioinformatics, including type

of data processing and presentation (McShane et al., 2003).

5. SUMMARY

This chapter describes the evidence that neuroendocrine hormones and the sympathetic neurotransmitter norepinephrine are involved in modulation of humoral immunity. It should be evident that a neuroendocrine-immune relationship indeed exists and that it influences the physiology and pathophysiology normally associated with each system individually. Data support the hypothesis that a disturbance in one component of the communication loop influences the functioning of another component and, thus, may contribute to both short- and long-term health consequences. By studying the mechanisms by which the multiple organ systems integrate with each other to function normally, we will gain better insight into how pathological processes develop from perturbation of the organism as a whole. Such insights will aid in the development of new therapeutic approaches and interventions that will contribute to the treatment and prevention of psycho- and immunopathology, as well as contribute to the enhancement of an individual's well being.

Behavioral Genetics

A. COURTNEY DEVRIES AND RANDY J. NELSON

INTRODUCTION

Behavioral genetics is the study of the relationship between genes and behavior. There are four main issues addressed by this scientific discipline: (1) understanding the extent to which individual behavioral differences are evoked by the effects of genes, (2) identifying genes that affect individual differences in behavior, (3) determining how the interaction between genes and the environment affect the development of behavior, and (4) discovering what genetic changes are involved in the evolution of a behavior (Maxson, 2002). The vast majority of behavioral genetics studies have been conducted in nematodes (*Caenorhabditis elegans*), fruit flies (*Drosophila melanogaster*), honey bees (*Apis mellifera*), mice (*Mus musculus*), or humans (*Homo sapiens*). This bias reflects complete, or nearly complete, genomic sequences in these species, and in the case of the nonhuman animals, the ease with which genetic mutants can be generated and maintained.

An appreciation of behavioral genetics is important in understanding psychophysiology. At its core, psychophysiology aims to illuminate the interrelationships among physiology, psychology, brain, and behavior (Cacioppo et al., 2006). Genes are inherited, but they are also responsive to the environment from conception and guide the development of structure-function relationships. The genes that produce physiological or behavioral phenotypes that fail to promote survival and reproductive success are omitted from the genome by natural selection, whereas genes underlying successful survival and reproductive output are retained. Differential expression of genes accounts for the plasticity, variability, and adaptability that forms the foundation of the psychophysiological approach (Cacioppo et al., 2006).

The field of behavioral genetics emerged far in advance of its name. The two general approaches in the field (i.e., genealogical and evolutionary) are traditionally considered to have arisen from the writings of two cousins in the nineteenth century: Charles Darwin and Sir Francis Galton. Indeed, the term genetics was coined in 1909,

just two years before Galton's death. Galton's work provoked modern studies of the causes of individual variation among human behaviors, especially cognition, personality, psychopathology, and addictions (Galton & Galton, 1997). He studied extensive family records to discern the inherited tendency of complex traits, often making comparisons between parents and their children and between monozygotic (identical) and dizygotic (fraternal) twins. This approach is especially relevant to psychophysiology and behavioral neuroscience. Darwin's writings stimulated modern research on the genetics of so-called adaptive behaviors in humans and nonhuman animals. The approach of studying the adaptive context of a behavior is more common in behavioral ecology than psychophysiology, but we believe that this approach is important for revealing relationships about genes and behavior that could also have translational value for humans. Indeed, evolutionary psychology has informed several traditional subdisciplines in Psychology including social, personality, developmental, and cognitive psychology (Buss, 1999; Durrant and Ellis, 2003).

It has been more than a half-century since Watson and Crick described the structure of deoxyribose nucleic acid (DNA), and concluded their report with perhaps the most profound understatement in the history of science, *viz.*, "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material" (Watson & Crick, 1953a). Identification of the helical structure of DNA offered insights into how genes are copied, how genes undergo mutation, and how they function (Watson & Crick, 1953b). Within five years after Watson and Crick described the structure and function of DNA, the importance of genes for understanding behavior was emphasized (Ginsburg, 1958). Ginsburg argued that genetics was a critical tool for understanding behavior because of the following reasons: (1) genetics can be used to dissect behavior into its fundamental units, (2) genes can be used to study the neural, endocrine, and other mechanisms underlying behavior, (3) genetics can be used as a tool to study the effects of the environment on behavior, and (4) understanding

genetics is critical to understand the evolution of behavior. Since the initial discovery of DNA, the biological sciences have made enormous progress in understanding the genetic, molecular, and cellular processes underlying normal function, as well as how aberrations in these processes lead to disease. Importantly, the field of molecular genetics appears to be on the threshold of even greater insights into biological mechanisms, linking genotype to phenotype. Because behavior represents an important phenotype, the number of behavioral genetics studies has grown exponentially in recent years. It would seem that the time is ripe for developing a major link between psychophysiology and behavioral genetics.

Methods in behavioral genetics

Screening animals to link a phenotype and genotype can proceed in either of two directions (Figure 17.1): (1) forward genetic screens begin with a phenotype and involve screening the genome to identify the gene or genes responsible for the phenotype, or (2) reverse genetic screens begin with animals possessing a mutated gene and involve extensive behavioral testing to describe the phenotype. Prior to recent advances in mutagenic and transgenic technologies, most behavioral genetics studies began with a phenotype then worked toward identifying candidate genes. Traditionally, in behavioral genetics, there have been two global approaches to reveal genetic contributions to non-human behavior: (1) crossing experiments and (2) selection experiments. To be successful, each type of study must be conducted in a constant environment. In both crossing and selection experiments, the most difficult problem is to choose suitable “units of behavior” for genetic analyses.

This problem of the appropriate phenotypic character is not unique for behaviorists. Gregor Mendel’s good fortune and genius was to choose characteristics in his pea plants that were clear-cut and could be quantified easily. In Mendel’s case, each “unit” (i.e., height of the plant, seed color, seed texture, etc.) essentially corresponded to a single gene. Mendel’s laws of inheritance can be applied successfully to predict inheritance of several monogenic disorders (such as Duchenne muscular dystrophy), however, there is little chance that a single gene will directly control a complex human behavioral, cognitive, or personality trait. Intelligence is a classic example; it is a hypothetical construct that defies precise definition, but is commonly assessed through the use of IQ tests. Overall, studies reveal a moderate to strong heritability for IQ in childhood and adulthood, respectively (Bouchard and McGue, 2003). However, despite a clear genetic influence on IQ, there has been no definitive identification of a gene or group of genes that influence performance on IQ tests or other measures of intelligence in humans. Interestingly, the popular press announced the discovery of the “intelligence

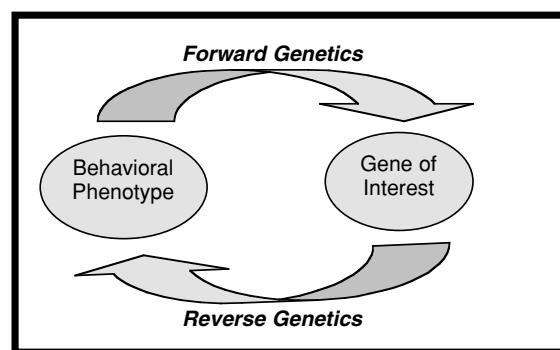

Figure 17.1. A *forward genetic screen* involves beginning with a behavioral trait then screening the genome to identify which gene or group of genes is responsible for the phenotype. Techniques utilized in forward genetics include QTL mapping and selective breeding. A *reverse genetic screen* involves mutating a gene, then performing behavioral tests to determine the phenotype. Techniques utilized in reverse genetics include targeted mutations, use of antisense, and viral gene transfaction.

gene” during the late summer of 1999. The study in question had reported that overexpression of the gene for the NMDA receptor 2B (NR2B) in the forebrains of transgenic mice was associated with enhanced activation of NMDA receptors, which improved performance in various learning and memory tasks (Tang et al., 1999). The authors concluded that their “...results suggest that genetic enhancement of mental and cognitive attributes such as intelligence and memory in mammals is feasible” (Tang et al., 1999). Although not much evidence exists in humans for a role of the NMDA 2B receptor in intelligence, it has been implicated in susceptibility to obsessive compulsive disorder (Arnold et al., 2004) and schizophrenia (Di Maria et al., 2004). Again, it is unlikely that intelligence or any other complex behavior is regulated by a single gene.

Selection studies. Walter Rothenbuhler’s work with honeybees (*Apis mellifera*) represents one of the best, early examples of choosing a simple behavior when attempting to study the influences of genes on behavior. Rothenbuhler proposed a two-gene model to explain the phenotypic variance observed in the removal of dead brood from honey bee colonies (Rothenbuhler, 1964a, b). Rothenbuhler’s model proposed that a single locus controls the uncapping of brood cells containing dead pupae, whereas a second locus controls the removal of the corpses from the cells. He referred to strains of bees that uncap cells and remove dead larva as “hygienic” bees. In contrast, worker bees of the so-called “unhygienic” strains essentially ignore cells containing dead larvae. The progeny obtained by crossing the two strains are unhygienic, which suggests that the unhygienic trait is dominant. Rothenbuhler (1964b) back-crossed the hybrids from 29 colonies to the recessive, hygienic strain with the following results: (1) approximately 31% uncapped cells containing dead

larvae, but did not remove the corpses (these were designated uuRr), (2) approximately 21% did not uncap cells, but would remove dead larvae placed in the colony by an experimenter (Uurr), (3) approximately 27% exhibited the unhygienic phenotype and failed to uncap cells or remove corpses (UuRr), (4) approximately 21% exhibited the hygienic phenotype and both uncapped cells and removed corpses (uurr). Thus, the proportion of the four phenotypic classes did not differ significantly from equality (25% per group) and supported the hypothesis that this behavior was influenced by two pairs of alleles, one of which controlled the expression of the uncapping pattern and the other that controlled the removal of dead larvae. However, these Mendelian results do not imply that a single locus controls the development and activation of the physiological machinery required for uncapping cells or removing dead larvae. Indeed, if unhygienic worker bees are provided with sufficient stimuli, they will begin to engage in hygienic behaviors, albeit at much lower levels than the hygienic strain. Thus, it was concluded that the U and u alleles actually serve as “behavioral switches” that determine the threshold at which the uncapping pattern is initiated (Rothenbuhler, 1964a). Indeed, modern molecular genetic techniques and quantitative trait loci (QTL) linkage mapping (described below) have revealed that the genetic basis of hygienic behavior may be more complex than originally proposed by Rothenbuhler (1964a), and that many genes are likely to contribute to this behavior (Lapidge et al., 2002). Seven suggestive QTLs were associated with hygienic behavior and each controlled only between 9–15% of the observed phenotypic variance in the characteristic.

Crossing studies. There are many other examples of complex behaviors that inherit completely or not at all. For example, duck courtship displays consist of a series of behavioral patterns that are well conserved throughout the duck family. Konrad Lorenz (1966) referred to one such behavioral pattern as the “down-up” display in which a drake dips his bill into the water and then by rapidly lifting his head, generates a plume of water. This courtship pattern is not observed, however, in the pintail (*Dafila acuta*) or in the yellow-billed teal (*Nettion flaviroster*). If individuals from these two species are bred, then the down-up display reappears in its typical form in the F₁ hybrids, which suggests that the absence of the down-up behavior in pintail and teals is mediated by different, recessive, species-specific blocking mechanisms (Lorenz, 1966). Presumably, the recombination of genes in the F₁ hybrids removes the constraints on the down-up behavior such that it is again performed in response to the appropriate social stimuli. However, the best test of this hypothesis would involve back-crossing the hybrids to the parental species, but as is common among such hybrids, they are infertile (Manning, 1967).

Although these so-called breeding experiments have become considered out-dated by many behavioral geneticists, there have been recent calls for their reinstatement (Phillips et al., 2002). Crossing and selection experiments can provide an important approach to understanding complex genetic and environmental interactions associated with both typical and aberrant behavioral processes. The use of controlled breeding experiments in genetic mapping is described in the following section in more detail.

Quantitative trait loci (QTL) linkage mapping. Some traits such as eye color are controlled by a single gene and fall within a few distinct phenotypic classes. In the case of such traits, if the genotype is known, then the phenotype can be predicted, and if phenotype is known, then the genotype can be predicted. For example, if a baby has blue eyes, then we know its genotype; if this individual grows up and fathers a child with a brown-eyed woman whose mother had blue eyes and father had brown eyes, then we can confidently predict the genotype of the offspring based on eye color. Such discrete phenotypes are called discontinuous traits.

Other traits such as intelligence, anxiety, learning abilities, or height, however, do not fall into discrete phenotypic classes. Rather, when a population is analyzed for these traits, a continuous distribution, often bell-shaped, is found. Indeed, most behavioral traits appear to follow a *polygenic* pattern of inheritance which leads to a continuum of phenotypes (Fisher, 1918; Wright, 1921). Continuous traits are often assigned a quantitative value and are referred to as quantitative traits. In keeping with the terminology, the loci controlling these traits are called quantitative trait loci or QTL.

Thus, the QTL contain the allelic variants (polymorphisms) that underlie individual variation in behavior. QTL tend to have only a small effect on phenotype as compared to Mendelian mutations (Flint, 2003). Overall, the proportion of the phenotypic variance that is attributed to QTL tends to be quite small, (i.e., less than 10% in most mouse studies) (Flint, 2003), and because there are a large number of genes with relatively small individual contributions to the phenotype, quantitative traits are a much greater challenge to map than Mendelian traits. Small sequence differences that may slightly alter behavior, for example contributing less than 5% to phenotypic variance, can easily be missed. Mapping of QTL involves identifying chromosomal regions that contain the genes that influence quantitative traits. Typically, quantitative traits are regulated by several genes and also may be responsive to environmental factors.

The first primitive version of QTL was used to map patterns of pigmentation in bean seeds (Sax, 1923). However, a dearth of easily identifiable, segregating genetic markers (DNA used as “landmarks” on the chromosome) limited the applicability of QTL analyses for nearly 60 years. It was not until polymerase chain reaction (PCR) became

commonly available in the 1980s that polymorphisms of a single nucleotide became readily detectable and molecular markers were easily detected and plentiful. In mice, detecting QTL often involves crossbreeding two behaviorally distinct inbred strains to produce the F₁ generation, then inter-mating the F₁ generation or backcrossing the F₁ generation to either of the parental strains to produce the F₂ generation (Flint, 2004). Analysis of molecular markers (i.e., polymorphisms) then signals which chromosomal segments segregated with the trait of interest. A goal in mapping these markers is to eventually identify the actual protein coding genes which affect the variation of a trait. The markers that are used for gene mapping to a region of a chromosome are usually DNA variants, including restriction fragment length polymorphisms (RFLPs), simple sequence length polymorphisms (SSLPs), and single nucleotide polymorphisms (SNPs) (Plomin et al., 2000; Plomin and Crabbe, 2000). These markers are used in mapping because: (1) many of them are closely spaced on the linkage map of each chromosome, and (2) they do not affect the measured traits. However, the mapping is fairly imprecise, and even with as many as 1000 animals, if the contribution of the QTL to the behavioral trait is less than 10%, the 95% confidence interval of the QTL will still include approximately 10 centimorgans (see Figure 17.2) and could include hundreds to thousands of genes (Flint, 2004). Mapping resolution can be improved further by repeating the loci mapping in heterogeneous stock, which reduces the QTL confidence interval to a few centimorgans (Mott et al., 2000).

Mapping QTL can be expensive, labor intensive, and tedious, but it provides a useful tool for exploring the genetic bases of complex psychological traits. For example, to identify a genetic basis for emotionality, behavioral and quantitative trait analyses were performed on approximately 900 mice from an F₂ intercross (Flint et al., 1995). The progenitors belonged to inbred mouse strains that were selected for either high or low open field activity (DeFries et al., 1978). The authors of the QTL study chose to use co-variation between exploratory behavior (a locomotor response) and defecation (an autonomic response) as an index of emotionality because there is no known physiological mechanism that can explain the covariation between these two measures. Yet, selection studies in both mice and rats suggest that these behaviors are genetically correlated; rodents bred to exhibit high locomotor responses in novel environments tend to excrete fewer fecal boli whereas rodents bred for high novelty-induced defecation tend to become immobile in novel environments (Flint et al., 1995). Indeed, QTL mapping identified three loci on mouse chromosomes 1, 12, and 15 that influenced four measures of emotionality (open field activity, Y-maze activity, defecation in novel environments, and open arm exploration in the elevated plus maze). Although the mouse study does not have sufficiently high mapping resolution to identify the specific genes regulating emotionality, it does suggest that variation at only three loci

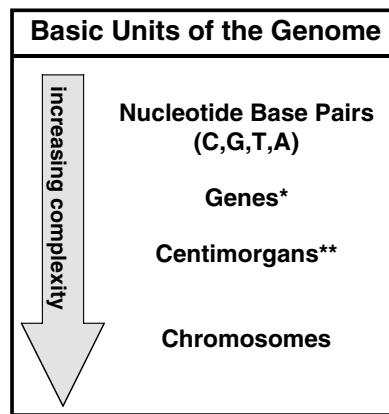

Figure 17.2. The basic units of the genome. The *sequence of nucleotides that is translated into RNA are the genes. The average genetic distance is approximately one million base pairs (i.e., 1 centimorgan**). Within this interval, there is a 1% chance of recombination. Chromosomes are species-specific collections of pieces of DNA. Mice have a chromosomal complement that includes 19 autosomes (non sex chromosomes) and the X and Y sex chromosomes. Humans have 22 autosomes and the X and Y sex chromosomes.

account for a large proportion of the observed individual differences in emotionality among the mice.

A similar study mapped QTL in an F₂ intercross of Roman high avoidance and Roman low avoidance strain of rats selectively bred to exhibit differential fear responses (Fernandez-Teruel et al., 2002). Roman high and low avoidance rats have well characterized behavioral profiles and have been extensively studied in anxiety paradigms. Several QTL with test-specific effects on measures of anxiety were identified, but only one QTL, which was located on rat chromosome 5, influenced behavior in several behavioral tests of anxiety (active avoidance, conditioned fear, elevated plus maze, and open field; Fernandez-Teruel et al., 2002). Whether allelic variation in homologous genes in other species affects emotionality and anxiety remains to be determined, but there is some evidence that rat chromosome 5 (which contains the anxiety QTL) is partially syntenic with human chromosome 1p, which contains a QTL that influences neuroticism (see the following section; Flint 2004). Unfortunately, the mapping resolution in both species was too low to definitively conclude that the same gene affects the trait in humans and rats.

QTLs underlying individual differences in behavior have been mapped in several species including nematodes (Segalat, 1999), fruit flies (Sokalowski, 1999), honey bees (Ruppell et al., 2004a; b), and humans (reviewed in Plomin and Crabbe, 2000; Ferreira, 2004). Studies involving non-human animals can exploit selective breeding to produce extreme phenotypes for the behavior of interest prior to attempting to map the genetic basis of the behavior. The most challenging aspects of conducting behavioral QTL studies in humans are (1) detecting the QTL, (2) obtaining high resolution mapping, and (3) enrolling a large enough cohort to be able to detect loci that may be contributing

only 5–10% of the total phenotypic variance (Flint, 2004). Indeed, few QTL studies attempting to map human personality traits have sufficient sample size or power to detect small genetic effects.

In studies of humans, two primary approaches are used to identify genes relevant to a specific trait or behavior: (1) Linkage analysis and (2) allelic association (also called linkage disequilibrium). In linkage analysis, several DNA sequence polymorphisms that are near (or within) a gene of interest are used to track the inheritance of a disease-causing mutation in that gene. Linkage analysis has been successful at identifying the causal agents for single gene (monogenic) disorders such as Huntington Disease or Duchenne muscular dystrophy, but this method is not particularly informative about genetic effects for polygenic traits of most interest to psychophysiolologists or other behavioral neuroscientists.

Allelic association is also called linkage disequilibrium. It is the non-random association of alleles at two or more loci on a chromosome. It describes a situation in which co-occurrence of a specific DNA marker and a disorder is at a higher frequency than would be predicted by random chance. For example, allelic association has been used to find an allele for the phospholipase A2 (PLA2) gene that is associated with depression among unipolar patients with at least 3 depressive episodes (Papadimitriou et al., 2003). This followed the observation of co-segregation in one family pedigree of bipolar affective disorder with Darier's disease. The gene of interest is on chromosome 12q23–q24.1; linkage and association studies revealed that PLA2, which is located nearby, may be involved in affective disorders. Eight alleles were examined, but only one was found to correlate with depression. Molecular studies can now investigate structural changes in this gene that may contribute to depressed affect (Papadimitriou et al., 2003).

Two QTLs for neuroticism have been identified through comparison of sibling genotypes and responses on depression and anxiety questionnaires (Nash et al., 2004). Interestingly, location of the QTLs was different for male sibling pairs (chromosome 6p) and female sibling pairs (chromosome 1p), which suggests that the genetic mechanism underlying neuroticism in humans may be sexually dimorphic (also see Fullerton et al., 2003; Abkevich et al., 2003). Putative QTLs for several disorders and traits related to neuroticism, including susceptibility for anxiety (Fullerton et al., 2003) and major depression (Nurnberger et al., 2001), also have been mapped to chromosome 1. The nature of genetic contribution to complex psychological traits and psychiatric disorders is not well understood (Flint et al., 1995). There has been only limited success in mapping psychiatric disorders in humans, which suggests that many genes contribute to the phenotype, each with a very small effect. Furthermore, because human populations are outbred and there is great individual variation in diet, medication, stress exposure, SES, and other environmental factors, statistical power tends to be low for most studies (Farrall, 2004).

No single genetic approach is likely to provide a comprehensive understanding of complex behaviors, and understanding behavioral traits with multiple genetic and environmental determinants represents one of the greatest challenges for genetic analysis (Phillips et al., 2002). Despite the use of QTL, once a trait is mapped, it is common to change the experimental focus to identifying individual genes (Phillips et al., 2002; Farrall, 2004). As the number of QTL mapping studies increase, and resolution of genetic mapping improves, the number of genes known to influence any given behavior will increase substantially. Yet, it will be difficult to isolate the effects of any single gene amid the contributions of other genetic and environmental influences (Phillips et al., 2002; Plomin & Crabbe, 2000). Furthermore, once the key genes underlying a behavior have been identified, determining the mechanisms through which the genetic variants affect behavior will be a major undertaking. The following sections discuss the process of identifying candidate genes.

Transgenic and knockout models. The development of gene targeting strategies in mice has revolutionized biological sciences (Sung et al., 2004). In order to inactivate, or “knockout,” a gene, molecular biologists rearrange the nucleotide sequence that encodes for the gene of interest. This has been accomplished for an astounding number of murine genes during the past fifteen years. Although now fairly routine, the creation of a mouse with targeted disruption (i.e., knockout) of a specific gene is a labor intensive process that combines several low probability events. The majority of mutant mice to date have been generated through pronuclei injection or homologous recombination in embryonic stem (ES) cells (Muller, 1999). Transgenic mice are generated via a procedure that involves injecting DNA consisting of the sequence of interest and an enhancer or promoter into the pronucleus of a one-cell mouse embryo (Bockamp et al., 2002). The DNA integrates into the genome, becomes functional and is passed on to subsequent generations. One potential shortcoming of the technique is that the transgene integrates into the genome at a random site and as a result may affect the function of surrounding genes. In contrast, homologous recombination in ES cells precisely determines the integration site of the mutated gene when producing a “knockout” or “knockin” mouse.

To begin, mouse embryonic stem cells are harvested from a mouse blasocyst (embryo) and cultured. A targeting vector is engineered to contain two homologous regions that flank a positive selection marker, such as the neomycin phosphotransferase gene (Sung et al., 2004). The vector is then introduced into the cultured ES cells either by microinjection or electroporation transfection. Homologous recombination will then incorporate a very small number of the altered genes into the DNA of the ES cells. PCR can be used to detect the cells in which homologous recombination has occurred. The mutated ES cells are inserted into otherwise normal mouse blastocysts,

then implanted into surrogate (pseudopregnant) mothers (Sung, 2004). Within developing mice, all of the descendant cells from the cloned stem cells will have the altered gene; the descendant cells of the original blastocyst cells will have wild-type (i.e., unaltered) genes. The resultant mouse, possessing copies of both mutant and wild-type (WT) cells is called a chimera. If the mutated stem cells are incorporated into the germ lines (the cells destined to become the sperm or ova), then some of the gametes will contain the mutant gene (Sung et al., 2004). Chimeric mice are then bred with wild-type mice; some of the offspring produced will be heterozygous for the mutation, that is, possess one copy of the mutant gene. If the heterozygous mice are interbred, then according to Mendelian segregation approximately one fourth of their offspring will be homozygous for the mutation, one fourth will be homozygous WT and half will be heterozygous for the mutant gene. These homozygous mice can be interbred to produce pure-lines of mice with the gene in question knocked-out (Sung et al., 2004). The product for which the gene typically encodes will be missing from all of the progeny. Behavioral performance is typically compared among WT (+/+), heterozygous (+/−), and homozygous (−/−) mice in which the gene product is produced normally, usually produced at reduced levels (i.e., knockdowns), or completely missing, respectively, though this assumption must be confirmed by directly assaying the gene product.

One limitation to the interpretation of behavioral data from knockout mice is that the targeted gene is missing throughout ontogeny (Nelson, 1997). Thus, any functional deficits may be due to the missing gene product at the time of behavioral testing and/or due to the absence of the gene product during key developmental processes throughout ontogeny. Furthermore, mutations of genes that are essential for normal development can induce embryonic lethality or produce profound deficits that limit or preclude behavioral testing. It also is possible that compensatory or redundant mechanisms might be activated when a gene is disrupted. For example, in mice lacking the gene for the neuronal isoform of nitric oxide synthase (nNOS^{−/−}), there is a 20% increase in the expression of the endothelial isoform of nitric oxide synthase (Burnett et al., 1996). A compensatory mechanism may spare behavioral function, and cloud interpretation of the normal contribution of the gene to behavior.

The availability of “inducible” or “conditional” knockouts, in which a specific gene can be inactivated at any point during development, or only inactivated in tissue-specific cells, will provide an important tool to circumvent the problem of ontogenetic interactions (Nelson & Young, 1998). Region- or cell-specific promoters are combined with genes that can be activated at any time by specific events induced by the investigators (e.g., exposure to tetracycline, ecdysone, or interferon; reviewed in Lewandoski, 2001). These substances bind to a special promoter transgenically attached to the gene of interest and terminate expression of a gene. In principal, restricted gene inactiva-

tion also can be accomplished in any tissue, at any developmental stage with Cre-loxP mediated gene targeting (Gu et al., 1994). This transgenic strategy is based on the Cre-loxP recombination system of bacteriophage P1 and can mediate loxP recombination in both ES cells or mice (Gu et al., 1994). This bacteriophage site-directed recombination method requires two mouse strains be developed and mated; one containing the *cre* transgene in a cell-type or developmental stage-specific manner and a second strain that has the gene of interest flanked by two loxP sites. In the resulting offspring, Cre-loxP site specific recombination will occur, thereby deleting the target gene only in the cells where *cre* is expressed while tissues not expressing *cre* will not be affected (Gu et al., 1994). Ecdysone, an insect hormone, also can be used to inactivate a gene during any point of pregnancy because it easily crosses the placenta-blood barrier and has no noticeable nonspecific effects in rodents (No et al., 1996). The widespread availability of inducible knockout and transgenic mice should prove extremely useful in behavioral studies because they will provide a method of studying genetic influences on behavior in the absence of ontogeny issues that often obscure interpretation of knockout mouse behavior. Furthermore, by testing conditional knockouts prior to and after gene deactivation, the potential confound of differential genetic background effects can be eliminated (Lee et al., 1998). Although thousands of genetic knockouts have been created, only a small proportion of these knockouts have been thoroughly phenotyped. Importantly, many knockouts have been examined in behavioral tests, but display no significant behavioral impairments (e.g., Nelson & Young, 2000). In contrast, some knockouts have exhibited phenotypes that appear to be highly influenced by the background strain, laboratory environment, or an interaction between these two factors (Wahlsten et al., 2003).

Random mutagenesis. Random mutagenesis involves exposing male mice of an inbred strain to a chemical mutagen. In behavioral neuroscience, the most commonly used chemical mutagen is N-ethyl-N-nitrosourea (ENU). It typically induces point mutations by modifying A-T base pairs. The mutations can lead to allelic alterations that begin a cascade of physiological changes and ultimately affect behavior. ENU mutagenesis is a major forward genetics screening strategy with the goal of finding genes that can cause variation in a behavioral trait (Maxson, 2002). Dominant mutants are detected in the first generation of progeny, whereas recessive mutants are detected in subsequent generations. Because the ENU-induced mutations occur at random, it is advantageous to be able to house large numbers of animals and to employ “high throughput” behavioral testing. Once an intriguing behavioral phenotype has been identified, the chromosomal location and the DNA sequence of each mutant gene is determined. Unfortunately, sometimes identifying the gene responsible for the altered phenotype is difficult. For example, fitness-1 (fit-1) mice were initially described in 1990, but

it was not until 13 years later that the gene mutation responsible for inducing hematopoietic metabolic abnormalities was identified (Klebig et al., 2003; reviewed in Sung et al., 2004). Large-scale mouse behavioral mutagenesis projects are currently ongoing at the Jackson Laboratory, Northwestern University, Oak Ridge Laboratories, the University of Tennessee, and elsewhere.

The mutagenesis approach also has been applied successfully to *C. elegans* (reviewed in Jorgensen & Mango, 2002) and *Drosophila melanogaster* (St. Johnston, 2002) using ethyl methane sulphonate, X-ray irradiation and insertion of P-transposable elements. The invertebrate models have several advantages over the vertebrate models including: (1) it is inexpensive to maintain large colonies, (2) the generation time is short (10 days for flies and 3 days for roundworms [*C. elegans*]), (3) they generate large numbers of offspring, and (4) they have many fewer chromosomes (4 for flies and 6 for roundworms) and genes (approximately 15,000 for flies and 20,000 for roundworms). Importantly, the completion of the human and fly genome projects has revealed that 178 out of 287 known human disease genes have known homologues in flies (Rubin et al., 2000; Fortini et al., 2000). The disadvantages of using flies and roundworms in behavioral genetics studies are (1) a fairly limited behavioral repertoire and (2) a relatively uncomplicated CNS, although most of the major vertebrate neurotransmitters systems have been confirmed in roundworms and flies (Wolf & Heberlein, 2003). Indeed, flies are an intriguing model for studying drug effects and addiction. For example, to screen for gene mutations that influence ethanol-induced behavior, large numbers of flies are rotated through an apparatus that releases ethanol vapor then quantifies the behavioral changes that follow (Park et al., 2000). Following exposure to ethanol vapor, flies exhibit behavioral changes that are similar to those observed among intoxicated humans, including increased locomotor activity at low concentrations versus decreased locomotor activity and loss of postural control at high concentrations. However, if a mutation is induced in the pka-RII (a protein kinase A regulatory subunit) gene, the flies exhibit improved coordination in a climbing task following ethanol exposure (Park et al., 2000). Similarly, PKA-RII β mutant mice voluntarily consume more ethanol, and are less sensitive to the sedative effects, than WT mice (Thiele et al., 2000). Thus, flies have been invaluable for elucidating signal transduction pathways, and it appears that they also may be a valuable tool in studying genetic influences on behavior.

Genetic screens in lower invertebrates have been used repeatedly to identify modifiers of preexisting genetic defects (i.e., modifier screens). Generally, animals with a genetic defect that produces a distinctive phenotype are exposed to random mutagenesis techniques and screened for mutations that reverse the phenotype. Recently, the first such screen was successfully used in mice to identify mutations capable of ameliorating congenital thrombocytopenia (reduced platelet count; Carpinelli et al., 2004).

Modifier screens provide a more sensitive background in which to detect changes in phenotype (Curtis, 2004). Usefulness of this technique in behavioral genetics of a complex behavior is limited by the absence of high throughput behavioral protocols for complex behaviors; an exception is circadian locomotor behavior which involves automated measurement of locomotor activity.

Viral vectors to transfer genes. Viruses have evolved to transfer genes into infected cells. This ability has been exploited to deliver experimental or therapeutic gene treatment to individuals. Among the various types of viruses used to transfer genes (retroviruses, adenovirus, adeno-associated virus, herpesvirus, and poxvirus) the use of retroviruses has become most prevalent because they provide high gene transfer efficiency and relatively high therapeutic gene expression in the recipient cells (Walther & Stein, 2000). The methodology of viral gene transfer is beyond the scope of this chapter but has been thoroughly reviewed in the literature (Walther & Stein, 2000; Lowenstein & Castro, 2001). Recent advances in the use of viral vectors to transfer genes include improvement of infectivity and the duration of novel gene expression, which is critical to improve the safety and efficacy of RNA- and DNA-viral vectors (see Walther & Stein, 2000 for a review). However, viral vectors have inherent risks such as toxicity, activation of the recipients' immune system, and viral recombination and further improvements are necessary before this method of gene therapy is clinically dependable. (Walther & Stein, 2000). However, the use of viral vectors to transfer genes to understand the genetic contribution to behavior is becoming an important tool (Lowenstein & Castro, 2001).

The behavioral effects of gene manipulations have been studied using primarily inbred rodent strains. However, one the goals of behavioral genetics should be to understand how naturally occurring genetic changes may have shaped evolution of a complex social behavior. An interesting example of such a phenomenon has been investigated in monogamous rodents using viral vectors. Most mammals are polygynous, which means that the males and females associate only during mating, and as a result females provide a large proportion, if not all, of the resources necessary to raise the progeny. Fewer than 3% of mammalian species are reported to exhibit a monogamous social system in which long-term pair bonds are formed between males and females and the fathers contribute to the raising of the young (Carter et al., 1995). How and why some mammals evolved to exhibit monogamy are intriguing questions. The explanation at an ultimate level of analysis involves whether maximal male reproductive fitness can be achieved by abandoning the female after fertilization and searching out additional mates versus remaining to assist in raising the progeny (Krebs & Davies, 1993). The proximate explanation may involve differential expression of a single gene, the vasopressin V1a receptor (V1aR). Much of the work related to understanding the

proximate regulation of monogamy has been conducted in vole species because there are several closely related species that vary in social structure from monogamous to polygynous. For example, prairie voles and pine voles are monogamous; males and females form social bonds and provide biparental care. In contrast, montane voles and meadow voles are polygynous; males and females do not form social bonds and only females provide parental care. Although the V1aR gene sequence is highly conserved among vole species, there is an alteration in the repetitive microsatellite DNA in the 5' regulatory region of the gene that is associated with social system (Young et al., 1999). Thus, the pattern of V1aR expression in vole brains is substantially different between monogamous and polygynous species (Lim et al., 2004; Young et al., 1999). A similar pattern of increased V1aR also has been reported in monogamous versus polygynous *Peromyscus* species (Bester-Meredith et al., 1999). Furthermore, transgenic mice that carry the prairie vole V1aR coding sequence and flanking regions, exhibit patterns of V1aR expression that are more similar to prairie voles than WT mice (Young et al., 1999). The transgenic mice with the altered V1aR expression also are more social than WT mice. Furthermore, increasing V1aR expression in ventral pallidum of polygynous meadow voles through viral vector-mediated gene transfer results in a shift in behavior that more closely resembles monogamy than polygyny (Lim et al., 2004). The genetically manipulated meadow voles exhibited a clear social preference for their partner versus a stranger, and spend four times as much time in physical contact with the stimulus animals as the unmanipulated meadow voles (Lim et al., 2004).

Taken together, these data suggest that differential gene regulation, rather than a mutation in the coding region, accounts for species differences in propensity to exhibit social behavior among prairie voles. These data suggest that a single gene polymorphism alters receptor expression and vastly influences behavior. Presumably, not all regions that express V1aR are involved in pair bonding, but the pattern in the ventral pallidum (high in monogamous voles low in polygynous voles) provided strong inference (Insel et al., 1994). Indeed, injecting V1aR antagonist directly into the ventral pallidum prevents the formation of partner preferences (Lim et al., 2004). Thus, converging evidence from several molecular, genetic, and pharmacological techniques provides evidence that altering expression of a single gene (that of course may have pleitropic or epistatic effects) can influence the formation of partner preference, the establishment of pair bonds and potentially the expression of a monogamous versus polygynous social system.

Antisense and gene function. Gene expression in adult animals can be modified through the use of "antisense technology." The DNA in the nucleus of each cell contains specific coding instructions for peptides. This "message" is carried by messenger ribonucleic acid (mRNA)

from the nucleus to the cytosol where protein production occurs. The mRNA sequence that codes for the protein is referred to as the "sense" strand because it provides the message with the instructions for making the protein. Once the mRNA sequence for a certain protein is known, a piece of DNA can be generated that consists of 10–30 complementary bases to the sense mRNA. This piece of DNA (oligodeoxynucleotide) is referred to as "antisense" because it consists of a sequence of bases that is the mirror image of the "sense" message (Galderisi et al., 1999). After entering a cell, the antisense binds to the mRNA and prevents the production of the protein that is normally coded by the mRNA.

One early use of antisense in behavioral neuroscience research examined sexual behavior in female rats (Mani et al., 1994). Typically, high estrogen concentrations provoke the expression of progesterone receptors in the ventromedial nuclei of the hypothalamus and elsewhere. Activation of these hypothalamic progesterone receptors promotes reproductive behavior in female rats. However, when sexually receptive females were treated with progesterone receptor (PR) antisense they did not display appropriate sexual behaviors. Follow-up assays confirmed low gene expression of PR in the hypothalamus. In contrast, females treated with the sense oligonucleotides, which do not bind the mRNA nor disrupt translation, displayed normal sexual behaviors (Mani et al., 1994).

Use of antisense is warranted when pharmaceutical techniques are not available, are nonspecific, or have undesirable side effects. For example both experimental and clinical data have implicated brain α 2-adrenoceptors in the regulation of many psychophysiological measures, including sexual behaviors, anxiety, and stress-coping behaviors (Tanaka et al., 2000), but the results of pharmacological interventions are often inconsistent (Shishkina et al., 2001). Lack of specific ligands for selectively blocking activation of any of the three unique α 2-adrenoceptor subtypes (α 2A, α 2B, and α 2C) may be partially responsible for the conflicting reports. Thus, antisense technology is superior to current pharmacological methods in elucidating the role of α 2-adrenoceptors in behavior because the anti-sense strands can discriminate among the mRNA encoding for the three isoforms. Indeed, administration of anti-sense oligodeoxynucleotides to inhibit α 2A-adrenoceptor expression in the locus coeruleus decreases anxiety-like behaviors in the elevated plus maze (Shishkina et al., 2001).

Gene expression assays. Another relatively new technology that has become extremely useful in both behavioral genetics and behavioral neuroscience is the DNA gene array (although RNA arrays are also used). The gene array technology represents a fusion between genomics and computer microprocessor manufacturing to provide high throughput monitoring of gene expression. The underlying principal of gene arrays is hybridization of complementary strands of nucleic acid (i.e., A-T and G-C for DNA; A-U

and G-C for RNA; Nisenbaum, 2002). Essentially, the gene of interest is represented by a minuscule spot containing probes (usually cDNA or oligonucleotide) that are affixed to a glass slide (or occasionally nylon matrix) in a precise location (Phimister, 1999). Purified RNA is obtained from the samples, then reverse transcribed, labeled with a fluorescent dyes and placed on the gene-chip to allow hybridization. Once the microarray has been processed, the relative levels of gene expression for several thousand genes can be deduced based on the fluorescent signal associated with each probe spot. This is obviously a dramatic increase in throughput as compared to the older molecular biology methods where only one or two genes could be assessed. However, due to the staggering volumes of data that can be derived from a single gene chip, it is necessary to use software to help with data mining and extracting the biologically important, as compared to unimportant, gene expression levels. Also, because the gene array only provides relative information about gene expression, an additional method, such as quantitative real-time PCR must be conducted on individual samples. In behavioral neuroscience, gene arrays might be used to determine relative gene expression during the onset of a behavior, or a change in developmental state, or among individuals that vary in the frequency of a given behavior or behavioral state. Honey bees (*Apis mellifera*) provide an exquisite example of how pheromones can mediate social influences on gene expression and age-related shifts in behavior. Honey bees have a complex social system in which pheromones are an important means of communication. For the first two weeks of their life, honey bees typically perform tasks within the hive, such as brood care (Grozinger et al., 2003). As they age, their physiology and behavior changes, they become better adapted to foraging for nectar and pollen outside of the hive, such that the last several weeks of their lives are spent foraging (Grozinger et al., 2003). In fact, microarray analysis revealed that the profiles of gene expression in the brains of bees are substantially different in bees that are foraging versus providing brood care (Grozinger et al., 2003; Whitfield et al., 2003) and it appears that a pheromone secreted by the queen (queen mandibular pheromone or QMP) regulates the genetic and behavioral changes that accompany the shift from brood care to foraging. Indeed, repeated exposure to a swipe of queen mandibular pheromone consistently activates several genes that are correlated with brood care and suppresses genes that correlate with foraging behavior. Thus, the queen may regulate the shift from hive work to foraging, essentially controlling the division of labor within the colony, through secretion of QMP (Grozinger et al., 2003). These data suggest great genomic plasticity in adult honey bee brains.

The heritability of behavior

The major goal of behavioral genetics is to understand what accounts for individual variation in traits. The meth-

ods of quantitative genetics (e.g., Falconer & Mackay, 1996; Flint, 2003; Phillips et al., 2002) are used to assess the relative roles of genes and environment in individual differences in behavior. As noted, selection and crossing are used in nonhuman animals. In humans and nonhuman animals, the similarities among relatives and non-relatives can be compared. Essentially, these methods allow the individual phenotypic variance to be partitioned into two components: (1) genetic (V_g) and (2) environmental (V_e). This variance is usually expressed as the ratio of genotypic to total variance (i.e., $h^2 = V_g/V_T$, where h^2 = heritability, V_g = variability attributable to genetic variation, and V_T = total phenotypic variability observed in the population); this ratio is known as the heritability of the trait (Griffiths et al., 1999). If either V_g or V_e are known, the other can be obtained by subtraction; i.e., $V_g = V_T - V_e$ and $V_e = V_T - V_g$. This ratio can vary from zero to one. Importantly, there are no traits that have heritability values of zero or of one. Therefore, all behaviors have both genetic and environmental contributions. A heritability quotient of .6 means that 60% of the observed population variability is due to genetic variability and this would be a high genetic influence. A heritability quotient of .3 is considered a moderate genetic influence, whereas a heritability quotient of .1 is considered a small genetic influence.

Although central to many facets of behavioral genetics, there are problems with the concept of the heritability quotient. First, total variation is comprised of variability attributable to genetic variation plus variability attributable to environmental variation plus any variation attributable to the interaction between genetic and environmental factors (i.e., $V_g + V_e + V_{e \times g} = V_T$) (Griffiths et al., 1999). Usually, $V_{e \times g}$ is assumed to be negligible and is typically not considered; thus, as noted above, the formula for determining total variance is usually reduced to $V_g + V_e = V_T$. It is not always apparent that this assumption is warranted because in many cases the effects of genes and environment are not additive, but rather truly interactive (multiplicative and probably non-linear) (Rice & Borecki, 2001). $V_{e \times g}$ suggests that some individuals are genetically more sensitive to environmental influences than others (Silventoinen, 2003).

The explanatory power of heritability ratios is limited, however, to the specific population studied and only in the environment in which the study was conducted (Rice & Borecki, 2001). If the population or the environment changes, then the heritability estimate also will change (Nicholson, 1990). For example, human body height is influenced by genetics, environment, and an interaction between genetics and environment. Although reports regarding the heritability of body height vary greatly, it appears that body height has a heritability of approximately .8 (Silventoinen, 2003). Although this is a very high heritability, this value does not have any predictive value about other populations and does not suggest low environmental influences. For example, some of the variability in reported heritability ratios of height may reflect

socioeconomic differences between study populations. For example, heritability of height is reduced when environmental conditions are poor (Silventoinen et al., 2000). Furthermore, parent-offspring correlations for body height can vary by nation (Mueller, 1976). Indeed, average height has consistently increased over the last several generations among inhabitants of industrialized nations, an effect that is more likely to be explained by increased standards of living than genetics alone (Silventoinen, 2003). Thus, heritability statements provide no basis for predictions about the expression of the trait in question for any specific individual and it is not a measure of genetic control over a phenotype.

Finally, even if the assumptions of additivity between genetic and environmental variances are accepted, heritability only measures the *relative* variability of genetic and environmental contributions, and not the degree to which a trait is inherited, as often claimed. For example, suppose the environment is held constant during a study to determine the contribution of genetic factors to impulsivity, then $V_e = 0$, $V_g = V_T$, and heritability = 1. In contrast, if genetically identical mice are used to examine impulsivity, then $V_g = 0$ and heritability is essentially zero. The extent to which the trait is genetically encoded or inherited is not likely different in the two studies. Therefore, heritability is not an estimate of the degree to which a trait is transmitted genetically. Despite this caution, many people have erroneously used heritability estimates to argue the extent to which a trait is innate (e.g., Jensen, 1973; Herrnstein & Murray, 1994). However, when heritability is high, phenotypic selection is more likely to be successful than when heritability is low. For example, treadmill running endurance in rats was assessed and within each of three generations, the two highest performing pairs and two lowest performing pairs were bred (Koch et al., 1998). The average distance traveled in the founder group was approximately 400 m; after three generations of selective breeding the average distance traveled among low endurance rats had not changed substantially, however, the average distance traveled by the high endurance rats had increased to approximately 650 m. The heritability was determined to be approximately 0.40, that is, 40% of variability in running endurance between high and low endurance rats was due to heritable factors (Koch et al., 1998).

It is now well accepted and documented that in all cases examined including in humans, individual differences in behavioral traits is a function of both genetic and environmental variability. In other words, heritability is neither 0 nor 1 in any studied outbred population. The interesting issues that extend beyond the so-called nature-nurture controversy and will become more central to behavioral genetics include: (1) identifying the genes that affect variance in a trait, (2) understanding how genes interact with each other and with the environment to affect phenotype, and (3) discovering the genetic mechanisms underlying population and species diversity in behavioral phenotypes. Molecular biology and genetics are critical approaches to

addressing these issues. The first step is well underway, *viz.*, identifying all of the genes through the various genome projects. Once these genes are identified, the function of those genes must be ascertained. Studies that identify genes that contribute to behavior and studies that determine the environmental contribution to gene expression are well underway. As genetic tools become more available and inexpensive, these tools will become a large part of psychophysiology research (Plomin & Crabbe, 2000). Completion of the primary genome projects will aid in that goal.

The genome projects

The genome of any individual consists of the DNA strands that comprise the chromosomes in the nucleus of its diploid cells. Each chromosome is comprised of one molecule of DNA. Human have 23 pairs of chromosomes: 22 autosomes and 2 sex chromosomes, termed X and Y. The immediate goal of the genome projects is to determine the sequence of the nucleotide bases (i.e., adenine [A], cytosine [C], guanine [G], or thymine [T]) of the nuclear genome of a single representative (or in some cases, several representatives) of a species. This goal in final and draft forms has been realized for *E. coli*, which has a genome size of 47 Mb (megabases), *C. elegans* which has a with a genome size of 100 Mb, *D. melanogaster* with a genome size of 165 Mb, and *Homo sapiens* with a genome size of ~2900 Mb, (Lander et al., 2001; Morton, 1991); identification of the genome is nearing completion for *Mus musculus*, an important model in mammalian genetics and a useful model in behavioral and biomedical sciences, which has a genome size of approximately 2500 Mb (International Human Genome Sequencing Consortium, 2001; Mouse Genome Sequencing Consortium, 2002).

It is important to note that most of the genome does not reflect coding genes. Indeed, it has been estimated that only 3–5% of the human genome encodes for genes (Lander et al., 2001). For mice and humans (and other mammals for which a draft of the genome is available), it is estimated that there is about one gene per 100,000 bases (International Human Genome Sequencing Consortium, 2001; Mouse Genome Sequencing Consortium, 2002; Rat Genome Sequencing Project Consortium, 2004). The function of non-coding DNA remains to be specified (Gardiner, 1995). The parts of DNA that specify the amino acid sequence of the protein that the gene encodes are called exons; the DNA areas that are interspersed between exons, which are trimmed from the RNA transcript prior to translation into protein, are called introns. Genes are also associated with regulatory regions that interact with other genes and binding proteins to regulate transcription of the gene.

Genomes contain a large quantity of repetitive sequences, which far exceeds the number of sequences necessary for protein-coding genes. For example, >50% of the human genome reveals repeat sequences (Lander et al., 2001).

The sequence variation defining a polymorphism involves either alteration of a single DNA base pair (i.e., single nucleotide polymorphism, or SNP) or tandem lengths of DNA that occur repetitively, with various numbers of repeat elements present in different individuals.

Several different types of repeats have been described including transposon-derived repeats (~45% in human), simple sequence repeats (SSR), and segmental duplications. Of these, SSRs, which are also termed satellite DNA, have been most useful in behavioral genetics. Generally, satellite DNAs show enormous variability among individuals, especially in the number of tandem repeats at a given locus. Units of repetition may be very short (e.g., di- and trinucleotide repeats [also termed microsatellites]) or contain longer DNA sequences known as Variable Number of Tandem Repeats (VNTRs). This variability has been important as a marker for individual variation in several behavioral traits (see the following section).

The number of protein coding genes can be estimated in the genome once the entire sequence is known for a given species. The number of genes in humans has been estimated to be between 35,000–45,000 genes. Also, the amino acid sequence in each protein can be deduced from the coding nucleotide triplets in the gene's structural region as the genome is finely identified.

The mitochondria in each cell also contain DNA; this DNA codes for some of the proteins involved in cellular energy metabolism. This DNA has been sequenced for many organisms including humans. Neurological effects of variants of these mitochondrial genes have been reported, which are important in typical and impaired behavior (Wallace, 1999, 2001).

Gene-environment interactions and behavior

Although genes and environment are often considered separate factors influencing physiology and behavior, genetic factors also can influence the impact of some environmental factors on the development of a particular trait. For example, a person may have a genetic variant that is known to increase his or her risk for developing emphysema from tobacco smoking, an environmental factor. If that person never smokes, then emphysema will not likely develop. Two more subtle examples of an interaction between genes and environment are provided in the following section.

Maternal care in rats. As with human mothers, maternal care varies greatly among rat mothers. Stable individual differences in time spent licking, grooming, and archback nursing (LG-ABN) emerge during the first week postpartum (Champagne et al., 2003). Such naturally occurring variations in the expression of maternal behavior are associated with differences in estrogen-inducible oxytocin receptors in the MPOA (Champagne et al., 2001). Offspring of mothers that exhibit high levels of LG-ABN display life-long attenuation of stress responses, decreased fearfulness, and enhanced cognitive ability (Liu et al.,

1997, 2000; Caldji et al., 1998; Francis et al., 1999). These individual differences in maternal care are transmitted across generations; LG-ABN mothers produce daughters that become high LG-ABN mothers, whereas low LG-ABN mothers produce daughters that become low LG-ABN mothers (Francis et al., 1999). Cross-fostering studies confirm that these behavioral and physiological traits are transmitted across generations via a non-genomic mechanism. In rats, a functional link has been established between central oxytocin receptor levels and behavioral differences in maternal care (Champagne et al., 2001; Francis et al., 1999; Insel & Shapiro, 1992), and oxytocin receptor binding in the MPOA of the hypothalamus is greater in high LG-ABN females as compared with low LG-ABN mothers (Champagne et al., 2001; Francis et al., 1999). Estrogen regulation of oxytocin receptors in the MPOA is dependent on the alpha but not beta estrogen receptor subtype (Young et al., 1998; Champagne et al., 2003).

In addition to altering oxytocin receptor binding, exposure to high LG-ABN produces an increase in glucocorticoid receptor gene expression in the hippocampus, which presumably contributes to efficient regulation of the hypothalamic-pituitary-adrenal (HPA) axis throughout life (McCormick et al., 2000). These effects on GR gene transcription in high LG-ABN offspring are achieved through decreased DNA methylation, and increased histone acetylation and nerve growth factor-induced gene A (NGFI-A, a transcription factor) binding to the GR promoter (Weaver et al., 2004). DNA methylation affects the promoter region of a gene and provides long-term gene silencing (Egger et al., 2004). Thus, the demethylation that occurs soon after birth as a result of exposure to high LG-ABN, presumably results in a significant increase in GR gene expression (Weaver et al., 2004). Furthermore, acetylation of the histones promotes transcription factor binding to the promoter sites. These differences in DNA methylation and histone acetylation exist between high and low LG-ABN offspring by postnatal day 6 and persisted into adulthood. The effects were reversed by cross-fostering high LG-ABN offspring to low LG-ABN mothers on the first day of life (Weaver et al., 2004). Thus, these maternally induced epigenetic influences (i.e., factors that influence phenotype without altering the genotype) persist into adulthood and can be passed on to subsequent generations. The extent to which such organizational effects of glucocorticoids, induced by relative subtle alteration in neonatal environment, apply to humans remains unspecified.

Monoamine oxidase A and human violence. Over a decade ago, a genetic study of a large Dutch kindred with a family history of impulsive violence (including attempted sexual assault, arson, and battery) was undertaken. Urine samples from the aggression study participants revealed disturbed monoamine metabolism; further genetic analysis identified a point mutation in the monoamine oxidase A (MAOA)

gene (Brunner et al., 1993). The mutation produces an early stop codon, which renders the affected males of this family completely devoid of MAOA activity (Brunner et al., 1993). The gene for MAOA is located on the X chromosome, so men have only one copy of the gene and if mutated exhibit impulsive behavior. In contrast, female obligate carriers of the mutated gene exhibit normal intelligence and behavior, presumably because the women have two X chromosomes, and therefore two copies of the MAOA gene. Subsequent work confirmed that male transgenic mice in which the gene for MAOA was deleted, also displayed elevated aggressive behavior (Cases et al., 1995; Shih, 2004; Holschneider et al., 2001). The correspondence between the rodent and human data suggests that the influence of MAOA on aggressive behavior is well conserved across species. However, the mutation described in the Dutch family is relatively rare, produces an extreme change in MAOA activity, and is not likely to account for a large proportion of variation in human aggression and violence. There is wide variability in MAOA activity in the normal population. For example, a repeat length polymorphism (VNTR) located upstream of exon 1 in the MAO A regulatory region contains four common alleles that have between three and five repeats of a 30-base pair (bp) sequence (Sabol et al., 1998). In vitro experiments indicate that these allelic differences in humans could result in two to ten-fold differences in transcriptional activity in the MAOA gene (Sabol et al., 1998). In all of the cell lines, the constructs that contained human alleles 2 and 3 (which have 3.5 or 4 copies of the 30 bp repeat, respectively) were expressed at significantly higher levels than the constructs containing alleles 1 and 4 (which have 3 or 5 copies of the 30 bp repeat, respectively; Sabol et al., 1998). When polymorphic variation in this 30 bp VNTR in the promoter region of the MAOA gene was assessed in a community sample of men, those with alleles 2 or 3 (the high transcription variants) exhibited reduced serotonergic responsivity and scored higher on a composite measure of aggressiveness and impulsivity than men with either of the other two alleles (Manuck et al., 2000). Furthermore, the high activity MAOA allele 3 also was more common among boys who were identified by parents and teachers as being persistently aggressive (Beitchman et al., 2004). Thus, both complete absence of MAOA activity (humans and mice) and increased MAOA activity within the physiological range (humans) are associated with increased aggressive behavior.

How important are environmental influences on a complex behavior such as aggression? In a recent path breaking study (Caspi et al., 2002), young men in New Zealand who were part of a long-term developmental study were examined for a link between anti-social behavior and high versus low activity MAO A. The cohort of 1037 people (52% male) was assessed every two to three years between the ages of 3 and 26 years. Remarkably, nearly 97% of the original birth cohort remained in the study at age 26. Between the ages of 3 and 11 years, 8% of the study children experienced "severe" maltreatment, 28% experienced "probable"

maltreatment, and 64% experienced no maltreatment (Caspi et al., 2002). The maltreated groups did not differ in MAO A activity from the group that was not mistreated, thereby implying that genotype did not influence exposure to maltreatment. However, among the maltreated groups, individuals with low MAOA gene expression had a higher likelihood to develop adult antisocial and aggressive behaviors than maltreated children with a genotype conferring high levels of MAO A expression (Caspi et al., 2002). These results may partially explain why not all victims of maltreatment develop into abusers themselves. Genes can moderate an individual's responsiveness to environmental perturbations. Allelic variation in MAOA activity also interacts with early environment in rhesus monkeys to influence the expression of aggressive behavior (Newman et al., 2005). Studies on gene-environment interactions promise to be highly informative in behavioral genetic studies of psychophysiology.

Twin studies provide insight into genotype x environment interaction. The comparison of physical and psychological measures in monozygotic (MZ) and dizygotic (DZ) twins provides an important tool for studying the interaction between genotype and environment (Boomsma et al., 2002; Legrand et al., 2005). MZ twins are genetically identical (or in rare cases, nearly identical), while DZ twins share 50% of their segregating genes on average. Thus, any heritable disorder will be more concordant in MZ than DZ twins. Twin studies also offer the added advantages of (1) removing the potential confound of age differences between siblings, (2) increasing similarities in prenatal and post-natal influences and environment experienced by the siblings, and (3) increasing certainty of shared paternity (Boomsma et al., 2002; see Figure 17.3). Using MZ and DZ twins from six European Union countries, it was determined that the heritabilities for resting blood pressure range from 44–66% for diastolic blood pressure and 52–66% for systolic blood pressure, and that 50% of the variance in blood pressure is due to genetic factors (Evans et al., 2003). Only in Finish twins did there appear to be an effect of shared environmental factors on resting blood pressure. The MZ-DZ design also has been used to confirm genetic and environmental influences on blood lipid concentrations (Knoblauch et al., 2000). QTL linkage analysis was then performed on the DZ subset (MZ twins are not useful in linkage studies because they are genetically identical) and strong evidence was provided for linkage at a chromosome 13q locus with HDL, LDL, total cholesterol, and body weight. Thus, the study led to the identification of a new gene that decreases blood lipid concentrations in apparently healthy humans (Knoblauch et al., 2000).

Twin studies also have been used to estimate heritable versus environmental influences on complex behavioral disorders, including vulnerability toward conduct disorder, adult antisocial behavior, drug dependence, and alcohol dependence (Hicks et al., 2004). General vulnerability toward these externalizing disorders among 17 year old twins was highly heritable ($h^2 = .8$); disorder-specific

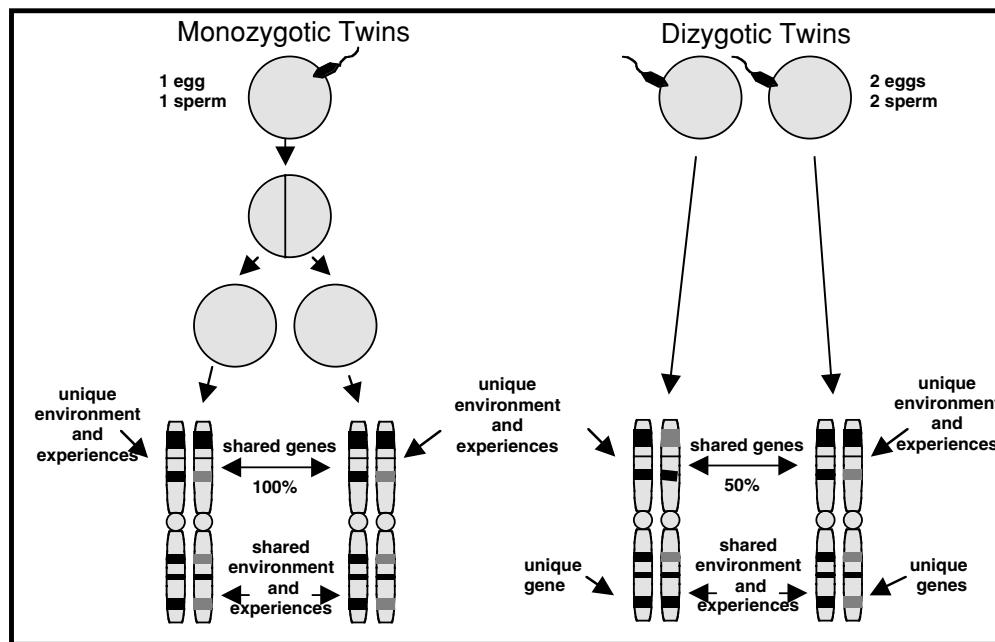

Figure 17.3. Twins are an effective way to assess genetic and environmental contributions to behavior in humans. Monozygotic (identical) twins develop from a single fertilized egg and share 100% of their segregating genes and some environmental influences and life experiences. Dizygotic (fraternal) twins develop from two separate fertilized eggs and share, on average, 50% of their segregating genes and some environmental influences and life experiences. Thus, any physiological or behavioral characteristic with a genetic influence is revealed through higher concordance among monozygotic than dizygotic twins.

vulnerabilities also were detected for each of these externalizing disorders except adult antisocial behavior (Hicks et al., 2004). Of course, exhibiting an “externalizing disposition” does not preordain an individual to behavioral disorders, there are many socially acceptable/beneficial ways in which externalizing tendencies could be expressed (i.e., engaging in high-risk occupations or hobbies).

What are the implications of behavioral genetics?

Researchers in the field of behavioral genetics have asserted that many behaviors, including aggression, impulsivity, homosexuality, parenting, learning, and nurturing have a genetic basis. A growing scientific and popular focus on genes and behavior has contributed to a resurgence of behavioral genetic determinism – the belief that genetics is the major factor in determining behavior. This contradicts the dominant *zeitgeist* in North American psychology during most of the twentieth century in which behaviorism prevailed. Fueled by John B. Watson’s impressive writings early in the twentieth century that only *overt* behavior could be considered the rightful topic of scientific studies on behavior, introspection was shed as a method of data collection. Paired with the distaste of North Americans for the misuse of genetics in the form of eugenics, the pendulum of the nature-nurture controversy stayed far in the range of “nurture” for most of the century. Watson’s famous assertion ruled out a significant role for genes: “Give me a dozen healthy infants, well formed, and my own specified world to bring them up in and I’ll guarantee

to take any one at random and train him to become any type of specialist I might select – doctor, lawyer, artist, merchant, chief, and yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors. There is no such thing as an inheritance of capacity, talent, temperament, mental constitution, and behavioral characteristics” (Watson, 1925). During the first decade of the twenty-first century, the pendulum may be swinging too far into genetic regulation of behavior (Plomin & Crabbe, 2000). Variation in behavior is a result of both environmental and genetic factors.

It would be useful to move beyond the nature-nurture controversy. The issue of considering whether behaviors are inbred, written indelibly in our genes as immutable biological imperatives, or whether environment is more important in shaping cognition and behavior, remains a false dichotomy. Behaviors only exist in the context of environmental influence. Regardless, the debate ignites again every few years, in response to genetic analyses of traits such as criminality, intelligence, or homosexuality, traits that bear significant social, legal, and political meaning. Ethicists, politicians, and members of society will have to wrestle with the social consequences of finding genes tightly associated with behavioral traits.

Probing the Mechanisms of Attention

MICHAEL I. POSNER, M. ROSARIO RUEDA, AND PHILIPP KANSKE

ABSTRACT

This chapter emphasizes the many methods currently being employed to study brain networks related to attention. We seek to set current studies into a historical background of efforts to understand how the brain selects among stimuli and resolves competing responses. We examine attention as an organ system with networks of neural areas related to several major functions such as maintaining the alert state, orienting to sensory events and resolving conflict between responses. We consider the anatomy and circuitry of these networks and examine the role of genes and experience in their normal development and of various pathologies. Finally we examine how our current knowledge of the psychophysiology of attention illuminates traditional issues in cognition about how attention operates.

The field of attention is one of the oldest in psychology. At the turn of the twentieth century Titchener (1909) called attention “the heart of the psychological enterprise.” Attention is relatively easy to define subjectively as in the classical definition of William James who said: “Everyone knows what attention is. It is the taking possession of the mind in clear and vivid form of one out of what seem several simultaneous objects or trains of thought.” (James, 1890, p. 403). However, this subjective definition does not provide hints that might lead to an understanding of mechanisms of attention that can illuminate its physical basis in terms of underlying physiological process nor clarify its normal development and pathologies. For these goals it is useful to think about attention as an organ system with its own anatomy and circuitry that develops in early life under the control of genes and experience. This will be the focus of our chapter.

The modern history of attention as an organ can be started with the important studies of Maruzzi and Magoun (1949) on the reticular activating system. About the same

time, Hebb (1949) called attention to the importance of networks of neural areas (cell assemblies and phase sequences) in building conscious representation of stimulus input (see Posner & Rothbart, 2004 for a review of Hebb’s contribution). In the last fifty years there has been steady progress in the development of methods that allow us to probe the mechanisms of attention at a physiological level. It is the development of these methods and their use to probe attentional networks that seems most relevant to the current handbook.

In this chapter we first trace history of the development of methods that allow study of attentional separately from other cognitive functions. We examine the methods used to link attention to underlying brain mechanisms including studies of lesioned patients, recording of electrical activity noninvasively in humans or by use of implanted electrodes and efforts to understand the genes related to attention. These include the use of microelectrodes in alert animals beginning in the 1970s and early studies of neuroimaging using hemodynamic methods starting in the 1980s. After our historical review, we examine current studies within cognitive psychology to get an idea of the functions of networks in vigilance, visual search, and cognitive control tasks. We then examine the anatomical networks that underlie these functions using whenever possible the combined methods that have developed over the last half century to explore neural networks. We then consider evidence of how genes and experience shape the development of attentional networks. At the end we return to some of the major questions in cognition that concern attention and review their current state.

MODERN HISTORY

1950s

D. O. Hebb (1949) argued that all stimuli had two effects. One of these, following the studies of Maruzzi and Magoun, involved the reticular activating system and worked to keep the cortex tuned in the waking state, whereas the other used the great sensory pathways and

The authors would like to thank Prof. Mary K. Rothbart for her participation in this research and colleagues at the University of Oregon and the Sackler Institute at Weill Medical College of Cornell University.

provided information about the nature of the stimulating event.

In the early 1950s, Colin Cherry (Cherry, 1953) initiated an epic series of experiments designed to examine how subjects selected stimuli that were presented simultaneously to each ear. A major result was that rapid presentation of pairs of digits one to each ear, led people to recall of all digits presented to the right ear first, followed by all presented to the left. Broadbent (1958) summarized these and other results by suggesting that a peripheral short-term memory system buffers sensory input prior to a filter, which selects a channel of entry (in this case an ear) and sends information to a limited capacity perceptual system.

A second line of attention research that emerged from studies conducted in the Second World War involved the study of sustained attention during vigilance tasks (Mackworth & Mackworth, 1956). During continuous tasks subjects tended to miss more signals as the task continued. Changes in the EEG suggested that there was an increase in a sleep-like state.

1960s

One of the big developments of the 1960s involved the ability to average electrical signals from the scalp to develop the event-related potential, as a series of electrical events time locked to the stimulus. The technique was applied to the study of attention. In 1965 Sutton (Sutton et al., 1965) reported that surprising or unexpected cognitive events, of the type that might be closely inspected produced a strong positive wave in the scalp potential called the P 300. This component has and continues to play an important role in attention research (Donchin & Cohen, 1967; Rugg & Coles, 1995).

At about the same time Gray Walter reported that the brain produced a marked DC shift during the period following a warning and prior to a target, this was called the contingent negative variation and was viewed as a sign that alerting was taking place (Walter et al., 1964). Reaction time improved markedly over the first 500 milliseconds following the warning and often, errors increased with warning interval, producing a tradeoff between speed and accuracy. This finding suggested that warning effects did not improve the accrual of information but instead made it faster to attend to the input and thus sped the response (Posner, 1978).

1970s

The work of Hubel and Wiesel (1968) using microelectrodes to probe the structure of the visual system began in the early 1960s. However, before this method could be applied to attention it was necessary to adapt the micro-electrode technique to alert animals. This was accomplished in the early 1970s by Evarts (1968) and applied by Mountcastle (1978) and Wurtz, Goldberg, and Robinson (1980) to examine mechanisms of visual attention in the

superior colliculus and parietal lobe. Their findings suggested the importance of both of these areas to a shift of visual attention. It had been known for many years that patients with lesions of the right parietal lobe could suffer from a profound neglect of space opposite the lesion. The findings of "attention related cells" in the posterior parietal lobe of alert monkeys suggested that these cells might be responsible for the clinical syndrome.

An impressive result from the microelectrode work, was that the time course of parietal cell activity seemed to follow a visual stimulus by 80–100 milliseconds. Beginning in the 1970s, Hillyard (van Voorhis & Hillyard, 1978) and other investigators explored the use of scalp electrode to examine time differences between attended and unattended visual locations. They found that the N1 and P2 components of the visual event related potential showed changes due to attention starting at about 100 milliseconds after input. These finding showed likely convergence of the latency of psychological processes as measured by ERPs in human subjects and cellular processes measured in alert monkeys. This finding was a very important development for mental chronometry because it suggested that scalp recordings could accurately reflect the underlying temporal structure of brain activity.

1980s

Posner (1980) studied the use of a cue in an otherwise empty visual field as a way of moving attention to a target. Electrodes near the eyes were used to insure there were no eye movements and because only one response was required there was no way to prepare the response differently depending upon the cue, making it clear that whatever changes were induced by the cue were covert and not due to motor adjustment of the eyes or hand.

It was found that covert shifts could enhance the speed of responding to the target even in a nearly empty field. Within half a second, one could shift attention to a visual event and, when it indicated a likely target at another location, move attention to enhance processing at the new location. It was shown (Shulman, Remington, & McClean, 1979) that response times to probes at intermediate locations were enhanced at intermediate times as though attention actually moved through the space and that it was possible to prepare to move the eyes to one location while moving attention covertly in the opposite direction (Posner, 1980). Whether attention moves through the intermediate space and how free covert attention is from the eye movement systems are still disputed matters (LaBerge, 1995; Rizzolatti et al., 1987), suggesting the limitation of purely behavioral studies.

At the time, it was also hard to understand how a movement of attention could possibly be executed by neurons. Subsequently it was shown that the population vector of a set of neurons in the motor system of a monkey could carry out what would appear behaviorally, as a mental rotation (Georgopoulos et al., 1989). After

that finding, a covert shift of attention did not seem too far-fetched.

It had been reported that patients with lesions of the parietal lobe could make same-different judgments concerning objects that they were unable to report consciously (Volpe, LeDoux, & Gazzaniga, 1979). It was possible to follow this result in more analytic cognitive studies. What did a right parietal lesion do that made access to material on the left side difficult or impossible for consciousness and yet still left the information available for other judgments?

This puzzle was partially answered by the systematic study of patients with different lesion locations in the parietal lobe, the pulvinar and the colliculus. These lesions all tended to show neglect of the side of space opposite the lesion. But in a detailed cognitive analysis it was clear that they differed in showing deficits in specific mental operations involved in shifting attention (Posner, 1988). These studies supported a limited form of brain localization. The hypothesis was that different brain areas executed individual mental operations or computations such as disengaging from the current focus of attention (parietal lobe), moving or changing the index of attention (colliculus), and engaging the subsequent target (pulvinar). If this hypothesis were correct it might explain why Lashley thought the whole brain was involved in mental tasks. Perhaps it's not the whole brain, but a widely dispersed network of quite localized neural areas.

1990s to Date

In the late 1980s, the Washington University School of Medicine was developing a PET center led by Marc Raichle. These studies helped establish neuroimaging as a means of exploring brain activity during cognitive functions in general and the study of attention in particular. (Posner & Raichle, 1994, 1998). In general, these studies have shown that most cognitive tasks, including those that are designed to separate mechanisms of attention, have activated a small number of widely scattered neural areas. Some people have argued that these areas are specific for domains of function like language, face perception, or episodic memory (Kanwisher & Duncan, 2004). In the area of attention it has been more frequent to consider the mental operations or computations carried out by a particular area (Corbetta & Shulman, 2002; Posner, 2004). These two ideas are not mutually exclusive. It is certainly possible to talk about the set of areas that are involved in language and at the same time maintain that the areas carry out different computations within that domain.

The findings from neuroimaging that cognitive tasks involve a number of different anatomical areas has led to an emphasis on tracing the time dynamics of these areas during tasks involving attention. Because shifts of attention can be so rapid it is difficult to follow them with hemodynamic imaging. To fill this role, algorithms have been developed (Scherg & Berg, 1993) to relate the scalp distribution recorded from high density electrical or magnetic sensors on or near the skull to brain areas active

during hemodynamic imaging (see Dale et al., 2000, for a review). In some areas of attention there has been extensive validation of these algorithms (Heinze et al., 1994) and they allow precise data on the sequence of activations during the selection of visual stimuli (see Hillyard, Di Russo, & Martinez, 2004 for a review). The combination of spatial localization with hemodynamic imaging and temporal precisions from electrical recording has provided an approach to the networks underlying attention.

At the turn of the century the overall sequence of the human genome had been accomplished (Venter et al., 2001). Although humans have a common genome there are differences among individuals, in many genes (polymorphisms). These differences make it possible to examine particular genes related to individual differences in behavior and in brain activity (Goldberg & Weinberger, 2004; Mattay & Goldberg, 2004).

COGNITIVE STUDIES

The cognitive approach to attention provides a variety of models and conceptual frameworks for brain studies. Perhaps the most general issue is whether to think of attention as one thing or as a number of somewhat separate issues. A classic distinction in the field is to divide attention by considering separately the intensive and selective aspects (Kahneman, 1973). Attentional states vary. They include slow wave sleep, coma, rapid eye movement sleep, and degrees of wakefulness that may vary over the course of the day (dirurnal rhythm), time on task or following warnings. These states can be contrasted with selective attention that involves the mechanisms in committing resources to some particular event.

In this chapter we follow a division of attention into three distinct networks: one of these involves a change of state and is called alerting. The other two are closely involved with the selection and are called orienting and executive control (Posner & Petersen, 1990). Alerting deals with the intensive aspect of attention related to how the organism achieves and maintains the alert state. Orienting deals with selective mechanisms operating on sensory input. The idea that new sensory stimuli lead to an orienting reflex goes back to the classic studies of Sokolov (1963) on peripheral changes underlying the orienting reflex, but much new has been learned about the brain systems involved. The executive network deals with conflict among competing responses and related to issues such as the development of self-regulation not only of thoughts but also of feelings and behavior (Rueda, Posner, & Rothbart, 2004). Although in much of our behavior all of these networks are involved simultaneously, the distinction allows us to review somewhat different literatures.

ALERTING

The state of wakefulness and arousal is influenced by internal and external signals (Hackley & Valle-Inclan, 1998). Intrinsic or tonic alertness clearly changes over the course

of the day from sleep to waking and within the waking state from sluggish to highly alert. Originally these effects were thought to involve a single mechanism, the reticular activating system, but current research considers the interplay of a number of midbrain neural modulators such as norepinephrine and dopamine to be involved. In all tasks involving long periods of processing the role of changes of state may be important. Thus vigilance or sustained attention effects probably rest at least in part on changes in tonic alerting system.

The presentation of an external stimulus can also increase alertness. The clearest case can be observed as a reduction in reaction times in tasks in which a warning signal is presented prior to a target. This effect is partly automatic as it can occur with an auditory accessory event, which does not predict a target. It is partly due to voluntary actions based on the information about the time of the upcoming target. These effects can be observed as a general DC shift in electrical activity of the EEG called the contingent negative variation (Walter et al., 1964). However, more specific negative shifts may also be seen in particular structures depending upon the target or activity required in the task (Rosler, Heil, & Roder, 1997).

Alertness reflects the state of the organism for processing information and is an important condition in all tasks. It is also possible distinguish effects of alertness on sensory input from its effect on motor systems (Sanders, 1998).

ORIENTING

When examining a visual scene there is the general feeling that all information about it is available. However, careful experimental studies (Rensink, O'Regan & Clark, 1997; Rock & Guttmann, 1981) have shown that this is not the case. Important semantic changes can occur in the scene without any report of the observer provided they take place away from the focus of attention and cues that are normally effective in producing a shift of attention such as luminance changes or movement are suppressed. These findings, called change blindness, underlie the importance of attention shifts for normal conscious perception.

The study of visual orienting has often involved the use of visual search tasks in which a particular object is defined as a target (Treisman & Gelade, 1980). Visual search has been used to study limits to the amount of information contained in a scene that is passed on to higher processing (Broadbent, 1958; Treisman & Gelade, 1980). A widely used metaphor for this capacity limit (Cavanagh, 2004) views attention orienting as a spotlight that enables examination of details within the spotlight while reducing what can be reported outside the spotlight.

When the target differs in a single element from all the background reaction times generally are similar irrespective of the number of elements as though they pop out from the background. However, when the target and background have attributes in common reaction times generally increase linearly with the number of background elements, conjunction search (Treisman & Galade, 1980). The

idea of conjunction search suggests a single focus of attention that is moved at all over the visual display. Indeed when the array is large, eye movements are a major vehicle for moving the focus of attention from one location to another. However, similar results can be obtained even when the eyes are fixed and this underlies the idea that attention can be viewed as a covert spotlight.

Several recent studies suggest the existence of multiple spotlights (Yantis, 1992; Kramer & Hahn, 1995). Awh and Pashler (2000) were able to demonstrate that just an extension in size of the spotlight is not sufficient to explain all of the extant data. However, it seems that the size of the selection region can vary extensively in correspondence to what is demanded by the task (Klein & McCormick, 1989). The minimal selection region within a fixation can be described as a covert acuity limit (Intriligator & Cavanagh, 2001). Cavanagh (2004) argues for another limitation he calls coding singularity. Within the selection region it is not possible to further scrutinize details, instead a single label is passed on for the entire region (Nakayama, 1990). Of course coding singularity is the basis for the acuity limit but the acuity limit determines the minimum selection region.

Visual orienting is an important model because of the close coordination between overt motor activity and internal covert selection. Overt and covert shifts of attention often go together. Shifts in gaze seem to be preceded by covert orienting of attention. This tight linkage between covert and overt orienting is supported by neuroimaging data showing extensive overlap in the corresponding brain regions. The behavioral and imaging data support the oculomotor readiness hypothesis (Klein, 1980; see also "pre-motor theory," Rizzolatti et al., 1987) stating that endogenous covert orienting is the preparation of an eye movement. However, the two predictions arising from this hypothesis, faster eye movements to attended locations and facilitated detection of events at locations to which an eye movement is being prepared, have not been completely supported (Klein, 2004; Hunt & Kingstone, 2003). It is possible that endogenous covert and overt orienting are isolable systems. Klein (2004) formulates three conclusions: "There is a tight linkage between saccade execution and covert visual orienting... overt and covert orienting are exogenously activated by similar stimulus conditions (and) endogenous covert orienting of attention is not mediated by endogenously generated saccadic programming."

Although head or eye movements can achieve overt orienting, most research on overt orienting has concentrated on one type of eye movement, namely saccades. If subjects are required to perform a saccade to a peripheral target, the saccadic reaction time is shortened when a fixation or another peripheral signal is turned off shortly, about 100–200 ms, before the target appears (gap effect) (Schiller, Sandell, & Maunsell, 1987). Klein and colleagues (Klein & Kingstone, 1993; Taylor, Kingstone, & Klein, 1998) proposed a three-component-model explaining this pattern: An offset of any stimulus in the environment can increase alertness by functioning as a warning signal. As depicted

above, reaction times decrease with increasing alertness. Also, because of the disappearance of a signal the oculomotor system will be exogenously disengaged and there has to be an endogenous disengagement of the oculomotor system as in the natural environment objects of fixation rarely disappears.

A task that is widely used to study endogenous control of overt orienting is the anti-saccade task in which a saccade away from a target is to be performed. However, Klein (2004) points out that this procedure is “messy” as it includes more than one endogenous orienting computation. The endogenous attentional computation as well as the endogenous execution of the saccade has to be performed. Additionally, an exogenously controlled saccade to the target has to be inhibited. The oculomotor capture paradigm (Theeuwes et al., 1998) explicitly enables exploration of the interaction between exogenous and endogenous orienting. Results of this research and the evidence provided above suggest a competition of endogenous and exogenous signals for control of the oculomotor system (Klein, 2004).

Another important characteristic of the orienting network is an inhibitory function. Inhibition in general in cognitive tasks is inferred from an increase in reaction time or an increased error rate. In orienting tasks when a peripheral cue is presented more than 300 ms before a target, inhibition takes place at the location of the cue and reaction time at that location increases. This effect called inhibition of return (IOR) (Posner & Cohen, 1984) suggested that the initial exogenous shift of attention to the cued location has been terminated and a return to that location is now inhibited. IOR can also be observed in tasks in which not only one peripheral cue is presented as described above (single-cue procedure) but also when a center cue is presented between the presentation of the peripheral cue and the target (double-cue procedure). Fuentes and colleagues (Fuentes, Vivas, & Humphreys, 1999) demonstrate that when more complex stimuli are presented at the cued location, and thus inhibited, they were less likely to elicit semantic priming compared to primes presented at an uncued location. These authors also applied Erikson’s flanker paradigm (Erikson & Hoffman, 1972, 1973), which consists of the presentation of a central stimulus (e.g., an arrow) accompanied by either congruous (arrows pointing in the same direction) or incongruous (arrows pointing in the opposite direction) stimuli. When the flankers are presented at the cued location, contrary to the usual results, congruous flankers produced longer RTs compared to incongruous flankers. Fuentes (2004) called this effect inhibitory tagging, a mechanism temporally inhibiting “the links between the activated representations of inhibited stimuli and their appropriate response.” Data from parietal and schizophrenic patients show that IOR and inhibitory tagging, although both affecting stimuli at already explored regions are separate inhibitory mechanisms (Vivas, Humphreys, & Fuentes, 2003; Fuentes et al., 2000). IOR fulfills an important function as it prevents re-examination of locations that have already been explored

(Klein, 2000). As alertness is increased with changing environmental conditions, it seems as if orienting and alerting bias the organism for novelty and change.

EXECUTIVE ATTENTION

An important vehicle for studying executive attention is to induce conflict between response tendencies particularly where the person is to execute the subdominant response while suppressing the dominant tendency (Botvinick et al., 2001). For example, in the Stroop task, a dominant because well-learned response (reading a color word) has to be oppressed in favor of a less dominant response (naming the color a word is printed in). The flanker task would be another example in which a target stimulus is surrounded either by congruent or incongruent flankers for a conflicting response situation. Executive attention is also required in error commission, in working memory tasks (Baddeley, 1993) or in problem solving.

Executive attention has been examined by developing neural network models. A theoretical model dealing with executive, controlling functions of attention has been presented by Cohen, Aston-Jones, and Gilzenrat (2004) by modifying an earlier model of the Stroop task (Cohen, Dunbar, & McClelland, 1990). The model is made up of units, which are organized in two pathways, a color naming pathway and a word pathway. Each pathway contains stimulus units projecting to associative units, which project to verbal response units. If the connections are stronger in the word pathway the model will be biased towards reading the word and not naming the color, similar to human behavior. To be able to also explain the human capability of overriding this prepotent response tendency – to name the color and not read the word – the model was modified. Task demand units were included each of which matches to a certain task (read a word or name the color). As these task demand units are connected to the associative units in the corresponding pathway, activation of a task demand unit will modulate the activity of these associative units and bias the system. It is now possible for the model to not read a word in favor of naming its color and thus to show executive control.

Similar models have been proposed to account for other functions of the executive attention network. Botvinick and colleagues (2004) demonstrated that adding a conflict monitoring unit to models of different tasks could account for behavioral and neuroscientific results, that occur with making an error.

Another approach to executive attention is to examine similarities between orienting to information in long-term memory and orienting to sensory information. A mechanism similar to inhibition of return in the orienting network has been described by Fuentes (2004). With sufficiently long intervals between the presentation of a semantically related prime and target (Neely, 1977) or the presentation of a semantically unrelated cue between prime and target (similar to the double cue procedure), negative priming was observed. Taken together with the results

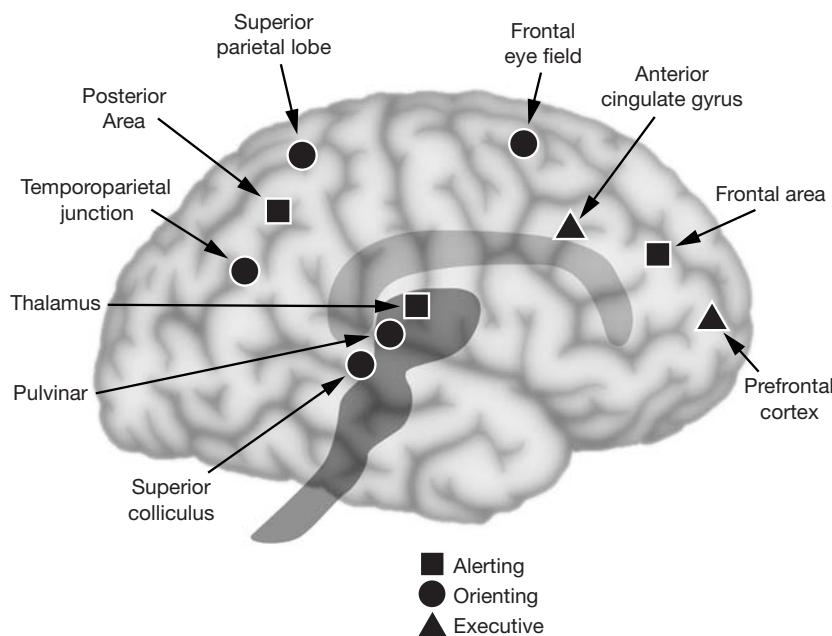

Figure 18.1. This figure illustrates brain areas involved in three attention networks. The alerting network (squares) includes thalamic and cortical sites related to the brain's norepinephrine system. The orienting network (circles) is centered on parietal sites (discussed in the following section) and the executive network (Triangles) includes the anterior cingulate and other frontal areas.

from studies (described above) examining how orienting and executive attention co-act when primes or flankers are presented at locations subject to IOR the bias for novelty seems to be "a pervasive property of the attention system" (Fuentes, 2004).

As indicated above cognitive theories of attention continue to be essential in understanding attentional phenomena, in the era of new methods such as neuroimaging.

ANATOMICAL NETWORKS

In this section we outline studies using all of the methods cited in our historical introduction to indicate the common anatomy and circuitry of attentional networks involved in alerting, orienting, and executive control. These are illustrated in cartoon form in Figure 18.1.

ORIENTING TO SENSORY EVENTS

The vast majority of studies of the physical basis of attention have involved orienting to sensory events, particularly visual events. The findings of these studies provide the basis for our limited understanding of how to approach brain mechanisms of attention. In this field a basic distinction is between those brain areas that are influenced by acts of orienting (sites) and those that are parts of the orienting network itself and thus the sources of the orienting influence. Although our discussion focuses mainly on vision, it is limited to the sources of the attention effect that appear to be similar in other modalities (Macaluso, Frith & Driver, 2000; Driver, Eimer, & Macaluso, 2004).

Sites and sources. Normally all sensory events act both to contribute to a state of alertness and to orient attention (Hebb, 1949). In order to distinguish the brain areas that are involved in orienting (See Figure 18.1) from the sites at

which they operate it is useful to separate the presentation of a cue indicating where a target will occur from the presentation of the target requiring a response (Posner, 1980; Corbetta & Shulman, 2002). This methodology has been used for behavioral studies with normal people (Posner, 1980); patients (Posner, 1988) and monkeys (Marrocco & Davidson, 1998); and in studies using scalp electrical recording (Hillyard, DiRusso, & Martinez, 2004) and event related neuroimaging (Corbetta & Shulman 2002).

Studies using event related fMRI have shown that following the presentation of the cue and before the target is presented a network of brain areas become active (Corbetta & Shulman, 2002; Kastner et al., 1999; Hillyard, DiRusso, & Martinez, 2004). These include the superior parietal lobe, temporal parietal junction and frontal eye fields shown in Figure 18.1. There is widespread agreement about the identity of these areas (see Orienting areas in Figure 18.1) but there remains a considerable amount of work to do in order to understand the function of each area.

When a target is presented at the cued location it is processed more efficiently than if no cue had been presented. The brain areas influenced by orienting will be those which that would normally be those used to process the target. For example, in the visual system orienting can influence sites of processing in the primary visual cortex, or, or in a variety of extra striate visual areas where the computations related to the target are performed. Orienting to target motion influences area MT (V5) while orienting to target color will influence area V4 (Corbetta et al., 1991). This principle of activation of brain areas also extends to higher-level visual input as well, for example, attention to faces modifies activity in the face sensitive area of the fusiform gyrus (Wojciulik, Kanwisher, & Driver, 1998). The finding that attention can modify activity in primary visual areas (Posner & Gilbert, 1999) has been of particularly important

because the microcircuitry of this brain area has been more extensively studied than another other.

When multiple targets are presented they tend suppress the normal level of activity they would have produced if presented in isolation (Kastner et al., 1999). This finding has become the cornerstone of one of the most popular views of attention in which emphasis is placed on competition between potential targets within each relevant brain area (Desimone & Duncan, 1995). This view places less stress upon top-down control or at least emphasizes that top-down control emerges from bottom-up competition.

Functional anatomy. Work with stroke patients showed that lesions of many brain areas result in difficulty shifting attention to locations or objects that were conveyed directly to the damaged hemisphere (Rafal, 1998). In neurology these patients would be said to be suffering from extinction in that when simultaneous stimuli are presented to both hemispheres only the one going to the undamaged hemisphere is consciously perceived. Experimental studies suggested that we could define different forms of extinction due to lesions of the parietal lobe, the midbrain or the thalamus (Posner, 1988). Data in the 1980s suggested that operations of disengage (parietal lobe), move (superior colliculus), and engage (pulvinar) were computed in different brain areas that formed a vertical network that together performed the task of orienting.

More recent studies involving both patients and imaging seem to support this general approach to localization, but suggest somewhat different separation of the operations involved. A paradox of the lesions studies of the early 1980s was that the superior parietal lobe seemed to be the area most related to producing a difficulty in disengaging from a current focus of attention. Yet most clinical data seemed to support the idea that clinical extinction arose from more from lesions of the temporal-parietal junction. Event related imaging studies have served to reconcile this difference (Corbetta & Shulman, 2002). There seem to be two separate regions both of which can both produce difficulty in shifting attention in contralesional space, but for quite different reasons. Lesions of the temporal-parietal junction are important when a novel or unexpected stimulus occurs (Corbetta & Shulman, 2002; Friedrich et al., 1998; Karnath, Ferber, & Himmelbach, 2001). When functioning normally, this area allows disengaging from a current focus of attention to shift to the new event. This area is most critical in producing the core elements of the syndrome of neglect or extinction in both humans and monkeys although the exact location of the most critical area may differ between the two species. In addition, there is much clinical evidence that in the human there is lateralization in the right temporal parietal junction that may be more important to the deficit than the left (Mesulam, 1981; Perry & Zeki, 2000).

A different region, the superior parietal lobe, seems to be critical for voluntary shifts of attention following the cue. In one event-related fMRI study (Corbetta et al., 2000) this

region was active following a cue informing the person to shift attention covertly to the target. The region is part of a larger network that includes frontal eye fields and the superior colliculus that appears to orchestrate both covert shift of attention and eye movements toward targets (Corbetta, 1998). When people voluntarily move their attention from location to location while searching for a visual target this brain area is also active.

There is evidence from other patient groups indicating brain areas involved in shifting attention. For example, patients with Alzheimer's disease involving degeneration in the superior parietal lobe (Parasuraman et al., 1992) have difficulty in dealing with central cues that inform them to shift their attention. There is also evidence that lesions of the superior colliculus may be involved in the preference for novel locations rather than locations to which one has already oriented (Sapir et al., 1999). Patients with lesions of the thalamus (most likely the pulvinar) also show subtle deficits in visual-orienting tasks that may be related to the access to the ventral information-processing stream. It seems that a vertical network of brain areas related to voluntary eye movements and to processing novel input are critical elements of orienting, but a precise model including a role for all of these areas is still lacking.

It is also necessary to reexamine the role of alerting in the cueing effects. There has been a great deal of evidence that damage to the right frontal lobe and to the right parietal lobe can produce difficulty in maintaining the alert state (for a summary see Posner & Petersen, 1990). However, recent work with fMRI has indicated that using a cue to warn a subject that a target will occur shortly activates a left hemisphere network (Coull et al., 1996; Coull, Nobre, & Frith, 2001; Nobre, 2004). Thus there are apparently roles for both the right a left hemisphere in the alerting process. It appears that right hemisphere centers are most important for tonic alertness, but the left hemisphere areas may play a more important role in phasic alerting produced by warning signals.

Circuitry. Cellular studies have shown that attention toward the location of an impending target can alter the baseline of cellular activity (Desimone & Duncan, 1995). This finding suggests that cuing attention to a location can induce changes in the visual system that alter the processing of a target. Evidence from high-density electrical activity suggests that cuing attention influences prestriate activity occurring 100–150 milliseconds after input. This information may in some circumstances then be fed back to influence activity within the primary visual cortex and perhaps also the thalamic relays of the visual information (O'Connor et al., 2002). These studies suggest a circuitry by which parietal activity can influence the visual analysis of a visual target, but direct evidence linking the more dorsal attention system with the more ventral object analysis system is still lacking.

The study of visual orienting has provided strong evidence that scalp recording can give an accurate time

course for the operation of generators found active in fMRI studies. Hillyard and associates (Hillyard, DiRusso, & Martinez, 2004) have exploited the fact that early visual areas are retinotopically organized. They have identified an early ERP component (C1) with the primary visual cortex operation at 50 or so milliseconds after input, they have shown that posterior P1 and N1 arise in prestriate areas. This work has led to the interesting finding that a cue to location does not influence the initial V1 activity but is fed back to influence later striate cortex component (Martinez et al., 2001).

It is likely that we still do not have the final answer as to the exact operations that occur at each location even in a relatively simple act like shifting attention to a novel event. Nonetheless, the data provide considerable convergence between clinical, neurophysiological, imaging and cognitive methods. The results of attentional studies as with many other areas of cognition support the general idea of localization of component operations.

Transmitters. It is very important to be able to link the neurosystem results, that suggest brain areas related to attention, with cellular and synaptic studies that provide more details as to the local computations. One strategy for doing so is to study the pharmacology of each of the attention networks (Marrocco & Davidson, 1998). To carry out these tests it is important to be able to study monkeys who are able to use cues to direct attention to targets. Fortunately cueing studies can be run successfully in monkeys.

A series of pharmacological studies with alert monkeys have related each of the attentional networks we have discussed with specific chemical neuromodulators (Davidson & Marrocco, 2000; Marrocco & Davidson, 1998). The component of alerting related to the influence of warning signal appears to involve the cortical distribution of the brain's norepinephrine (NE) system arising in the locus coeruleus of the midbrain. Drugs like clonidine and guanfacine that act to block NE, reduce or eliminate the normal effect of warning signals on reaction time, but have no influence on orienting to the target location (Marrocco & Davidson, 1998).

Cholinergic systems arising in the basal forebrain play a critical and important role in orienting. Lesions of the basal forebrain in monkeys interfere with orienting attention (Voytko et al., 1994). However, it does not appear that the site of this effect is in the basal forebrain. Instead it appears to involve the superior parietal lobe. Injections of scopolamine directly into the lateral interparietal area of monkeys, a brain area containing cells, which are influenced by cues about spatial location, have been shown to have a large effect on the ability to shift attention to a target. Systemic injections of scopolamine have a smaller effect on effect on covert orienting of attention than do local injections in the parietal area (Davidson & Marrocco, 2000). Cholinergic drugs do not affect the ability of a warning signal to improve performance and thus there appears to be double dissociation that relates NE to the alerting

network and Ach (acetylcholine) to the orienting network. These observations in the monkey have also been confirmed by similar studies in the rat (Everitt & Robbins, 1997) and by studies of nicotine in humans. Of special significance in the rat, studies comparisons of the cholinergic and dopaminergic mechanisms have shown that only the former influence the orienting response.

The evidence relating Ach to the orienting network and NE to the alerting network provides strong evidence of dissociation between the different attentional networks. In the [next section](#) we show that the frontal executive network is closely related to dopamine as a neural modulator.

EXECUTIVE ATTENTION NETWORK

Executive control is most needed in situations which involve planning or decision-making, error detection, novel responses, and in overcoming habitual actions (Shallice, 1988). Although these concepts are somewhat vague, a more explicit version of the idea of executive attention stresses the role of attention in monitoring conflict between computations occurring in different brain areas (Botvinick et al., 2001). Although this view may not be adequate to explain all of the existing data, it provides a useful model for summarizing much of what is known.

Functional anatomy. A very large number of functional imaging studies have examined tasks that involve executive attention. These "thinking" tasks often activate a wide range of frontal areas. For example, (Duncan et al., 2000) examined verbal, spatial and object tasks selected from intelligence tests that all had in common a strong loading on the factor of general intelligence (g). These items were contrasted with perceptually similar control items that did not require the kind of attention and thought involved in problem solving. This subtraction led to differential activity in two major areas. One was the anterior cingulate and the second was lateral prefrontal cortex.

Moreover, manipulations of the content of material have often shown that the same areas may be active irrespective of whether the stimuli are spatial, verbal, or visual objects. This has led some to conclude that the frontal lobes may be an exception to the specific identification of brain areas with mental operations that we have discussed for orienting (Duncan & Owen, 2000).

A specific comparison of three conflict tasks within one study (Stroop, spatial conflict, and flanker) showed two areas of common activation by the three tasks (Fan et al., 2003). These were the anterior cingulate and a left lateralized area of the prefrontal cortex (area 10). A summary of many imaging studies using the Stroop task or variants of it that involved conflict among elements (Bush, Luu, & Posner, 2000) showed consistent action in the dorsal anterior cingulate.

An event-related functional MRI study of the Stroop effect used cues to separate presentation of the task

instruction from reaction to the target (McDonald et al., 2000). Lateral prefrontal areas were responsive to cues indicating whether the task involved naming the word or dealing with the ink color. The cue did not activate the cingulate. When the task involved naming the ink color the cingulate was more active on incongruent than congruent trials. This result reflects the general finding that lateral areas are involved in representing specific information over time (working memory), whereas medial areas are more related to the detection of conflict.

Another cue to the functional activity in these areas comes from studies of generating the use of a word. In a typical version of this task, subjects are shown a series of forty simple nouns (e.g., hammer) (Raichle et al., 1994). In the experimental condition they indicate the use of each noun (for example, hammer -> pound). In the control condition, they simply read the word aloud. The difference in activation between the two tasks illustrates what happens in the brain when subjects are required to develop a very simple thought, in this case how to use a hammer. Practice that is sufficient to automatize the responses results in eliminating the activation of the anterior cingulate and lateral areas, but increases activity in the anterior insula which is active during word reading, but reduced during generating a new use. These results illustrate that the anatomy of this high-level cognitive activity is similar enough among individuals to produce focal average activations that are both statistically significant and reproducible.

Circuitry. To examine the time course of these activations it is possible to use a large number of scalp electrodes to obtain scalp signatures of the generators found active in imaging studies. (Abdullaev & Posner, 1998). When subjects obtain the use of a noun, there is an area of positive electrical activity over frontal electrodes starting about 150 milliseconds after the word appears. This early electrical activity is generated by the large area of activation in the anterior cingulate.

A left prefrontal area (anterior to the classical Broca's area) begins to show activity about 200 milliseconds after the word occurs. This area appears to be activated when the task involves a semantic content, but the early time course of the activation and its close relation to the cingulate seem to make it more related to attention to semantic content. The left posterior brain area found to be more active during the processing of the meaning of visual words did not appear until a much later time (500 milliseconds). This activity is near the classical Wernicke's area; lesions of which are known to produce a loss of understanding of meaningful speech. An examination of correlations among distant electrodes showed evidence of the transfer of information from left frontal electrodes to the posterior area at about 450 milliseconds into the task (Nikolaev et al., 2002). Because the response time for this task was about 1,100 milliseconds this would leave time for the generation of related associations needed to solve the task.

These studies provide a start in understanding the functional roles of different brain areas in carrying out executive control. The medial frontal area appears most related to the executive attention network and is active when there is conflict among stimuli and responses. It may be serving as a monitor of conflict, but it is possible that it plays other roles as well. The lateral prefrontal area seems to be important in holding in mind the information relevant to the task. Even when a single item is presented, it may still be necessary to hold it in some temporary area while other [whereas is not correct while means at the same time as] brain areas retrieve information relevant to the response. Together these two areas are needed to solve nearly any problem, that depends upon attention to the retrieval of stored information. Both of these areas could be said to be related to attention, or one might identify only the medial area with attention and the lateral one with working memory. In either case they begin to give us a handle on how the brain parses high tasks into individual operations that are carried out in separate parts of the network.

Lesion studies. Classical studies of strokes of the frontal midline including the anterior cingulate showed a pervasive deficit of voluntary behavior (Damasio, 1994; Kennard, 1955). Patients with akinetic mutism can orient to external stimuli and follow people with their eyes, but they do not initiate voluntary activity. Recent studies of patients with small lesions of the anterior cingulate (Ochsner et al., 2001; Turken & Swick, 1999) show deficits in conflict related tasks, but these patients frequently recover from their deficits suggesting that other areas may also be involved. In some cases lesions of the mid frontal area in children and adults may produce permanent loss of future planning and appropriate social behavior (Damasio, 1994). Early-childhood damage in this area can produce permanent deficits in decision-making tasks that require responses based on future planning (Anderson et al., 2000).

Cellular mechanisms. The anterior cingulate and lateral frontal cortex are target areas of the ventral tegmental dopamine system. All of the dopamine receptors are expressed in layer five of the cingulate, which in turn is connected to many other important cortical areas (Goldman-Rakic, 1988).

The association of the anterior cingulate with high-level attentional control may seem rather odd because this is clearly a phylogenetically old area of the brain. Although the anterior cingulate is an ancient structure, there is evidence that it has evolved significantly in primates. Humans and great apes appear to have a unique cell type found mainly in layer V of the anterior cingulate and insula, a cell type not present in other primates (Nimchinsky et al., 1999). These cells also undergo a rather late development in line with the findings that executive control systems develop strongly during later childhood (Allman, 2001) (see also next section). Although the precise function of

this cell is not known, high correlations between its volume and encephalization suggest a likely role in higher cortical functioning. The proximity of these cells to vocalization areas in primates led Nimchinsky and colleagues to speculate that these cells may link emotional and motor areas, ultimately resulting in vocalizations that convey emotional meaning. There is as yet no direct evidence linking the cellular architecture of the anterior cingulate to activity detected during neuroimaging studies.

Several replicated human genetic studies demonstrate an association of one of the dopamine receptor genes D4 (DRD4) located on chromosome 11p15.5 and an attentional disorder common in childhood (attention deficit/hyperactivity disorder or ADHD) (Swanson et al., 2000). About 50% of the ADHD cases have a 7-repeat allele whereas only about 20% ethnically matched control subjects have a 7-repeat allele. However, a direct comparison of children with ADHD who either have or do not have the 7 repeat allele suggest that attentional abnormalities are more common in those children without the 7 repeat (Swanson et al., 2000). The authors suggest that there are different routes to ADHD only some of which involve a specific reduction in cognitive ability.

INDIVIDUAL DIFFERENCES

Although there is strong evidence of common networks underlying cognitive processes, there are also individual differences in details that influence the efficiency of these networks. Individual differences are likely to reflect both genes and experience. The rapid development of fMRI methods has begun to provide a basis for understanding differences among individual brains both anatomically and in terms of functional activations. These differences are to be expected because people are not identical in their thoughts, feelings, or behaviors. Several studies have shown that individual differences in functional activation can be reliably assessed (Miller et al., 2002; Reiss, Backus, & Heeger, 2000).

To study these individual differences an attention networks test (ANT) has been used to examine the efficiency of the three brain networks we have described in the previous section (Fan et al., 2002). As illustrated in Figure 18.2 the test provides three scores that represent the skill of each individual in the alerting, orienting, and executive networks. In a sample of 40 normal persons each of these scores were reliable over repeated presentations.

The ability to measure differences in attention among adults raises the question of the degree to which attention is heritable. In order to deal with this issue, the attention network test was used to study 26 pairs of monozygotic and 26 pairs of dizygotic same sex twins (Fan, Fossella, & Posner, 2001). Strong correlations between the monozygotic twins for the executive network, led to an estimate of heritability of the executive network of .89. Because of the small sample, the estimate of 95% confidence interval for heritability is between .3 and .9. In fact a more recent study

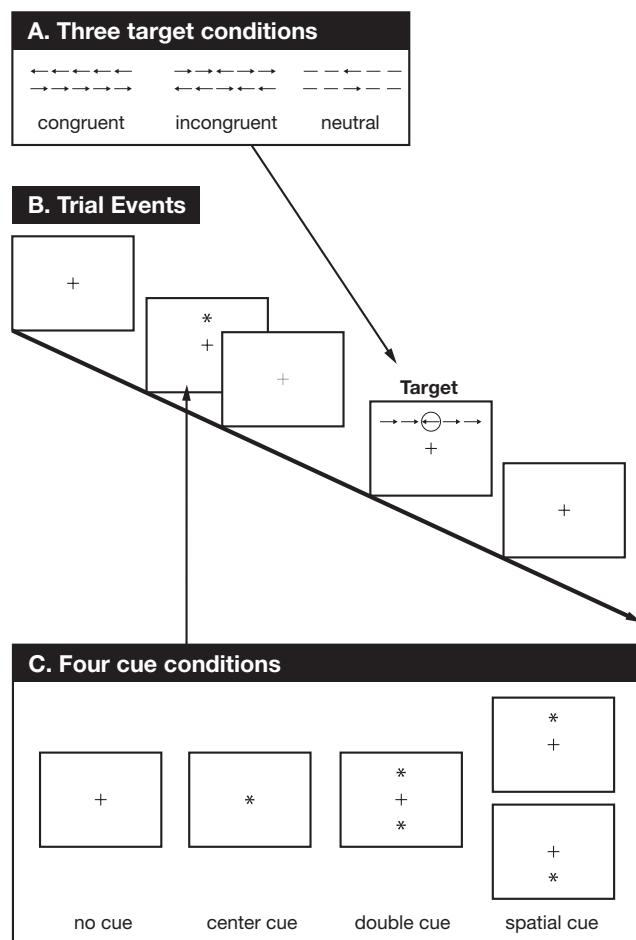

Figure 18.2. A schematic of the Attention Network Test. The task requires a left key press when the central arrow points left and a right key press when it points right. The arrow is surrounded by flankers pointing in the same (congruent) or opposite direction (incongruent). Before the target cues inform the person of when and where a target will appear. At the bottom of the figure are three subtractions that yield information on the efficiency of three attentional networks. (Adapted from Fan et al., 2002).

using a somewhat different task has failed to show heritability among children with the flanker task (Stins et al., 2004), although they did find substantial heritability with another executive attention task, the Stroop task. Possibly this discrepancy related to the importance of errors in the child data. Nonetheless, these data overall support a role for genes in executive attention.

The Attention Network Test (ANT see Figure 18.1) has been used to examine candidate genes related to chemical neuromodulators of attentional networks. Alleles of two cholinergic genes have been found to influence a visual search task related to the orienting network (Parasuraman, Greenwood, Kumar, & Fossella, 2004), whereas alleles of several dopamine genes influence performance in the flanker task and when compared produced a significant difference in activation in the anterior cingulate (Fossella et al., 2002; Fan et al., 2003). Alleles of additional gene (COMT) have been found to relate to a different conflict related phenotype (Diamond et al., 2004).

Studies have also examined the role of genetic differences in the strength of activation of networks involved in attention and memory in fMRI studies (Mattay & Goldberg, 2004). These studies demonstrate that at least part of the variability in strength of activation is due to having different versions (alleles) of genes related to the network.

Genetic differences observed to date account for only a small part of the variance found in behavior and imaging. However, a major contribution of these differences is that they serve as clues to the genes involved in network development. These genes can be examined in comparative animal studies to address questions like how genes related to hippocampal development may have affected behavior in species even before there was a hippocampus. These genes can also be examined in species for which the hippocampus plays a role in forms of memory that may be precursors of the explicit recollection found to be its role in humans. In the case of the DRD4 gene, which in humans is related to attention deficit disorder (Swanson et al., 2000) and to the normal monitoring of conflict in the mouse, seems to be related to exploration of the environment (Grandy & Kruzich, 2004; Han, Touathaigh, & Koch, 2004). These studies have the potential of improving our understanding of the role of genes in shaping the networks common to all humans.

Gene by environment interactions. One reason for the relatively modest effect of genetic alleles in accounting for behavioral differences may be that they interact with experience during development of the network. The existence of gene by environment interaction is not controversial, and it is well known that gene expression can be influenced by the microenvironment in the brain area where it is expressed. Moreover, there is ample evidence that in primates, gene expression can be influenced by events, which, like maternal separation, can be a part of human development (Soumi, 2003). These findings make more important the examination of how attentional networks actually develop during infancy and childhood, a topic to which we turn in the [next section](#).

DEVELOPING NETWORKS OF ATTENTION

A study using the child version of the attention network test (Rueda et al., 2004), examined the development of the attentional networks in a cross-sectional study involving 6- and 10-year-old children and adults. Results indicated no changes in the orienting scores in the age range studied, whereas alertness showed evidence of change up to and beyond age 10. Executive attention measured by conflict resolution scores appeared stable after age 7 up to adulthood. These findings are placed in context below.

Orienting

Studies of orienting summarized in Ruff and Rothbart (1996) have suggested that only voluntary movement speed

and the accuracy of termination continue to improve in late childhood. The ANT involves a very simple sense of orienting to visual locations that uses the ability of a peripheral cue to redirect attention to one of two places above and below fixation and therefore, would appear to be a task whose requirements would suggest an early developmental course. Most of the work in this area, including developmental studies summarized by Trick and Enns (1998) compares valid and invalid cue conditions (cost plus benefit) and thus provide stronger evidence of the time to disengage and reorient from an attended location. Studies made under conditions where orienting involved an invalid cue and thus required a voluntary shift of attention have shown that the time to disengage from a cued location is reduced with age, but the movement of attention toward a peripheral cue shows no change between six year olds and adults (Akhtar & Enns, 1989). They also found that children show a strong tendency for an interaction between orienting and conflict that is reduced between 5-year-olds and adults.

Alerting

During the first year of life, children show a remarkable development of their ability to achieve and maintain alert states. However, there are still considerable differences between children and adults in both speed of preparation from alerting cues and maintenance of that preparation (Morrison, 1982). Both preparation and vigilance might be playing a role in the differences found in alertness among children and adults in the child ANT study. These phasic and tonic aspects of alertness may influence RT when alertness is measured by comparing trials with and without warning cues. Age differences in preparation certainly affect RT to cued trials, whereas differences in vigilance might affect non-cued trials.

A study by Berger, et al. (2000) showed that 5-year-old children reduce their reaction time to stimuli that are preceded by an alert cue although, unlike the adults, children showed reduced RT benefits with cue-target intervals greater than 500 ms, suggesting increased difficulty for children to maintain preparation produced by the alerting cue. Moreover, young children have increased difficulty compared to older children and adults when dealing with situations that require more complex strategies to prepare, as when the interval between the alert cue and the target varies across trials.

On the other hand, Lin, Hsiao, and Chen (1999) examined sustained attention abilities in 6–15 year-olds using the Continuous Performance Test (CPT). They found progressive improvement in performance (measured by hits and false alarms) with age, reaching asymptotic levels around age 13. The percentage of children that complete the CPT at preschool ages is informative of their ability to sustain attention. Levy (1980) found that less than 50% of the children between 3 and 4 years of age were able to complete the test, whereas the percentage increased to 70% for children between 4 and 4½ years old and was close to 100% after that age.

The influence of phasic and tonic components on the efficiency of alertness has been compared between 6 and 10 year-olds and adults (Rueda et al., in process). In this experiment, participants performed 4 blocks of trials of a Go/No-Go task with a low percentage (25%) of Go trials. To examine differences in phasic alertness the presence (75% of the trials) or absence (25% of the trials) and the time interval (simultaneous, short, and long) between the warning cue and the target were all manipulated. Compared to trials with no warning cue, children and adults showed reduced RT to targets preceded by a cue, but only adults showed reduced RT when cue and target were presented simultaneously. In this experiment, both 6- and 10-year-old children showed a continuous increase in RT across blocks, whereas adults had equivalent RTs in all blocks. In addition, 6-year-old children showed greater percentage of omissions than 10 year-olds and adults. Interestingly, this difference was significant only when no warning cue was presented or when cue and target were presented simultaneously, whereas no age differences were found when the warning cue preceded the target, especially at long cue-target intervals. Taken together, these results suggest that children seem to have greater difficulty than adults sustaining attention during extended task performance. This difference appears to be more remarkable for young children, although their reduced vigilance can be overcome by presenting warning cues with some time in advance. The influence of warning signals on performance may vary with age because of the greater difficulty children have in retaining the set toward task instructions.

Executive attention

The finding of little or no development in the executive network after age 7 in the child ANT study may not extend to more difficult executive tasks as those involving strategic decisions or other functions like rule-holding, planning, set switching, and so on. However, developmental studies of executive attention have shown the greater development of conflict resolution to happen between 2 and 6 years of age (Rueda, Posner, & Rothbart, submitted).

Infant studies have stressed the relative lack of executive control during the first year of life (Ruff & Rothbart, 1996). However, a sign of the control of cognitive conflict is found at the end of the first year of life. Infants younger than 12 months fail to search for an object hidden in a location when previously trained to reach for the object in a different location. After the first year, children develop the ability to inhibit the prepotent response toward the trained location, and successfully reach for the object in the new location (Diamond, 1991).

From two years of age and older, children are able to perform simple conflict tasks in which their reaction time can be measured. The Spatial Conflict Task (SCT; Gerardi-Caulton, 2000) induces conflict between the identity and the location of an object. Between 2 and 4 years of age, children progressed from an almost complete inability to carry out the task to relatively good performance.

Although 2-year-old children tended to perseverate on a single response, 3 year-olds performed at high accuracy levels, although, like adults, they responded more slowly and with reduced accuracy to incompatible trials (Gerardi-Caulton, 2000; Rothbart et al., 2003). The detection and correction of errors is another form of action monitoring. While performing the SCT, 2 1/2 and 3-year-old children showed longer RT following erroneous trials than following correct ones, indicating that children were noticing their errors and using them to guide performance in the next trial. However, no evidence of slowing following an error was found at 2 years of age (Rothbart et al., 2003). A similar result with a different time frame was found when using a version of the Simple Simon game. In this task, children are asked to execute a response when a command is given by one stuffed animal, while inhibiting responses commanded by a second animal (Jones, Rothbart, & Posner, 2003). Children of 36–38 months were unable to inhibit their response and showed no slowing following an error, but at 39–41 months, children showed both an ability to inhibit and a slowing of reaction time following an error. These results suggest that between 30 and 39 months children greatly develop their ability to detect and correct erroneous responses and that this ability may relate to the development of inhibitory control.

The importance of being able to study the emergence of executive attention is enhanced because cognitive measures of conflict resolution in these laboratory tasks have been linked to aspects of children's temperament. Signs of the development of executive attention by cognitive tasks relate to a temperamental measure obtained from caregiver reports called effortful control (Gerardi-Caulton, 2000; Rothbart, Ellis, & Posner, 2004). Children relatively less affected by conflict received higher parental ratings of temperamental effortful control and higher scores on laboratory measures of inhibitory control (Gerardi-Caulton, 2000). We regard effortful control as reflecting the efficiency with which the executive attention network operates in naturalistic settings.

Empathy is strongly related to effortful control, with children high in effortful control showing greater empathy (Rothbart, Ahadi, & Hershey, 1994). To display empathy towards others requires that we interpret their signals of distress or pleasure. Imaging work in normals shows that sad faces activate the amygdala. As sadness increases, this activation is accompanied by activity in the anterior cingulate as part of the attention network (Blair et al., 1999). It seems likely that the cingulate activity represents the basis for our attention to the distress of others.

Developmental studies have identified different routes to the successful development of conscience. The internalization of moral principles appears to be facilitated in fearful preschool-aged children, especially when their mothers use gentle discipline (Kochanska, 1995). A strongly reactive amygdala would provide the signals of distress that would easily allow empathic feelings toward others and improve socialization abilities. In the absence of this

form of control development of the cingulate would allow appropriate attention to the signals provided by amygdala activity. Consistent with its influence on empathy, effortful control also appears to play a role in the development of conscience. In addition, internalized control is facilitated in children high in effortful control (Kochanska et al., 1996). Thus, two separable control systems, one reactive (fear) and one self-regulatory (effortful control) appear to regulate the development of conscience.

Some developmental studies have been carried out using ERPs and conflict tasks aimed at understanding the brain mechanisms that underlie the development of executive attention. In one of these studies, a flanker task was used to compare conflict resolution in three groups of children aged 5 to 6, 7 to 9, and 10 to 12, and a group of adults (Ridderinkhof & van der Molen, 1995). In this study, developmental differences were examined in two ERP components, one related to response preparation (LRP) and another one related to stimulus evaluation (P3). The authors found differences between children and adults in the latency of the LRP, but not in the latency of the P3 peak, suggesting that developmental differences in the ability to resist interference are mainly related to response competition and inhibition, but not to stimulus evaluation.

In adult studies, the N2 has been related to situations that require executive control (Kopp, Rist, & Mattler, 1996) and has been directly associated to activation coming from the anterior cingulate cortex (van Veen & Carter, 2002). We have recently conducted an ERP study in which we used the child-friendly version of the flanker task used in the child ANT study with 4-year-old children and adults (Rueda et al., 2004). Adults showed larger N2 for incongruent trials over the mid frontal leads. Four-year-old children also showed a larger negative deflection for the incongruent condition at the mid frontal electrodes that, compared to adults, had a larger size, greater amplitude, and were extended over a longer period of time. Whereas the frontal effect was evident for adults at around 300 ms post-target, children did not show any effect until approximately 550 ms after the target. In addition, the effect was sustained over a period of 500 ms before the children's responses, in contrast with only 50 ms in the case of adults. The difference observed between children and adults over the frontal channels differed from other components observed at mid parietal channels. For both children and adults, we found a greater positivity for incongruent trials over mid parietal leads. For adults, this effect was observed at approximately 400 ms post-target, in the time window of the P3, whereas it was more delayed in the case of children (between 800 and 1100 ms post-target). This parietal effect could reflect developmental differences in the difficulty of evaluating the display depending on the congruence of surrounding flankers, while the frontal effect could reveal differences in the time course of conflict resolution.

Another important difference between 4-year-old children and adults was the distribution of effects over the scalp. In adults, the frontal effects appear to be focalized on

the mid-line, whereas in children the effects were observed mostly at pre-frontal sites and in a broader number of channels, including the mid-line and lateral areas. In addition, the effect on the P3 appears to be left lateralized in the adult data but lateralized to the right side in the children. The focalization of signals in adults as compared to children is consistent with neuroimaging studies conducted with older children, where children appear to activate the same network of areas as adults when performing similar tasks, but the average volume of activation appears to be remarkably greater in children compared to adults (Casey et al., 1997; Durston et al., 2002; Casey et al., 2002). Altogether, these data suggest that the brain circuitry underlying executive functions becomes more focal and refined as it gains in efficiency. This maturational process involves not only greater anatomical specialization but also reducing the time these systems need to resolve each of the processes implicated in the task.

ATTENTIONAL PATHOLOGIES

Attention is a very frequent symptom of many forms of psychopathology. However, without a real understanding of the neural substrates of attention, this has been a somewhat empty classification. This situation has been changed with the systematic application of our understanding of attentional networks to pathological issues. Viewing attention in terms of underlying neural networks provides a means of classifying disorders that differs from the usual DSM IV symptom related criteria. A number of abnormalities involving attention, including Alzheimer's dementia, anxiety, attention deficit hyperactivity disorder (ADHD), autism, borderline personality disorder, depression, and schizophrenia have been studied either with the attention network task (Fan et al., 2002), that measures the efficiency of all three networks (see Figure 18.2) or with parts of the task that measure one or two of the networks. These studies have shown that different disorders are associated with problems in different networks, although there is not a one to one relation between diagnosis and disorder. Below we review a number of common disorders in relation to abnormalities in attentional networks.

ALERTING

Patients with anterior and posterior right hemisphere damage have problems when tasks are given without warning (Posner et al., 1987; Robertson et al., 1998). This arises because patients, like young children, have very long RTs in the absence of warning. Robertson has argued that the inability to maintain the alert state absent a warning signal is a major contributor to the reduced attention to the side of space opposite the lesion found more strongly in patients with right than with left posterior lesions.

A study using the ANT has shown that normal elderly persons also show dramatically larger alerting effects than young adults, resembling what is found with children

(Fernandez-Duque & Black, *in press*). The study also found that the normally developing adults and Alzheimer's patients showed the same elevated alerting scores, but only the Alzheimer's patients showed increased difficulty in resolving conflict (see executive attention section).

ADHD. Studies of ADHD have linked the disorder to aspects of both attention and sensation seeking (Swanson et al., 2001). Many theories of ADHD have suggested a deficit in executive functions (Barkley, 1997). However, in early work using a spatial orienting task, the most compelling deficit appeared to be a difficulty in maintaining the alert state in the absence of a warning signal (Swanson et al., 1991). This difficulty might arise from right hemisphere damage, which has also been reported to be a feature in many studies of ADHD.

More recent studies using the ANT have also shown problems with alerting, again mostly due to the inability to hold the alert state when no warning signal was used. In one study (Booth, Carlson, & Tucker, 2002), the ANT was used to attempt to discriminate the inattentive subtype from normals and the combined subtype. The alerting network best distinguished the different forms of ADHD, with inattentive children showing less ability to maintain the alert state in the absence of warning signals.

Neuroimaging studies of ADHD children have generally shown right frontal, cingulate and basal ganglia deficits (Casey et al., 1997). Because right frontal areas have been related both to problems with the alert state and with inhibitory control there could be links between the ANT results and these imaging studies, but this research has not yet been conducted.

Casey, Durston, and Fossella (2001) used three different tasks that rely upon different processes (stimulus selection, response selection, and response execution) to analyze executive functions in different types of developmental disorders (Schizophrenia, Sydenham's Chorea, Tourette's Syndrome, and ADHD). They suggest that each of the cognitive operations is implemented in a particular basal ganglia-thalamo-cortical circuit. Stimulus processing seems to be related to connections between basal ganglia, thalamus and the dorso-lateral prefrontal cortex, whereas response processing is associated with connections of subcortical structures to the lateral orbital frontal cortex. Schizophrenic patients exhibited deficits in stimulus election, Sydenham's chorea in response selection, Tourette's syndrome children in response execution, and ADHD children in both stimulus selection and response execution, suggesting that specific cognitive operations related to executive attention can be independently damaged.

For a number of years it has been thought that ADHD related to problems with dopamine and other catecholamine (Wender, 1971). In molecular genetics research, the dopamine theory found support in replicated findings that one allele (7 repeat) of the dopamine 4 receptor gene is over-represented in children with ADHD and also is associated with a temperament featuring high sensation seeking

(see Swanson et al., 2001 for a recent summary). Sensation seeking is a lower order construct of extraversion. This finding has been well replicated for the syndrome of ADHD, but has not been found to produce a cognitive deficit in executive function (Swanson et al., 2000). One study of children with and without the 7 repeat allele confirmed it is associated with ADHD, but showed that it was not associated with the cognitive deficit that usually accompanies ADHD (Swanson et al., 2000). This finding led to the suggestion that there may be two routes to ADHD. One route would involve a temperamental extreme of sensation seeking (or extraversion), the frequency of which might be increased by the presence of the repeat version of the Dopamine 4 receptor gene. This route need not involve a cognitive deficit. A second route to ADHD would involve cognitive deficits that might either be genetic, or due to early brain injury or other experiential factors.

ORIENTING

Anxiety and depression. There is much new information explicating the role of attention in anxiety, depression, and mood disorders. In a series of studies, sub-clinical college students with high scores on trait anxiety were cued to attend to a location by a positive, negative, or neutral face. Trials on which the cue to the location was negative and invalid produced longer reaction times for the trait anxiety subjects (Fox, Ricardo, & Dutton, 2002; Fox et al., 2001). These results replicate and extend previous studies by Derryberry and Reed (1994), and together they suggest that trait anxiety influences the ability to disengage particularly from threat stimuli. Derryberry and Reed suggest that this finding may be dependent upon relatively low levels of effortful control. Those subjects high in effortful control but suffering from depression did not have difficulty disengaging from negative affect.

A symptom of depression is the tendency to dwell on negative ideation (Beck, 1976). Vasey and Macleod (2001) have reviewed recent studies on trait anxious children, finding evidence for the children making threatening interpretations of ambiguous stimulus material, overestimating the likelihood of future negative events, and showing a negative bias toward threatening information. Negative bias has also been noted in children's speeding of detection of dot probes in the vicinity of threatening words (Bijttebier, 1998; Schippel et al., 2003). In temperament research, the ability to control attention was found to be negatively related to negative affect (Derryberry & Rothbart, 1988; Rothbart, Ahadi, & Evans, 2000), congruent with the interpretation that good attentional mechanisms may serve to protect against negative ideation. Children who have had a history of abuse have also been found to be hypersensitive to the recognition of angry faces, misclassifying objectively neutral faces as actually angry (Pollak & Kistler, 2002). Together these findings suggest that both temperament and experience can influence aspects of attention toward threat stimuli, perhaps by both enhancing the

boundary of classification and increasing the time to dwell on these stimuli. Because orienting to cues and targets can be studied in children from birth onward (Pollak & Kistler, 2002) it would be possible to use these findings to obtain more information on the effect of anxiety on normal development and to determine the degree to which it predicts later problems, given stressful experience.

The brain systems related to unipolar depression have been explored in a number of imaging studies (Drevets & Raichle, 1998; Liotti et al., 2003). These studies have generally shown the importance of midline frontal areas including the anterior cingulate and orbital prefrontal cortex. In normal persons these areas are related to the experience and control of emotion (Bush, Luu, & Posner, 2000), behavior and cognition (Drevets, 2000), and self-image (Gusnard et al., 2003). The areas appear to function abnormally in depressed persons exposed to material producing a sad mood, whether or not they were currently depressed. The overlap between brain activities in currently depressed people with those who have suffered from depression in the past may explain the frequent occurrence of multiple depressive bouts.

Autism. Autism is a disorder that has been linked to the orienting system (Akshoomoff, Pierce, & Courchesne, 2002; Landry & Bryson, in press). It is well known that autistic persons do not normally orient to faces. However, Landry and Bryson report their difficulty in orienting in tasks that involve non-social stimuli similar to those used in the ANT. Similar deficits in the ability to disengage and move attention have been reported in autism in relation to abnormal development of the cerebellum (Akshoomoff, Pierce, & Courchesne, 2002). We do not know if this abnormality is due only to cerebellar deficits because many of the patients also show parietal abnormalities as well. Rodier (2002) has some evidence that the abnormalities found in autism might relate to a gene associated with migration of cells in early development.

EXECUTIVE FUNCTION

Borderline. Borderline personality disorder is characterized by very great lability of affect and problems in interpersonal relations. In some cases, patients are suicidal carry out self-mutilation. Because this diagnosis has been studied largely by psychoanalysts and has a very complex definition, it might at first be thought of as a poor candidate for a specific pathophysiology involving attentional networks. However, we focused on the temperamentally based core symptoms emotionality and difficulty in self-regulation. We found that patients were very high in negative affect and relatively low in effortful control (Rothbart, Ahadi, & Evans, 2000), and defined a temperamentally matched control group of normal persons without personality disorder who were equivalent in these two dimensions. Our study with the ANT found a deficit specific in the executive attention network in borderline patients (Posner et al., 2002). Preliminary imaging results suggested over-

generalization of responding in the amygdala and reduced responding in the anterior cingulate and related midline frontal areas (Posner et al., 2002). Patients with higher effortful control and lower conflict scores on the ANT were also the most likely to show the effects of therapy. This methodology shows the utility of focusing on the core deficits of patients, defining appropriate control groups based on matched temperament, and using specific attentional tests to help determine how to conduct imaging studies.

Schizophrenia. A number of years ago, never medicated schizophrenic patients were tested both by imaging and with a cued detection task similar to the orienting part of the ANT. At rest, these subjects had shown a focal decrease in cerebral blood flow in the left globus pallidus (Early et al., 1989) a part of the basal ganglia with close ties to the anterior cingulate. The subjects showed a deficit in orienting similar to what we had shown for left parietal patients (Early et al., 1989). When their visual attention was engaged, they had difficulty in shifting attention to the right visual field. However, they also showed deficits in conflict tasks, particularly when they had to rely on a language cue. It was concluded that the overall pattern of their behavior was most consistent with a deficit in the anterior cingulate and basal ganglia, parts of a frontally based executive attention system. This deficit in orienting rightward has been replicated in first break schizophrenics, but does not seem to be true later in the disorder (Maruff et al., 1995), nor does this pattern appear to be part of the genetic predisposition for schizophrenia (Pardo et al., 2000). First break schizophrenic subjects often have been shown to leave hemisphere deficits and there have been many reports of anterior cingulate and basal ganglia deficits in patients with schizophrenia (Benes, 1999). It appears that the anterior cingulate may be part of a much larger network of frontal and temporal structures that operate abnormally in schizophrenia (Benes, 1999).

A recent study using the ANT cast some light on these results (Wang et al., 2005) in this case the schizophrenic patient were chronic and they were compared with a similarly aged control group. The schizophrenic patients had a much greater difficulty resolving conflict than did the normal controls. The deficit with these patients was also much larger than that found for borderline personality patients, however, there was still a great deal of overlap between the patients and normal indicating that the deficit is not suitable for making a differential diagnosis. The data showed a much smaller orienting deficit of the type that had been reported previously. These findings suggest that there is a strong executive deficit in chronic schizophrenia, as would be anticipated by the Benes theory. It remains to be determined whether this deficit is prior to the initial symptoms or whether it develops with the disorder.

Chromosome 22q11.2 deletion syndrome. This syndrome is a complex one that involved a number of abnormalities including facial and heart but also a mental retardation

that is due to deletion of a number of genes. It is known that the children are at a high risk for the development of schizophrenia. Among the genes that are deleted in this syndrome is the COMT gene, which has been associated with a conflict task (Diamond et al., 2004) and with schizophrenia (Egan et al., 2001). In light of these findings it was to be expected that the disorder would produce a large executive deficit (Simon et al., 2005; Sabin et al., 2004). Sabin has suggested in a further paper that the deficit in resolving conflict is associated the ability to inhibit a blink following a cue that a loud noise would be presented shortly (pre-pulse inhibition). The authors suggest that the association of the high-level attention and pre-pulse inhibition deficit suggests a pathway that includes both the basal ganglia and the anterior cingulate.

Many neurological and psychiatric disorders produce a difficulty in attention. Data to date suggest that disorders have specific influences on attentional networks. However, a number of disorders influence the same network (e.g., schizophrenia, borderline and Alzheimer's dementia affect executive attention) and the same disorder can influence more than one network (e.g., schizophrenia may affect both the executive and orienting network although perhaps at different stages of the disorder). These findings reduce the utility of attention as a means of classifying disorders, but they may be useful in suggesting methods of treatment at least of the attentional symptoms.

RESOLVING ENDURING ISSUES IN ATTENTION

Modularity

There has been a great deal of discussion in the cognitive psychology literature of the concept of modularity. These discussions have often defined modularity in a way which required a system to be unaffected by top down (attentional) influences in order to be modular. According to this view only a very few vertical sensory and motor systems could be modular (Fodor, 1983). However, the evidence that even primary sensory systems can be modulated by attention makes it unlikely that any higher-level brain systems will meet the criterion of modularity so defined.

Imaging data provides a rather different perspective on modularity. The material reviewed in this chapter suggests that even brain networks that reflect voluntary activity such as executive attention may be modular in the sense that very specific brain areas perform computations reflecting their component operations. This form of modularity does not suggest that these mechanisms will operate in the same way irrespective of strategy or context. However, they do provide a starting place for linking cellular and genetic mechanisms to brain areas and then to cognitive operations and behavior.

Early and late selection

One of the oldest issues in the field of attention is how early in processing can attention influence input. This

issue arose before there was much discussion of specific brain mechanisms of attention. Many empirical studies were done to determine if attentional changes showed up as alterations in the beta (decision) parameter of a signal detection analysis or whether instead they involved changes in the d' (sensitivity) parameter.

Although many elegant studies were conducted attempting to clarify this issue, there has been no final resolution (although it seems likely that both parameters can be varied by some experimental conditions).

The early versus late question can be resolved into three somewhat interdependent issues. (1) How early in the nervous system can attention influence stimulus input? The results suggest that it can be as early as V1 (Posner & Gilbert, 1999) under some conditions, but more often attention influence is in extrastriate visual areas (Kastner et al., 1999). (2) How quickly after input can attention influence information processing? Again the cellular and physiological data indicate that it can be about as early as clear evidence of cortical processing can be obtained, although in many situations the influence is not present until 80–100 milliseconds after stimulus onset (Martinez et al., 2001). The timing issue is of particular importance because activation of a particular brain area may be either along the input pathway, or could be due to feedback from higher areas. (3) What does early selection mean for the processing of information both selected and unselected? Here the answer is more complex. It seems to mean that certain aspects of complex scenes may be available for conscious report whereas other aspects will only be available if they succeed in producing reorienting. Unattended objects, however, may still be processed to fairly high levels and the processing itself may summon attention. The depth of cognitive processing of unattended objects and the possibility of attention to higher level codes suggests that early selection does not have the cognitive consequence originally implied. Selecting one stimulus over others does not mean that unselected items will not produce a reorienting of attention or still influence behavior.

Priming

Priming refers to the influence of one event on the processing of subsequent events. Behavioral studies suggested that reaction time could be improved to a target by the presentation of a stimulus (prime) that shares a part of the same pathway. Priming can occur in either of two ways. In one way a stimulus activates a pathway automatically and a second stimulus that shares the same pathway is improved in performance (Posner, 1978). These effects can occur even when the prime is presented and masked so that subjects are not able to report its identity. Although there has been a great deal of dispute about how to measure conscious processing, it appears clear that priming can occur when subjects are unable to report even when stopped in the middle of the trial the nature of the prime (Cheesman & Merikle, 1984). Most unconscious priming has been of sensory or semantic codes, but under some conditions

(Dehaene et al., 2003) even responses can be primed without explicit knowledge of the nature of the prime.

A second way that priming can occur is if a person attends to some feature that will be shared by the target. For example, if people are taught that the word “animal” should be interpreted as a body part, the target finger will be primed. The priming is from the subject’s attention to body part not from automatic activation of finger by the prime animal.

Data from imaging studies of priming by input and by attention support this distinction by showing very different effects on neural activity in the primed area. If priming occurs automatically by input the target shows reduced activation of the primed cells. On the other hand, attending to an area will enhance neural activity and increase the effect of the target (Corbetta et al., 1991).

The newer imaging data shows the reality of the distinction between automatic priming and priming by attention. However, it is not at all clear how the brain brings about similar changes in performance sometimes by reducing and sometimes by increasing the activity of the target. This puzzle remains to be explained by future studies.

Relation to neuropsychology

The ability to image the human brain has also provided new perspectives for neuropsychologists in their efforts to understand, diagnose and treat insults to the human brain that might occur as the result of stroke, tumor, traumatic injury, degenerative disease, or errors in development (Fernandez-Duque & Posner, 2001).

As we have argued, attention networks have anatomical and functional independence, but that they also interact in many practical situations. Damage to a node of these networks, irrespective of the source, produces distinctive neuropsychological deficits. This principle has been best established with respect to damage to the parietal lobe. Studies have shown that damage to parietal neurons that occur in stroke, due to degeneration in Alzheimer’s disease, blocking of cholinergic input, due to lesions of nucleus basalis, temporary damage from transcranial magnetic stimulation, direct injections of scopolamine, or closed head injury all lead to difficulties in using cues to process targets in the visual field opposite the major insult. Recently, normal persons who have one or two copies of the (4 allele of the apolipoprotein E APOE4) gene which increases the risk of Alzheimer’s disease, have also been shown to have increased difficulty in orienting attention and in adjusting the spatial scale of attention, however, they had no difficulty with maintaining the alert state (Greenwood et al., 2000).

In one sense the convergence between imaging, lesions and pharmacology in terms of cognitive effect is obvious. If computations of parietal neurons lead to shifts of visual attention damage to these neurons should produce difficulties. Yet there has been the notion in neuropsychology that localization is not as important as the cause of the

lesion. Moreover, there has also been the argument that imaging does not provide a good account of the computations that can predict the effect of damage (Uttal, 2001). Here we see that the imaging results provide clear evidence of the importance of areas of the parietal lobe in shifts of attention and damage to these areas regardless of cause or organism interferes with orienting.

In addition, to efforts to better understand the nature of the brain disorder there have been efforts to adopt these ideas related to the physical basis of attention to for rehabilitation. Some recent studies have tried to rehabilitate specific attentional networks (Sohlberg et al., 2000; Sturm et al., 1997). These studies suggest that rehabilitation procedures should focus on the particular attentional operations of the lesioned area, while at the same time considering the contribution of those deficits to other attentional functions.

In one study (Sturm et al., 1997), a computerized rehabilitation program was designed to try to enhance specific attentional networks. The authors concluded from these findings that vigilance and alertness are the most fundamental functions in the hierarchy, and that selective attention and divided attention recruit these functions for their normal operation. Another study that utilized a practice-oriented therapy (attention process therapy) with brain-injured patients showed an overall improvement in performance (Sohlberg et al., 2000). In some tasks the group that had relatively high vigilance scores showed better effects of the therapy in agreement with the Sturm idea.

A third rehabilitation study tested the possible interaction between vigilance and orienting by training patients to increase their self-alertness, and exploring whether the rehabilitation of self-alertness had an impact on patients’ neglect (i.e., orienting deficit) (Robertson et al., 1995). Exogenous alertness was used as a basis for training patients to self-alert. External warning signals were presented, and patients were instructed to generate a self-alertness signal in response to it. Exogenous alertness, as produced by a loud noise, depends on a thalamo-mesencephalic path and is relatively unimpaired in right parietal patients. After the training procedure was explained, the patient started the task and at variable intervals the experimenter knocked on the table while at the same time saying “Attend!” in a loud voice. At the next stage in the training, it was the patient who shouted “Attend!” each time the experimenter knocked on the table. Later, the patient would do both the knocking and the vocal command, first loudly, then subvocally, and finally mentally. Patients were encouraged to try this self-alertness method in their everyday life. This rehabilitation training not only improved patient’s self-alertness, but also reduced the extent of their spatial neglect.

Taken together, these findings reveal benefits of systematically analyzing interactions and dissociations of the attentional networks, instead of treating attention as a monolithic concept. They also demonstrate that behavioral therapy can be successful in improving vigilance

skills. The availability of imaging as a means of examining brain networks prior to and following rehabilitation have provided opportunities for fine-tune both behavioral and pharmacological interventions. For example, both cognitive behavioral and pharmaceutical therapies have been reported to be about equally effective in the treatment of severe depression. Mayberg (2003) found that the two worked on entirely different parts of the impaired network. Although the cognitive behavioral theory improved cortical parts of the network involved with attention, the pharmaceutical therapy tended to improve subcortical parts of the network. This study shows the importance of taking a network approach to intervention, the additional of genetic information may further improve an understanding of who might benefit from particular forms of therapy.

Integrative Physiology: Homeostasis, Allostasis, and the Orchestration of Systemic Physiology

GARY G. BERNTSON AND JOHN T. CACIOPPO

1. INTRODUCTION

Since the seminal work of Walter Cannon, the concept of homeostasis has been a major force in the historical development of views of autonomic regulation and control. The homeostatic construct also importantly shaped many twentieth century psychological concepts and theories, including models of reinforcement, motivation, perception, personality, and psychosomatic disorders. This construct has been particularly salient in psychophysiology and behavioral medicine, because of the putative role of homeostatic processes in the regulation of autonomic and neuroendocrine systems. The present chapter will explore the current status of the homeostatic model, and the emergence of modern concepts of allostasis and allodynamic regulation.

A second aim of the chapter is to consider the underlying neural systems and mechanisms that give rise to autonomic regulation and psychophysiological relationships. A complication in drawing clear psychophysiological relations is the fact that these associations cut across systems and processes represented at distinct levels of conceptualization and analysis. One goal of multi-level integrative analyses is to bring the concepts, processes and terms of the two levels of analysis into registration, to permit a more accurate appreciation of the underlying links and organizations (Cacioppo et al., 2000). The construct of fear, for example, has a long tradition in psychology and brain systems mediating this state are beginning to be elucidated. What is less clear is how brain *processes*, not just areas and structures, give rise to fear – that is, how the physiological and psychological domains map onto one another. Rapprochement between psychological and physiological constructs and theories will likely require refinements in conceptualization and quantification within both the physiological and psychological domains. Integrative analysis across psychological and physiological levels is still very much a work in progress and psychophysiology resides at a critical intersection to pursue this integration. In considering the psychophysiology of the autonomic nervous system, the present chapter will identify some aspects of a

broad framework that may contribute to the emergence of a true *neuropsychophysiology*.

1.1. Homeostasis and homeodynamic regulation

1.1.1. Origins of the homeostatic concept

The notion of natural balancing or equilibrium-seeking tendencies may be traced back as early as Hippocrates (Cofer & Appley, 1964). The term homeostasis, and the contemporary negative feedback model of homeostatic regulation has a more recent history. Claude Bernard (1878/1974) reflected on the relative constancy of the internal environment (*milieu intérieur*) of living creatures. This constancy was seen to reflect an organism's ability to stabilize the cellular environment, despite powerful entropic forces that threaten to disrupt the biological order essential for life. Mechanisms underlying this constancy permit warm-blooded creatures to live what Bernard termed a "free and independent life" (Bernard, 1878/1974, p 89). Cannon (1929, 1939) extended this perspective, coining the term *homeostasis* to refer to the processes by which the *constancy of the fluid matrix* is maintained. The concept of homeostasis was so central to Cannon's view that he virtually equated homeostatic adjustments with adaptive responses.

Cannon's concepts significantly shaped contemporary views of autonomic regulation and control. Legacies from the Cannon era include the concepts that (1) the autonomic nervous system is reflexively regulated for homeostasis, (2) the sympathetic and parasympathetic branches generally exert opposing effects on end organs, and (3) the sympathetic and parasympathetic branches are subject to reciprocal central control. From a homeostatic perspective, the concept of reciprocal control is natural. A reciprocal pattern of autonomic control would maximize autonomic resources in the maintenance of a homeostatic set point as the two branches would act synergistically in this process. The concepts of homeostasis and reciprocal control were echoed in Fulton's (1949) influential *Textbook of Physiology*: "The autonomic nerves . . . are the regulators concerned with emergency mechanisms, with repair, and

with preservation of the constancy of the internal environment" (Fulton, 1949, p. 222); and "In the reflex regulation of the heart rate, the sympathetic and parasympathetic nervous systems are reciprocally linked in their central representations" (Fulton, 1949, p. 668). Homeostasis remains the dominant organizing concept of autonomic function in the contemporary physiological literature, and the notion of reciprocal control of the autonomic branches continues to be advanced. Malliani (1999), for example, asserts: "In most physiological conditions, sympathetic and vagal activities modulating heart period undergo a reciprocal regulation" (p. 111).

The concept of homeostasis has also had a powerful impact on psychophysiological theory. Homeostatic compensatory adjustments were viewed by Lacey (1956) as an important secondary, reflexive contributor to observed patterns of psychophysiological response, while Obrist (1981) considered homeostatic processes to contribute more directly to the primary response. In his construct of cardiac-somatic coupling, for example, Obrist viewed heart rate responses in behavioral contexts to reflect, at least in part, homeostatic adjustments associated with increased metabolic demands.

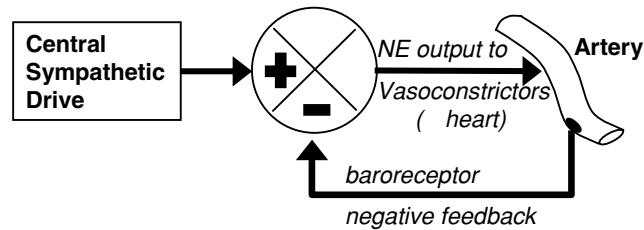

The concept of reciprocal control of the autonomic branches also has had a continuing influence on psychophysiological constructs. Examples include Wenger's classic index (\bar{A}) of *autonomic balance* along a continuum extending from sympathetic to parasympathetic dominance (Wenger, 1941). A more recent example is the application of the ratio of low to high frequency heart rate variability (LF/HF ratio) as an index of *sympathovagal balance* (e.g., Malliani, 1999).

1.1.2. Some mechanisms of homeostasis

A number of factors contribute to the relative constancy of internal states. These include peripheral processes such as buffering systems of the blood that maintain plasma pH, and the inherent elasticity of the vasculature that tends to minimize pressor variations due to changes in blood volume. These mechanisms are included in the general class of peripheral *autoregulatory* processes that contribute to stability in physiological dimensions (see Dworkin, 1993).

In contrast to peripheral autoregulatory processes, central reflex mechanisms have generally been of greater interest in psychophysiology. An important aspect of the homeostatic model is that reflexive networks achieve sensitivity to the functional state of some regulated dimension (e.g., blood pressure), by means of visceral feedback (e.g., via baroreceptors), and generate compensatory responses to restore detected imbalances. Like the thermostatic control of room temperature, homeostatic reflexes may operate as feedback controlled servomechanisms, continually adjusting autonomic outflow to compensate for perturbations in the target dimension. This is the classic feedback-controlled model of homeostasis.

A. Schematic Baroreflex Circuit

B. Human Baroreceptor Cardiac Reflex

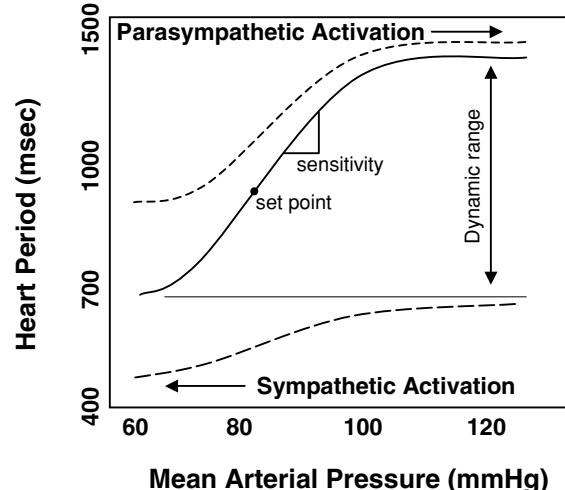

Figure 19.1. **A.** A basic servocontrolled homeostatic system with negative feedback **B.** Baroreceptor-cardiac reflex function in humans. The solid line illustrates changes in heart period with variations in mean arterial pressure. The solid dot depicts the resting blood pressure set point, the slope of the line represents the sensitivity of the reflex, and the distance from the minima to the maxima is the dynamic range. Note that increases in blood pressure yield an increase in parasympathetic activation and a reciprocal decrease in sympathetic activity. The dashed lines illustrate the separate sympathetic and parasympathetic contributions during selective blockades of the other branch. (Data are derived from Robinson et al., 1966; see Berntson, Cacioppo, & Quigley, 1993).

1.1.3. A prototypic homeostatic mechanism:

The baroreceptor-heart rate reflex

As illustrated in Figure 19.1, a typical feedback-controlled homeostatic system is characterized by a set-point that represents the regulatory level or the central tendency of the regulatory system (see Table 19.1). Deviations from this regulated level contribute to the critical feedback control signal that triggers a compensatory response. These homeostatic features are instantiated in the baroreceptor-cardiac reflex depicted in Figure 19.2. As illustrated in this figure, an increase in blood pressure triggers (via baroreceptor afferents) a reflexive withdrawal of cardiac sympathetic tone and a reciprocal increase in vagal outflow to the heart. The coordinated changes in the two autonomic branches synergistically lead to a decrease in heart rate and ventricular contractility, which contribute to a reduction in cardiac output. These responses and the associated

Table 19.1. Regulatory parameters**1. Set point:**

The set point is the functional status that is actively regulated, and physiologically defended, by compensatory responses to perturbations. In the absence of over-riding perturbations, it can be indexed by the central tendency of the regulated dimension.

2. Operating Characteristics:

- Dynamic range.** The dynamic range characterizes the limits of a compensatory process. It represents the regulatory capacity of the system, and is generally expressed as the difference between the maximal and minimal asymptotes of the response (e.g. the maximal and minimal heart rates seen to perturbations of blood pressure associated with the baroreceptor-heart rate reflex).
- Sensitivity (threshold and "gain").** Sensitivity represents the threshold of perturbation in the regulated dimension that is just capable of initiating compensatory responses, and gain is the magnitude or compensatory capacity of the initiated response. This is often represented as the slope of the response function (e.g., the compensatory change in heart rate to a unit change in blood pressure).
- Linearity.** This refers to the shape of the activation (response) function across the dynamic range of control. Deviations from linearity represent variations in gain along the response function for a given increment in the relevant stimulus (deviation from regulatory level). In physiological systems, response functions are often sigmoidal, but in many cases, may be approximated by a linear function within the typical operating ranges.
- Temporal dynamics.** Temporal (dynamic) aspects of the control system, including dimensions such as latency, time course, recovery time, frequency response, and phase lag.
- Stability.** Stability of a process is its reliability or reproducibility, for a given set of conditions. Variations may be random (noise), or systematic (e.g., hysteresis resulting from baroreceptor adaptation, so that the heart rate for a given blood pressure may differ for an increasing pressor ramp than for a decreasing ramp).

withdrawal of sympathetic tone to the vasculature tend to oppose the pressor perturbation.

1.2. Beyond homeostasis: Homeodynamic regulation

Based on the work of Pavlov, Cannon recognized that learned autonomic adjustments could be made in anticipation of a visceral perturbation (Cannon, 1928). Such anticipatory responses can not be viewed as mere reflexive adjustments to a physiological perturbation. More recently, Dworkin has re-emphasized the potential importance of higher learning processes in homeostatic regulation (Dworkin, 1993; Dworkin & Dworkin, this volume). Dworkin proposes that by appropriately calibrated

conditioned responses, learned autonomic adjustments may minimize or preclude homeostatic disturbances from otherwise perturbing stimuli. Dworkin outlines a sophisticated control-theory framework for homeostatic regulation, incorporating anticipatory *feed-forward* components. This model offers an important advance over traditional feedback-controlled models of homeostatic regulation. Although not incompatible with the homeostatic concept, the existence of anticipatory controls highlights an important limitation of the simple feedback model of homeostatic regulation illustrated in Figure 19.1.

In addition to these basic lower-level reflexes, autonomic regulation is also impacted by higher central processes. When blood pressure goes up, baroreceptor reflexes tend to compensate by driving heart rate (and hence cardiac

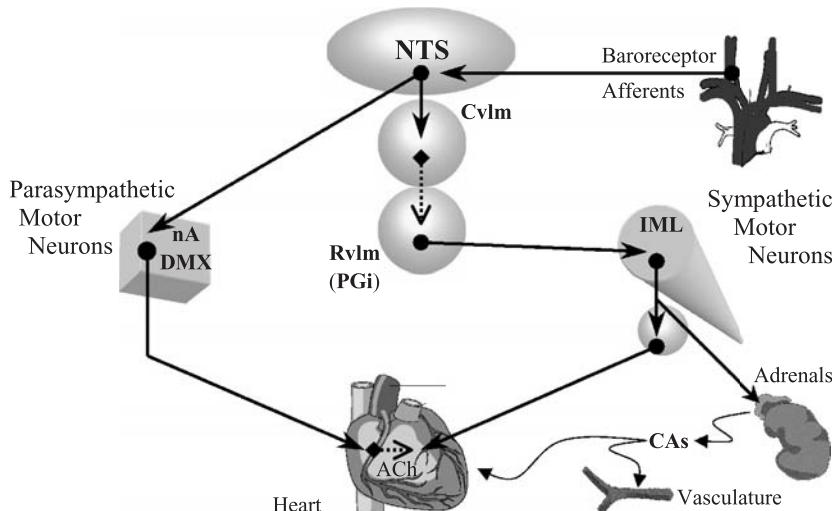

Figure 19.2. Summary of brainstem systems underlying baroreceptor cardiac reflex. Baroreceptor afferents project to nucleus tractus solitarius (NTS), which in turn leads to activation of parasympathetic motor neurons in the nucleus ambiguus (nA) and dorsal motor nucleus of the vagus (DMX). The NTS also activates the caudal ventrolateral medulla (CvIm) which in turn inhibits the rostral ventrolateral medulla (Rvlm), leading to a withdrawal of excitatory drive on the sympathetic motor neurons in the intermediolateral cell column of the cord (IML). Abbreviations: ACh, acetylcholine; CAs, catecholamines; NE, norepinephrine; PGi, paragigantocellular nucleus (partially coextensive with Rvlm).

output) down. Consequently, blood pressure and heart rate often show a negative covariation. During stress, however, both blood pressure and heart rate may increase in apparent violation of the baroreflex pattern, and the increase in heart rate can further contribute to the pressor response in a distinctly non-homeostatic fashion. Although not homeostatic, this may be highly adaptive in providing the metabolic resources for effective response (fight or flight). It is now clear that a range of stressors, including moderate cognitive stressors, can reduce the gain or set-point of the baroreceptor-heart rate reflex (Lucini et al., 2002; Steptoe & Sawada, 1989; Van Roon et al., 2004). By suppressing baroreceptor reflexes, together with more direct descending controls over autonomic source nuclei, higher neural systems can by-pass or override homeostatic reflexes. This allows for a more flexible allostatic (other level) pattern of autonomic control, in which organ systems can be regulated at alternative (allostatic) levels in the face of changing circumstances.

Summary. The considerations above suggest that the simple feedback-control, set-point model may not adequately represent the complexity of visceral regulation. Moreover, the emphasis on static levels and the fixedness implied by the term *homeostasis* does not capture the variability and dynamic features of visceral control systems. A more appropriate construct may be that of *homeodynamic regulation*, which recognizes the fact that regulatory mechanisms are multiple and complex, including both feedback and feedforward components, as well as multiple levels of control extending from lower reflexes to descending regulation from higher neurobehavioral substrates. The concept of homeodynamic regulation does imply a single regulatory level, but recognizes that variations around this level may be rather broad, reflecting the operations of multiple dynamic influences. This represents an important conceptual advance over the rigidity implied by the term homeostasis.

1.3. Heterostasis, allostasis, and alldynamic regulation

1.3.1. Heterostasis

Although variations in gain, dynamic range or other operating characteristics can alter the efficiency, capacity, and time course of regulatory processes, as long as the regulatory set-point remains constant these processes could be subsumed under the construct of homeodynamic regulation. Selye (1973), however, argued that regulatory levels are not rigidly fixed, but may be actively altered in the face of exogenous challenges or pathogens. For Selye, homeostatic processes may continue to operate at the basic regulatory level, being sensitive to *internal* physiological stimuli that signal deviations from a regulated set point. According to Selye, however, *exogenous* stimuli may reset regulatory levels, either directly or via a humoral route, to facilitate resistance or adaptation to the exogenous stressor. Such readjustments of set-point deviate from homeo-

static or homeodynamic processes, as they represent active alterations of the regulatory level. In contrast to homeostasis, Selye applied the term *heterostasis* to this class of regulatory adjustment (from the Greek *heteros* meaning “other” or “different” and *stasis* meaning “fixity” or “lack of movement”).

An example of heterostatic regulation is a fever, which differs from hyperthermia arising from a thermoregulatory failure (e.g., due to extreme heat or exercise). Instead, illness-induced fever reflects the adoption of a higher set-point, which is actively regulated and defended. An artificial reduction in body temperature during a fever is met with active compensatory thermogenic processes (e.g., shivering, metabolic thermogenesis, behavioral thermoregulation; Romanovsky, 2004; Werner, 1988). The elevation in temperature associated with a fever may be of benefit in mobilizing energy resources to combat infections or other adaptive challenges. Because a fever reflects the adoption of a *new* regulatory set point, it is more appropriately considered a heterostatic rather than a homeostatic or homeodynamic process. Selye (1973) emphasized the role of hormones and the chemical environment in heterostatic regulation. As will be considered below, however, modulation of regulatory mechanisms can also arise from central process and these processes may mediate or interact with changes in the hormonal and chemical environment of the body.

1.3.2. Allostasis

More recently, Sterling and Eyer (1988) introduced the term *allostasis*, (from the Greek *allos*, meaning “other”) to capture the complexities of visceral regulation. Sterling and Eyer recognized that regulatory levels are not fixed, but may be flexibly adjusted to meet changing demands. Although allostasis also entails the concept of changing regulatory set-points, the construct is conceptualized more broadly than Selye’s heterostasis. The allostatic concept of Sterling and Eyer incorporates the view that many visceral dimensions are regulated by multiple interacting mechanisms that are subject to a wide range of modulatory influences. Blood pressure, for example, is not constant throughout the day, but shows systematic fluctuations associated with circadian cycles of sleep and waking and with varying diurnal patterns of activity throughout the day. These alterations in set-point are not consonant with simple homeostatic or homeodynamic models. Nor do they necessarily involve the exogenous agents or pathological conditions of Selye’s model. Rather, they are seen as reflecting the natural adaptive readjustment of regulatory levels in view of changing physiological demands.

An additional feature of Sterling and Eyer’s concept of allostasis regulation is that it reflects the operations of higher neural systems that control and integrate a broad range of more basic “homeostatic” reflexes. Consequently, allostatic control is not constrained to a single functional dimension or even to a large set of parallel regulatory processes. Rather, allostatic control may achieve greater flexibility in maintaining integrative regulation across

visceral functions. In the regulation of a functional end-point such as maintenance of circulation, for example, higher neural systems can modulate a wide range of functional dimensions that influence this end-point. These include heart rate, cardiac contractility, vascular tone, blood pressure, and renal function; each of which can alter cardiovascular dynamics and can be in turn adjusted by a combination of autonomic and neuroendocrine influences. An implication of this integrative model is that the end-point of regulation may not be adequately characterized by a single dimension of visceral function, such as sympathetic outflow, heart rate, vascular tone, or blood pressure. In view of the multiplicity and integrative nature of allostatic control, central abnormalities that contribute to hypertension, for example, may not be effectively normalized by clinical treatment of a single visceral parameter (e.g., diuretics or beta-blockers). This is because allostatic regulatory processes are speculated to control many response parameters in the regulation of the target visceral dimension. Treatment of one dimension may merely lead to a compensatory alteration in another, which may maintain the abnormal regulated state of blood pressure. This concept has substantive implications for behavioral medicine, an issue to which we will return below (see Inferential Context).

Summary. The term heterostasis was proposed by Selye to reflect the alterations in regulatory levels that may be triggered by exogenous stimuli. The concept of allostasis was subsequently introduced by Sterling and Eyer to represent a wider set of central integrative controls over visceral regulation, related to both endogenous and exogenous conditions. The construct of allostasis subsumes and broadens Selye's concept of heterostasis, and is particularly significant for psychophysiology because rostral brain systems that underlie behavioral processes can exert complex patterns of regulation over neuroendocrine and autonomic function. Consequently, the optimal approach to understanding and alleviation of stress-related disorders is not merely the identification and palliation of a peripheral pathology. Rather, the origins of the dysregulation must be sought in central-visceral interactions (Thayer & Lane, 2000). Similarly, consideration of the central integrative processes that give rise to physiological responses may help to clarify psychophysiological relations, a subject to which we will return below.

1.3.3. Allodynamic regulation

The constructs of homeostasis and homeodynamic regulation both entail a relatively fixed regulatory set-point, although the homeodynamic concept explicitly recognizes the dynamic features of regulatory systems. The notion of heterostasis and the broader concept of allostasis similarly assume a regulatory set-point, although both emphasize the fact that regulatory levels may be variable, rather than fixed. It remains unclear, however, whether deviations from a fixed functional level universally represent

an allostatic-like adoption of a new set-point. We will consider below (see Physical Context) the possibility that at least some physiological changes associated with behavioral states may reflect the active inhibition of set-point regulation, rather than the adoption of an altered regulatory level. This is an issue of fundamental importance for conceptions of the nature of visceral control and for its health implications.

In view of these considerations, we introduce as a heuristic starting point the construct of *allodynamic regulation* (see Table 19.1). This construct is intended to broadly subsume the wide range of regulatory processes represented by the concepts of homeostasis, homeodynamic regulation, heterostasis, and allostasis. In addition, the allodynamic concept recognizes the potential limitations of regulatory processes, and the possibility that visceral reactions may not always be regulated about a set-point level.

2. PHYSICAL CONTEXT

2.1. Classical baroreceptor reflex and homeostatic regulation

Figure 19.2 presents a schematic depiction of the basic baroreceptor reflex circuit (Dampney et al., 2003; Spyer, 1990). Baroreceptor afferents increase their rate of firing in response to an increase in blood pressure and this afferent activity is conveyed to the nucleus of the tractus solitarius (NTS) in the medulla, which is the primary visceral receiving area in the brainstem. The NTS issues direct and indirect excitatory projections to vagal motor neurons in the nucleus ambiguus and the dorsal motor nucleus, leading to a reflexive increase in parasympathetic outflow. The NTS also projects to a "depressor area" in the caudal ventrolateral medulla (CVLM), which in turn inhibits sympathoexcitatory neurons of a "pressor area" in the rostral ventrolateral medulla (RVLM). This leads to a decrease in activity of the sympathetic motor neurons in the intermediolateral cell column of the cord. Through this circuitry, baroreceptors achieve reciprocal reflexive control over sympathetic and parasympathetic outflows and contribute to the homeostatic feedback-regulation of blood pressure.

2.2. Complexities in autonomic control

This homeostatic feedback-controlled model is elegant in its simplicity and, together with the construct of a set-point or regulatory level, could contribute to the relative stability of blood pressure over time. This simple model, however, belies the complexity of cardiovascular control (for a more comprehensive model, see Van Roon et al., 2004). Although baroreceptor reflexes importantly serve to oppose transient blood pressure perturbations, they may not wholly account for the long-term stability of blood pressure. Like other interoceptors, baroreceptors are subject to adaptation and it has been argued that they cannot reliably report steady-state levels (Dworkin, 1993). Although more recent studies raise the possibility that this adaptation may

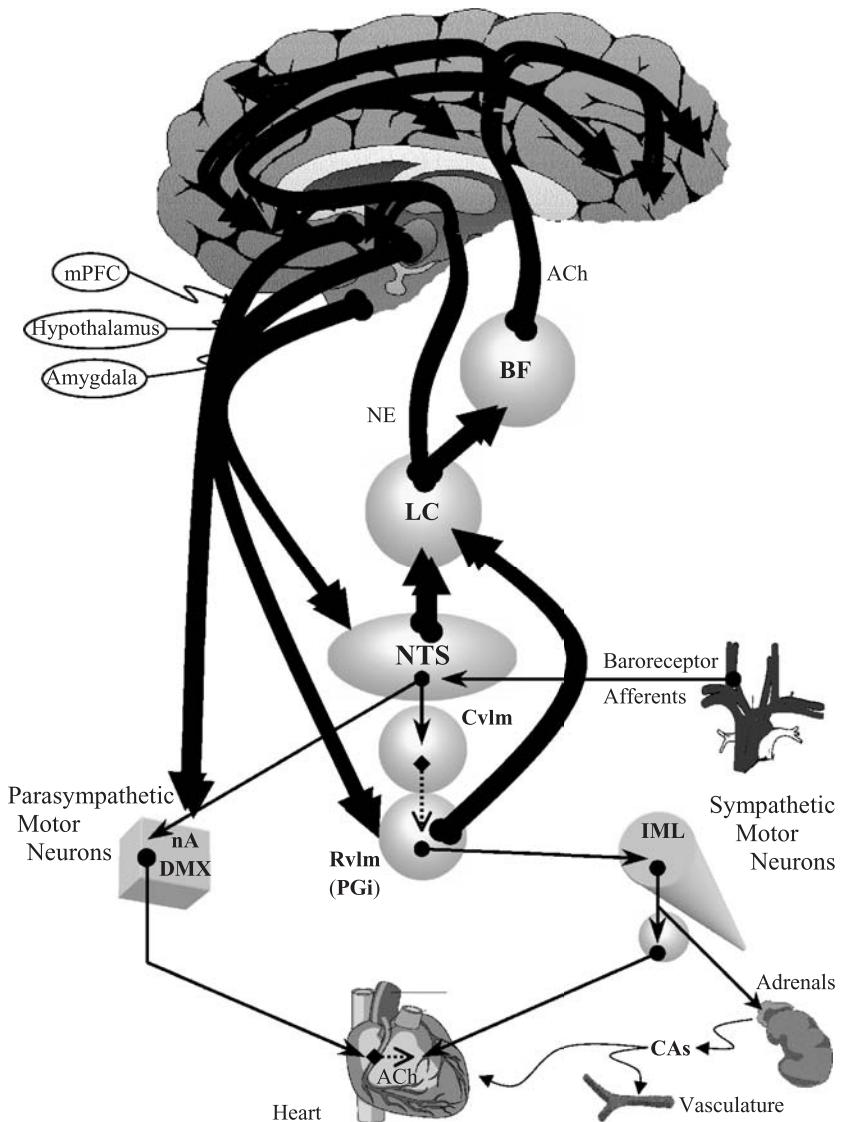

Figure 19.3. Expansion of the baroreflex circuit of Figure 19.2, to illustrate the ascending and descending pathways to and from rostral neural areas such as the medial prefrontal cortex (mPFC), hypothalamus (Hypo), and amygdala. Ascending systems include routes from the rostral ventrolateral medulla (Rvlm) and the nucleus of the tractus solitarius (NTS) to the locus coeruleus (LC) noradrenergic system, and indirectly to the basal forebrain (BF) cortical cholinergic system. Abbreviations: ACh, acetylcholine; CA, catecholamines; NE, norepinephrine; PGi, paragigantocellular nucleus (partially coextensive with Rvlm).

not be complete, steady-state levels of blood pressure are also regulated by a variety of factors, including peripheral (autoregulatory) processes, hormonal influences, and brainstem generators of autonomic tone that are at least in part independent of baroreceptor activity. Adding to this complexity are the contributions of rostral neural systems and anticipatory modulations of lower autonomic mechanisms.

2.3. Rostral influences

Rostral neural structures exert potent controls over brainstem regulatory systems. Respiratory mechanisms of the

brainstem are closely regulated by chemoreceptive feedback from blood gases, but can be modulated or overridden by higher-level systems associated with vocalization, anticipation of exercise, affective modulation of respiration, or volitional breath-holding (Harper, 1996). These latter influences appear to be mediated by descending pathways from the hypothalamus, amygdala, and the cerebral cortex. As illustrated in Figure 19.3, these structures project to autonomic regulatory substrates in the brainstem, including the NTS and the ventrolateral medulla, as well as to lower central autonomic motor neurons (Chen & Toney, 2003; Neafsey, 1990; Sequeira et al., 2000; Shih, Chan, & Chan, 1995; Wallace, Magnuson & Gray, 1992). Of particular relevance for psychophysiology is the fact that the rostral sources of these descending projections include limbic and forebrain areas that have been implicated in behavioral processes. Stimulation or lesions of these rostral structures have been shown to be capable of facilitating, inhibiting, or even bypassing basic brainstem autonomic reflexes to modulate autonomic outflow in a direct fashion (Inui et al., 1995; Koizumi & Kollai, 1981; Neafsey, 1990; Oppenheimer & Cechedo, 1990; Sequeira et al., 2000; Sevoz-Couche et al., 2003; Spyer, 1990). Stimulation of the central nucleus of the amygdala or the hypothalamus, for example, can inhibit barosensitive neurons in the rostral ventrolateral medulla (Gelsema et al., 1989) as well as the baroreflex response (Sevoz-Couche et al., 2003). It is likely that descending influences such as these serve as the conduit by which psychological stressors can inhibit the baroreflex and yield a concurrent increase in blood pres-

sure and heart rate in direct opposition to this reflex (see also Van Roon et al., 2004).

Although baroreceptor reflexes may exert a classical pattern of reciprocal control over the autonomic branches, rostral systems appear to be much more flexible. The traditional concept of reciprocal central control of the autonomic branches has undergone considerable qualification in the light of contemporary findings, and it is now apparent that the two autonomic branches can vary reciprocally, coactively, or independently (Table 19.2; Berntson, Cacioppo, & Quigley, 1991, 1993; Berntson et al., 1994; Koizumi & Kollai, 1992; see Van Roon et al., 2004). Descending influences from higher neural systems are

Table 19.2. Conceptual models of autonomic regulation

Set point	Operating characteristics	
	Fixed	Variable
Fixed	Homeostatic	Homeodynamic
Variable	Allostatic	Allodynic

capable of modulating the operating characteristics of brainstem homeostatic mechanisms, and can generate highly flexible patterns of autonomic outflow. Hypothalamic stimulation, for example, can evoke each of the basic modes of reciprocal, coactive, or independent changes in the activity of the autonomic branches (Koizumi & Kollai, 1981; Shih, Chan, & Chan, 1995). These descending integrative influences likely serve as important substrates for allodynic regulation of the viscera.

Clearly, autonomic state cannot be viewed as lying along a single reciprocal autonomic continuum extending from sympathetic dominance at one end to parasympathetic dominance at the other. Although reflex systems may tend toward reciprocal patterns of control, higher neurobehavioral networks exert a much broader and more flexible range of controls over the autonomic branches. When considering rostral influences, sympathetic and parasympathetic activities are more properly conceptualized by a bivariate autonomic plane (Figure 19.4). This parallels the somatic motor system, where extensor and flexor muscles are subject to reciprocal innervation by spinal reflexes. Reflexes that excite motor neurons for a given muscle (e.g., flexion and limb withdrawal from a pain stimulus) also inhibit the opponent (extensor) motor neurons. Despite this reciprocal innervation at the spinal cord level, we can volitionally contract both flexor and extensor muscles concurrently, as in a stiff-arm.

2.4. Afferent links and ascending influences

Of particular relevance for emerging neurobehavioral models of the links between psychological processes and autonomic control is the fact that interactions between rostral and caudal neural systems are bidirectional (see Figure 19.3). The potential role of visceral afference in higher level processes has long been of interest to psychologists, but has proven very difficult to characterize and quantify. Although the role of visceral afference in emotion and cognition remains speculative (see Cacioppo, Berntson, & Klein, 1992; Damasio, 1994), empirical findings document potent influences of visceral afferent information in central nervous system functions. Baroreceptor afferents to the brainstem represent the afferent limb of reflexes which subserve basic homeostatic functions. Visceral afferents, however, play a much broader and far more flexible role in behavioral processes. Baroreceptor activation, for example, has been shown to modulate afferent pain transmission and reduce pain perception (Dworkin

et al., 1994; Edwards et al., 2002). Visceral afferents may also impact more directly on activity in higher brain systems. Ascending projections from brainstem autonomic substrates project directly to forebrain areas that have been implicated in neurobehavioral processes, including the amygdala, cerebral cortex and basal forebrain cholinergic system (Aston-Jones et al., 1996; Berntson, Sarter, & Cacioppo, 2003; Zardetto-Smith & Gray, 1995).

As depicted in Figure 19.3, baroreceptor afferents terminate in the nucleus of the tractus solitarius (NTS). In addition to participating in local reflex circuits, baroreceptor afferent activity is relayed via the NTS to the nucleus paragigantocellularis (PGi), which provides a tonic drive on sympathetic motor neurons (Figure 19.3; for review see Berntson, Sarter, & Cacioppo, 2003). Consequently, the PGi (which is coextensive with the rostral ventrolateral

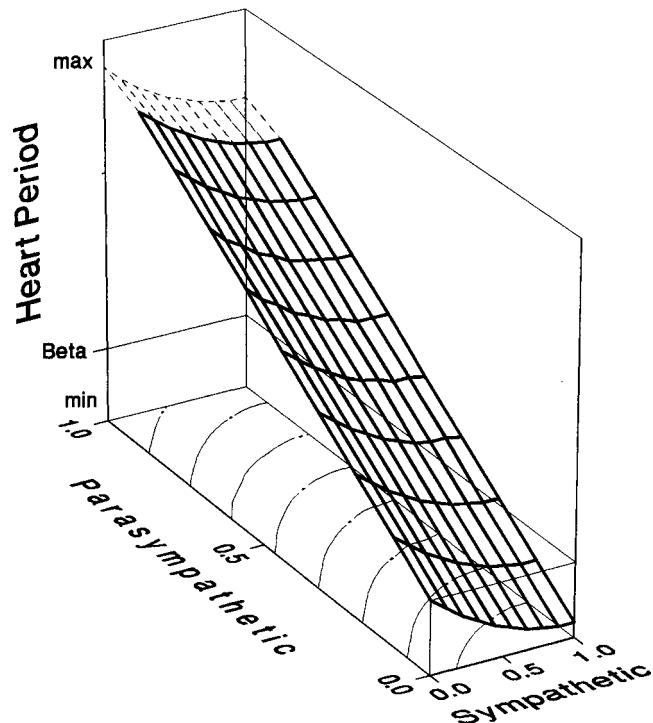

Figure 19.4. Bivariate autonomic plane and associated chronotropic effector surface. The plane bounded by the parasympathetic and sympathetic axes represents all possible combinations of sympathetic and parasympathetic activities (on a relative scale from 0 to 1). The effector surface overlying the autonomic plane represents the chronotropic state of the target organ, expressed in heart period, for all loci within autonomic space (see Berntson et al., 1993 for details on derivation). Parasympathetic activation exerts relatively linear effects on heart period, whereas sympathetic activation yields somewhat nonlinear effects. The dotted surface at maximal levels of parasympathetic activation represents the ambiguity in effects at this extreme. For illustrative purposes, the relative lengths of the axes are scaled in proportion to relative dynamic ranges of control of the autonomic branches, and Beta represents the “intrinsic” heart period in the absence of autonomic input. The curved lines on the autonomic plane represent isoeffector contours projected from the effector surface onto the autonomic plane. These contour lines illustrate loci on the autonomic plane that yield equivalent chronotropic effects.

medullary pressor area) would be expected to be highly sensitive to the state of activity in the sympathetic branch. The PGi also projects to the locus coeruleus, a structure that has been implicated in arousal and anxiety (Aston-Jones et al., 1996; Berntson et al., 1998, 2003), and the LC in turn issues an ascending noradrenergic projection to the limbic system and cerebral cortex. The activity of this ascending noradrenergic pathway would thus be expected to be modulated by the level of sympathetic tone.

In addition to its direct projections to limbic areas, the locus coeruleus also projects to the basal forebrain, which is the primary source of cholinergic innervation of the cortex (for review see, Sarter & Bruno, 1997). This cholinergic projection appears to enhance cortical processing, and has been implicated in cognitive and attentional processes (Sarter & Bruno, 1997). Degeneration of the basal forebrain-cortical cholinergic system is considered one of the major neuropathological conditions leading to the attentional and cognitive decline in Alzheimer's disease. In contrast, increased activity in this cholinergic system has been suggested to underlie cognitive aspects of anxiety, by virtue of the enhanced processing of anxiogenic stimuli (Berntson et al., 1998, 2003). The prototypic anxiolytic agents, the benzodiazepine receptor agonists such as chlor diazepoxide (*Librium*) and diazepam (*Valium*), appear to exert their anti-anxiety actions, at least in part, by attenuating activity in the basal forebrain cholinergic system. These ascending pathways likely mediate the affective and cognitive effects of visceral afference.

Over a century ago, William James (1884) proposed that the perception of visceral afferent information may constitute an important component of emotional experience (see Cacioppo, Berntson, & Klein, 1992). Research on human subjects with high spinal transections (quadriplegia or tetraplegia) has not yielded strong support for the necessary involvement of visceral activity and associated visceral afference in emotion (Chwalisz, Diener, & Gallagher, 1988). This, however, does not rule out an important modulatory role of visceral afference in emotion (see Cacioppo, Berntson, & Klein, 1992). High spinal cord transections do disrupt descending control of sympathetic outflow, but eliminate neither parasympathetic responses nor vagally conveyed visceral afference. Further, given the modulatory role of norepinephrine and acetylcholine on cortical activation and reactivity, the ascending pathways of Figure 19.3 would be expected to enhance cortical/limbic processing generally. Hence, ascending visceral afference may be more likely to prime or bias, rather than strictly determine, affective states. Affective and autonomic reactivity may be driven by a cognitively related top-down activation (e.g., in affective imagery) of the descending system depicted in Figure 19.3, and the resulting autonomic reactivity may further bias rostral systems toward the processing of affective stimuli via ascending pathways. Alternatively, visceral afference may yield a bottom-up priming of cognitive/affective processing even in the absence of an affective context via the pathways in Figure 19.3.

The early study of Schachter and Singer (1962) on emotional priming by epinephrine was consistent with this model, although serious questions have been raised over the generality of these results (Cacioppo, Berntson, & Klein, 1992; Reisenzein, 1983). More recent work offers substantial support to the view that visceral afference can modulate higher cognitive/emotional processing. Vagal stimulation or systemic administration of epinephrine has been reported to enhance cortical processing and to potentiate memories in rats and humans, and these effects can be blocked or attenuated by vagotomy, inactivation of the NTS, or by direct infusions of adrenergic blockers into the basal forebrain or the amygdala (Berntson et al., 2003; Cahill & Alkire, 2003; Clark et al., 1999; Hassert, Miyashita, & Williams, 2004; Williams & Clayton, 2001). Visceral afference also appears to play an important role in the allodynamic regulation of body temperature, as the fever associated with behavioral stress or exogenous mitogens appears to be mediated at least in part by a vagal afferent message (Hansen et al., 2001). Further work is clearly needed in this area, but the existing data are in accord with the bidirectional interaction among rostral and caudal neural substrates in the control of affective and autonomic reactivity.

Summary. Both ascending and descending neural systems appear to participate in affective states and autonomic control. Although the contributions of descending pathways have been more fully studied, ascending visceral information may prove to be equally important in biasing psychological processes and mediating psychophysiological relations. Findings at a neurobiological level focus attention on the complex interactions between central systems, autonomic regulation, and peripheral afferent signals. The convergence of visceral afference on common rostral neural systems, together with the hierarchical, integrative control these systems exert on lower autonomic substrates, likely contributes to the broader integration of behavioral and autonomic processes implied by the concept of *allodynamic regulation*. Homeostatic mechanisms can be highly adaptive, but there are many conditions in which it may not be optimal to maintain a fixed steady-state. In view of the limitless adaptive challenges an organism can encounter, it is hardly surprising that evolutionary pressures led to the development of sophisticated learning mechanisms that support behavioral flexibility and adaptability in overcoming these challenges. It would be most surprising if these same evolutionary pressures ignored the control of autonomic and neuroendocrine functions that provide the visceral support for adaptive response.

3. PSYCHOLOGICAL CONTEXT

3.1. The cardiac-somatic hypothesis: Psychophysiology and metabolic demands

The relationships between somatic effort, metabolic demand, and autonomic regulation have led to the

suggestion that cardiovascular reactions in psychological contexts can be attributable to metabolic factors. Based on the apparent correspondence between the direction and magnitude of cardiac change and variations in somatic response, Obrist proposed that “the metabolically relevant relationship or linkage between cardiac and somatic events is also relevant to behavioral events” (Obrist et al., 1970, p. 570). Obrist recognized, however, that many psychological tasks are metabolically trivial and that the cardiac response in psychological contexts often exceeds that expected on the basis of metabolic demands (Obrist, 1981; Turner, 1994). This is clearly apparent in the autonomic responses that can be invoked, in absence of somatic response, in curarized animals (Dworkin & Dworkin, 1990) and paralyzed human subjects (Berntson & Boysen, 1990).

Obrist later revised the concept of cardiac-somatic coupling, arguing that the fundamental linkage between cardiac and somatic events is attributable to a central coupling rather than peripheral metabolic feedback (Obrist, 1970, 1981). According to this view, it is not the somatomotor response, per se, that triggers cardiovascular responses but rather the central command for motor action. A strong test of the revised cardiac-somatic hypothesis would require measures of central somatic motor outflows in paralyzed subjects. Data relevant to this issue was provided by a study of Dworkin and Dworkin (1990) in which cardiovascular variables and somatic nerve activities were concurrently recorded in a paralyzed rat preparation during the course of discriminative Pavlovian conditioning. Even under complete paralysis, animals evidenced consistent discriminative conditioning (to footshock), as evidenced by EEG desynchronization, somatic (tibial) nerve activity, and cardiovascular responses. Both the conditioned (CR) and unconditioned (UR) central somatic responses entailed an increase in tibial nerve activity. From the standpoint of the cardiac-somatic hypothesis, this was consistent with the tachycardia observed as a UR to shock, but was at variance with the overall bradycardia to the CR despite the associated increase in somatic nerve activity.

Summary. Metabolic effects associated with somatic effort are known to trigger potent reciprocal autonomic adjustments, and this potential contribution needs to be considered in psychophysiological studies. Metabolic effects in many behavioral contexts, however, are insufficient in magnitude or in the wrong direction to account for observed cardiac responses to changing psychological states. There is little doubt that rostral central systems orchestrate coordinated somatic and autonomic responses, and do so in a fashion which transcends simple reflexive adjustments.

3.2. The neuropsychophysiological perspective

The alldynamic model and the rostral neuroanatomical systems depicted in Figure 19.3 suggest a considerable

richness in the neurobiological substrates underlying psychophysiological relations. The *neuropsychophysiological* perspective affords the basis for a powerful multilevel analysis of the links between psychological processes and visceral functions. The value of this perspective lies in the fact that psychophysiology can both inform and be informed by neurobiological data, constructs, and theories. The parallels between the central organization and evolution of the somatic and autonomic systems (Folkow, 2000) have not always been fully appreciated and this has sometimes led to unrealistic expectations of simple isomorphic relations between psychological processes and autonomic states.

Illustrative is the pessimism expressed by Obrist (1981) over the use of heart rate in the psychophysiological study of behavioral processes. Commenting on the fact that attention to environmental events is often associated with a decrease in heart rate (HR) whereas increased HR is typically observed in active avoidance, Obrist remarks “...both types of conditions have an obvious attentional component. If we assume for the moment that a decrease in HR is indicative of the attentional factor, then it must be overridden by some other aspect of the task during shock avoidance. It is anything but a parsimonious situation and leads to interpretive difficulties.” (Obrist, 1981, p. 198). But since attentional responses frequently entail a decrease in behavioral activity, it may be instructive to substitute the term “behavior” for “HR” in the above comment. Given our understanding of the multiple determinants of behavior, the mere occurrence of a decrease in behavior can not be taken to imply attention nor can an increase in behavior be interpreted as a lack of attention (see Cacioppo & Tassinary, 1990). This is insufficient reason to be disillusioned over the study of behavior, or for that matter, of heart rate. In both cases, a more productive strategy would be to define and disentangle the multiple determinants and processes operative in a given context, and to clarify the underlying relationships and mechanisms.

3.2.1. Rostral descending influences and the modes of autonomic control

Rostral neurobehavioral systems can exert relatively direct and selective influences on central autonomic outflows and their actions may not adhere to simple principles of homeostasis and reciprocal control (Recordati, 2002). Rather, descending systems are capable of evoking a wide range of autonomic modes of control. The autonomic origins of the cardiac responses of humans subjects to orthostatic stress (assumption of an upright posture) and to typical psychological stressors (mental arithmetic, reaction time, and a speech stress task) were evaluated by pharmacological blockades that yielded quantitative estimates of the sympathetic and parasympathetic contributions to cardiac response (Berntson et al., 1994a; Berntson et al., 1994b; Cacioppo et al., 1994). At the group level, the orthostatic and psychological stressors yielded an essentially equivalent pattern of heart rate increase, characterized by sympathetic activation and parasympathetic withdrawal. For

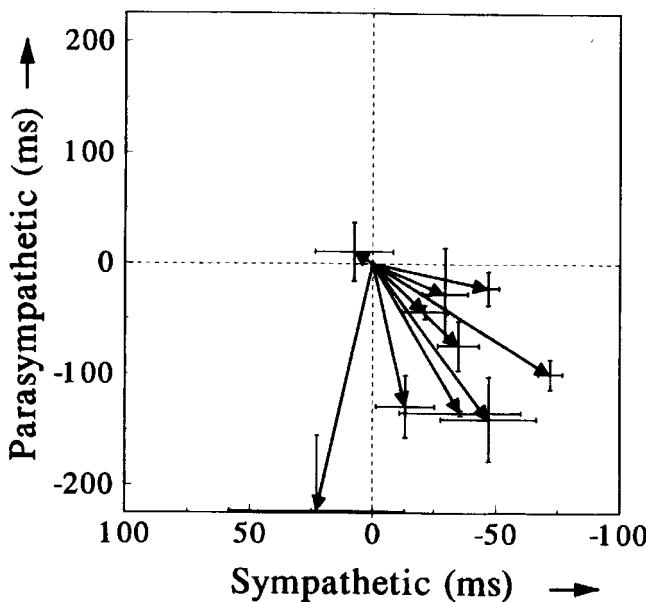

Figure 19.5. Individual patterns of response to stress depicted on the autonomic plane. The intersection of the dotted lines in the center of the graph represents the basal resting state, and the arrows depict the individual response vectors along the sympathetic and parasympathetic axes, with the peak response at the arrowheads. Vectors were derived from independent estimates of the contributions of the autonomic branches under selective pharmacological blockades. Note that some subjects responded primarily with parasympathetic withdrawal, some primarily with sympathetic activation, and some with reciprocal sympathetic activation and parasympathetic withdrawal. These individual response vectors were stable. Three stressors were used (mental arithmetic, a reaction time task, and a speech stressor), and the error bars at the tip of each response vector illustrate the standard errors of the response across the three tasks. Units on the axes are in milliseconds of heart period. (Figure is adapted from Berntson, Cacioppo, Binkley et al., 1994).

the orthostatic stressor, the cardiac response reflected a relatively tight reciprocal central control of the autonomic branches, as evidenced by the significant negative correlation between the responses of the autonomic branches across subjects ($r = -0.71$). Although the group response to psychological stressors was similar, there were considerable individual differences in the pattern of response, and there was no significant correlation between responses of the autonomic branches. The individual patterns of autonomic response were highly reliable across different psychological stressors, but subjects differed considerably in their mode of response. As illustrated in Figure 19.5, some subjects showed primarily sympathetic activation, some reciprocal sympathetic activation and parasympathetic withdrawal, and others primarily parasympathetic withdrawal.

Individual differences in the pattern of autonomic response may have special relevance to psychophysiological relations and psychosomatic disorders. Cardiovascular reactivity to acute laboratory stressors can predict endocrine and immune responses to stress, with high heart rate reactors showing greater changes in cortisol, natural killer cell activity, and T cell activation (Bachen et al., 1995;

Bosch et al., 2003; Cacioppo, 1994; Cacioppo et al., 1995; Sgoutas-Emch et al., 1994). As illustrated in Figure 19.5, however, there can be sizeable individual differences in the autonomic origins of heart rate responses to stress, and these distinct autonomic modes of control may have differential implications for neuroendocrine and immune responses. It is the sympathetic component of the heart rate response, rather than the parasympathetic component or the heart rate response *per se*, that is most predictive of neuroendocrine and immune reactions to stress (Bosch et al., 2003; Cacioppo, 1994; Cacioppo et al., 1995). This is in keeping with the finding that some immune responses to laboratory stressors can be prevented by selective sympathetic blockade (Bachen et al., 1995; Benschop et al., 1994).

Summary. Descending projections of rostral neurobehavioral systems confer a high degree of flexibility over patterns of autonomic outflow, and can lead to reciprocal, coactive, or independent changes in the activities of the autonomic branches. The allodynamic model incorporates the central integrative nature of behavioral, neuroendocrine, and visceral control, and affords a more comprehensive framework for psychophysiology than does the more limited construct of homeostasis. The allodynamic model also fosters a neuropsychophysiological perspective that recognizes that psychophysiology can both inform and be informed by neurobiological analyses.

4. INFERENTIAL CONTEXT

The homeostatic model emerged from the early physiological literature, and continues as an important organizing construct in both physiology and psychophysiology. There is considerable appeal to the elegant simplicity of the homeostatic construct and the associated reciprocal model of autonomic control. These models, however, do not provide a comprehensive conceptualization of autonomic control in behavioral contexts. Deviations from the reciprocal homeostatic model were recognized in the early physiological literature, but it has been psychophysiological findings that have offered the strongest evidence against these restrictive constructs. The allodynamic model subsumes homeostatic processes, but offers a more comprehensive framework for psychophysiology.

The neuropsychophysiological perspective is particularly relevant within the allodynamic framework, as allodynamic systems quintessentially entail higher central integrative processes. Psychophysiology entails a multi-level approach to the study of the mind-body problem and the relations between psychological and physiological processes. Historically the discipline was often forced to bridge the wide chasm between cognitive and psychological operations on the one hand and rather peripheral physiological dimensions on the other. This was attributable largely to the accessibility of peripheral measures and the relative lack of knowledge of brain systems underlying

cognitive and behavioral processes. Although early electroencephalographic studies did obtain more direct measures of brain function, they did not offer much anatomical precision and they focused largely on global states of sleep and arousal. Within the past several decades, however, emerging understandings of neurobiological systems and explosive developments within behavioral and cognitive neuroscience now permit much more direct and specific studies of the central mediators of psychophysiological relations, which is the essence of neuropsychophysiology. Psychophysiological data provide the ultimate subject matter for neurobehavioral studies and the means for validating neurobiological models. At the same time, knowledge of underlying neural mechanisms can inform and constrain psychophysiological theories and facilitate interpretation of psychophysiological data.

4.1. Neuropsychophysiology: Peripheral mappings, measurement, and quantification

The fact that the autonomic branches can be independently controlled has substantial implications for psychophysiological theory and measurement. The autonomic space model (Figure 19.4) suggests that meaningful psychophysiological measures of dually innervated organs require attention to the specific autonomic origins of the end organ state (Berntson et al., 1991). That is, a change in heart rate associated with sympathetic activation may have considerably different psychological and physiological significance than an equivalent change due to parasympathetic withdrawal. Although heart rate measures may continue to have utility in psychophysiology, there is an inherent source of variance that is not adequately parsed by measures of heart rate alone. This variance is relegated to error, and tends to obscure lawful psychophysiological relationships.

The importance of neurophysiologically meaningful measurement of psychophysiological signals is not limited to the heart. Other dually innervated organs, such as the iris of the eye are subject to the similar considerations. Pupillary diameter is a joint function of parasympathetically innervated sphincter (pupillary constrictor) muscle and sympathetically innervated radial (dilator) muscle (see Cohen, this volume). Although there is a degree of reciprocity among the autonomic controls of the iris, changes in pupillary diameter can arise from distinct central systems and can be differentially influenced by the autonomic branches (Loewy, 1990). Parasympathetic control is predominant in accommodation and light reflexes, whereas variation in sympathetic activity is the primary determinant of pupillary responses in behavioral and stress contexts. Again, similar end organ responses arising from different modes of autonomic control may have distinct psychophysiological implications.

Careful elucidation of peripheral autonomic end-organ mappings is important from the perspective of measurement. Equally important are the implications of peripheral mappings for conceptual models and psychophysiologi-

cal theories. The autonomic space concept of Figure 19.4 is not a mere measurement model, but has substantial implications for psychophysiological concepts. In an early influential theory, Eppinger and Hess (1915) proposed a classification of people as vagally dominant (vagotonic) or sympathetically dominant (sympathicotonic). This view entailed not only a bipolar concept of autonomic control, but a dichotomous individual differences model of autonomic balance. The subsequent studies of Wenger (1941) suggested that “autonomic balance,” at best, is continuous rather than dichotomous. More recent studies outlined above (Psychological Context) reveal that the pattern of autonomic response cannot be characterized even along a single continuum, but requires a bivariate model of autonomic control. These findings mandate a more comprehensive conceptualization of the relations between psychological processes, the modes of autonomic control, and potential dispositional biases in psychophysiological disorders.

4.2. Neuropsychophysiology: Central mappings and the relation between psychological processes and brain systems

Evidence outlined above indicates that rostral neural systems can modulate autonomic control in a fashion that is not easily reconciled with a simple homeostatic model. As illustrated in Figure 19.3, there are multiple descending neurobehavioral systems that serve to orchestrate and integrate behavioral, autonomic, and neuroendocrine responses. A greater appreciation of the functional contributions of these systems (i.e., a clarification of the mappings between psychological and neural processes) is likely to contribute to the understanding of complex psychophysiological relations. As neurobehavioral mechanisms are increasingly elucidated, joint studies of psychological and neural functions can be mutually informative.

The literature on arousal offers an example of the mutual benefits of an integrative approach across levels of analysis (behavioral and physiological) and provides an illustration of the increasing complexity of autonomic control at higher levels of the neuraxis. Arousal has been an important concept in physiology, psychology, and psychophysiology over the past five decades. Much of the impetus for arousal theories and for concepts of the role of general arousal in behavior came from work in the 1940s and 1950s on the brainstem reticular formation (for review see Magoun, 1963). Historically, the reticular formation was viewed as a relatively undifferentiated, highly interconnected set of neurons that exerted relatively nonspecific activational effects on rostral neural systems. Results of early stimulation, lesion and recording studies led to the construct of an Ascending Reticular Activating System (ARAS), which was believed to regulate the state of arousal of cortical and neurobehavioral systems (Magoun, 1963). The ARAS model resonated with psychologists because it was recognized that, apart from associative or structural determinants of behavior, there were important

motivational or activational (arousal) contributions (Hebb, 1955; Duffy, 1957). The construct of general arousal is appealing in its inherent simplicity and parsimony, which is likely one reason it has been so resilient in the face of contradictory evidence. Even early studies revealed that the effects of arousal were not truly generalized and that behavioral and cortical arousal could be dissociated (Bradley & Elkes, 1953; Feldman & Waller, 1962). Moreover, psychophysiological measures commonly purported to be indices of arousal (e.g., heart rate, EDR) often do not covary highly with each other or with behavioral performance (e.g., see Lacey, 1959, 1967). Autonomic control, at least that arising from higher-level neurobehavioral substrates, does not lie along a single arousal continuum and does not reflect a simple homeostatic process. Paralleling the emerging recognition of the limitations of the construct of general arousal in psychology and psychophysiology were developments in neuroscience. These included a growing appreciation that the reticular formation was not as nonspecific as originally conceived. More refined neuroanatomical methods and neurochemical markers revealed a great deal of differentiation within what was classically considered an undifferentiated system (Sarter, Bruno, & Berntson, 2003). It is now apparent that there are multiple ascending activating systems, each having differential patterns of afferent input, dissimilar projection fields, and distinct neurochemical mediators (Krout, Belzer, & Loewy, 2002; Robbins et al., 1998). These include ascending noradrenergic, dopaminergic, cholinergic and serotonergic systems. The precise roles of these ascending systems in behavior and autonomic control remain to be fully elucidated, but their functions are clearly differentiated. The mesolimbic dopaminergic system has been implicated in reward, incentive, and behavioral activation (Robbins et al., 1998; Gray & McNaughton, 1996); the locus coeruleus noradrenergic system in cortical and motivational arousal (Aston-Jones et al., 1996); the cholinergic system in cortical/cognitive processing (Robbins & Everitt, 1995; Sarter & Bruno, 1997), and the serotonergic system in attention and behavioral inhibition (Robbins & Everitt, 1995; Gray & McNaughton, 1996). Each of these neurobehavioral systems have distinct anatomical projections, differentiated roles in behavioral processes, and distinct links to autonomic control systems. In contrast to the early work on the ARAS and on autonomic control, psychological, psychophysiological, and neurobiological data concur that neither arousal nor autonomic control can be viewed as a unitary process along a single continuum.

Research on arousal systems illustrates the mutual benefit of multilevel analyses. Psychological, psychophysiological, and physiological perspectives were each essential for ultimate progress in this area. Although psychological concepts of generalized arousal antedated the emergence of the ARAS construct, it required neurophysiological studies on the reticular formation to crystallized this construct and embody it within a neuroanatomical substrate. In the light of current understandings, the ARAS

model may seem primitive, but it represented an important conceptual advance at the time. The ARAS, for example, offered the first viable psychobiological account for why an organism did not simply lie inert in the absence of evocative environmental stimuli (Hebb, 1955). Psychological and psychophysiological data provided the early support for the ARAS construct, but it was those same disciplines that ultimately posed the strongest challenges to the concept of generalized arousal. Moreover, it was findings and perspectives from those same disciplines that ultimately spearheaded efforts to refine both the ARAS construct and the homeostatic model of autonomic control.

4.3. Neuropsychophysiology of stress-related disorders

Psychophysiological disorders have often been viewed as homeostatic dysfunctions (e.g., Cannon, 1932; Holmes & Ripley, 1955; Selye, 1956), and stress has been defined by some researchers as a state of threatened homeostasis (Johnson et al., 1992). The homeostatic construct, however, has been applied so broadly, across such a diverse range of phenomena, that its status as an explanatory construct warrants re-examination and refinement.

Although homeostatic processes and disturbances may impact health, more recent attention has shifted to the potential health implications of allostatic or allostodynamic regulation. It is important to recognize that the mere labeling of a condition as a homeostatic or allostodynamic dysfunction contributes little to scientific understanding. For meaningful progress, the origins, mechanisms and implications of dysfunctions ultimately must be clarified. The significance of the constructs of homeostasis, allostasis, or allostodynamic regulation lies more in the strategic guidance they offer for research efforts, and in the directions and potential mechanisms that they focus attention on.

4.3.1. Psychophysiological disorders as specific homeostatic dysfunctions

Some researchers have considered psychophysiological disorders as manifestations of constitutional dispositions toward specific patterns of autonomic response to stress. An historical example is the Eppinger and Hess (1915) constitutional model, as considered above. According to this view, exaggerated activity in one of the autonomic branches can bias toward specific disorders such as asthma (parasympathetic) or Raynaud's disease (sympathetic). Further consistent with this notion of a dispositional bias were the reports of Moos and Engel (1962) and Malmo (1975) of exaggerated psychophysiological reactivity appearing specifically in organ systems that evidenced psychosomatic dysfunctions. Hypertensive patients, for example, were reported to respond to stress with exaggerated cardiovascular responses, whereas arthritic patients were more likely to show EMG abnormalities around affected joints. Although these patterns of psychophysiological response could represent consequences

of the specific disorders rather than markers of inherent dispositions, some prospective studies are consistent with the dispositional model. The normotensive offspring of hypertensive parents are at risk for the subsequent development of hypertension, and several studies have reported exaggerated basal or reactive cardiovascular activity in these individuals even prior to the development of hypertension (Fredrickson & Matthews, 1990; Maver, Strucl, & Accetto, 2004; Turner, 1994).

Additional support for constitutional contributions to hypertension comes from animal models. The spontaneously hypertensive rat (SHR) and the borderline hypertensive rat (BHR) represent potentially important genetic models of hypertension. SHR and BHR animals may also display exaggerated cardiovascular reactions to challenge stimuli (Kirby et al., 1989) and a regimen of behavioral stress can transform normotensive BHR animals to permanently hypertensive (Sanders & Lawler, 1992). Exaggerated sympathetic activity appears to contribute importantly to the conditions leading to hypertension in these animals (Korner, 1995a) and to cardiovascular disorders in humans (Grassi, 2004). These findings are consistent with a dispositional bias interacting with a stress context. SHR rats, and some hypertensive humans, show a lowered sensitivity of baroreceptor reflexes that could be interpreted to reflect an underlying homeostatic deficit (Head, 1995; Korner, 1995c; Maver et al., 2004; Watkins et al., 1996). This is intriguing in view of the fact that behavioral stress, which is known to suppress baroreflexes and increase sympathetic outflow, is able to exacerbate the hypertensive condition in the BHR rat. Although this model of homeostatic dysfunction has appeal, it is at best oversimplified. Baroreflexes can buffer short-term changes in blood pressure but do not appreciably contribute to long-term blood pressor regulation. Baroreceptor damage in humans or sino-aortic denervation in animals manifests primarily in acute blood pressure lability rather than chronic hypertension and basal hypotension may even be apparent (Franchini & Krieger, 1992; Robertson et al., 1993). These findings do not rule out the possibility that homeostatic deficits contribute to hypertension, but they do suggest that hypertension is not simply a baroreflex anomaly. The complexity and interactions of the determinants of hypertension may be more in keeping with a model of allodynamic regulation.

4.3.2. Generalized features of stress: Allostatic load

In addition to the multitude of specific regulatory deficits that may underlie stress-related disorders, more generalized features of stress have been recognized. For Cannon (1932) these were related to the generalized activation of the sympathetic nervous system. Selye (1956) further developed the generalized model of stress response, but shifted the focus from the autonomic nervous system to the pituitary adrenocortical system. In addition to potential specific reactions to stressors, Selye (1956) argued that the stressors typically elevate adrenocorticosteroid

hormones, a component of what he termed the General Adaptation Syndrome (GAS). In Selye's view, autonomic activation contributes primarily to the initial reaction to stress (the alarm stage) whereas the adrenocorticosteroid response was considered to represent the generalized and persistent effect of stress (the resistance stage). Adrenocorticosteroids have widespread effects on insulin release and metabolic processes, muscle contractile strength, psychological states, and immune functions. The corticosteroid response was viewed by Selye as an adaptive mobilization to counter stress challenges, through syntoxic actions such as anti-inflammatory effects that minimize tissue damage, and catatotoxic actions that enhance bodily defenses. In the GAS model, if the stress is not adequately resolved, defensive resources are ultimately depleted and the individual becomes increasingly susceptible to disease (exhaustion phase).

The generalized consequences of stressors continue to attract attention. Although the negative effects of stress are often the focus of psychophysiological studies, it is important to recognize that stress reactions can confer positive benefit in dealing with adaptive challenges and can protect and restore vital functions. The adaptive utility of stress reactions were inherent in Selye's (1973) syntoxic and catatoxic features of the stress response, and it is increasingly recognized that acute stress may enhance immune reactions (Bosch et al., 2005; Dhabhar, 2003). Moreover, moderate early stress has been shown to enhance development and improve vigor of organisms, and mild infant stress may reduce subsequent stress effects in adulthood (Gandelman, 1992; Meaney et al., 1996).

Severe or prolonged stress, however, may have negative consequences (McEwen & Wingfield, 2003; Seckl & Meaney, 2004). McEwen and Stellar (1993) argue that specific patterns of stress response may vary considerably across individuals and contexts, but that they also show common allostatic features. In contrast to simple homeostatic systems that are focused around a set point on a single dimension (e.g., blood pressure), allostatic systems entail multiple dimensions that are integrated and orchestrated by central, autonomic, and endocrine processes. Within allostatic systems, functional set points are subject to change, and disturbances in one dimension may lead to compensatory fluctuations in another. McEwen and Stellar (1993) propose that repeated or prolonged allostatic fluctuations extract a physiological cost, a sort of "wear and tear" that they term *allostatic load*. This allostatic load is seen to be cumulative, and to dispose toward a broad range of stress pathologies, such as atherosclerosis and hypertension (McEwen & Stellar, 1993). A wide variety of psychosocial stressors, for example, have been suggested to confer an aggregate risk for acute myocardial infarction as revealed in one of the larger cohorts studied (INTERHEART study; Rosengren et al., 2004). This risk was independent of physical and demographic variables and was comparable to that of hypertension and obesity. An aggregate score putatively reflecting global allostatic load has

been reported to predict not only physical health outcomes but the cognitive and functional decline associated with aging (Karlamangla et al., 2002; Seeman et al., 2001).

Glucocorticoids assume special importance in allostatic load and the consequences of stress because they modulate a wide range of functions. Adrenal steroid secretion is under the control of pituitary ACTH, which in turn is regulated by hypothalamic corticotropin releasing hormone (CRH). In addition to its role in adrenocortical control, CRH has been implicated as a trigger of the central stress response (de Kloet, 2003; Gray & Bingaman, 1996). This circuit is regulated by an inhibitory glucocorticoid feedback signal which modulates CRH release. One of the consequences of stress is the allostatic alteration of the operating level of this system, yielding higher basal levels of CRH and glucocorticoids (see Schulkin et al., 1994; McEwen & Wingfield, 2003 for reviews). The hippocampus is an important target site of the glucocorticoids, where binding serves to dampen or shut off stress related CRH release from the hypothalamus. But repeated stress can trigger atrophy of pyramidal dendrites in the hippocampus (via conjoint actions of glucocorticoids and excitatory amino acids), and severe and prolonged stress may even lead to loss of hippocampal neurons (McEwen & Wingfield, 2003; Sapolsky, 2003; Uno et al., 1989). This could lead to higher than normal levels of glucocorticoids during stress and impose a further allostatic load due to impaired feedback regulation, which may further contribute to stress pathology.

In addition, social but not physical stressors have been reported to foster a specific allostatic adjustment entailing glucocorticoid resistance associated with alterations in glucocorticoid receptor processes. Despite normal levels of immunomodulatory glucocorticoids, animals with glucocorticoid insensitivity display exaggerated immune reactions, which under some conditions may in fact be potentially life-threatening (Quan et al., 2003). Other neural, neuroendocrine, metabolic, and immune pathways also likely contribute to the health consequences of stress and allostatic load, and in the aggregate may underlie the generalized relations between allostatic load and health.

Summary. Stress reactions may entail both specific and generalized features, arising from homeostatic and allodynamic processes. Consequently, stress related pathology may not be conceptualized adequately within a restricted homeostatic framework. Stress disorders arising from allodynamic disturbances may have multiple origins in complex interacting systems, where disturbances in one domain may manifest in another, and compensatory responses can be orchestrated across several functional domains. Consequently, treatment strategies directed to a single perturbed target dimension (e.g., blood pressure) may not be optimal, as they may simply result in compensatory changes in another dimension that could perpetuate the disturbance. An important issue for future research is

the extent to which allostatic "load" represents a truly generalized consequence of stress or to what extent it may manifest differentially based on the individual and the stress context.

4.3.3. Specific consequences of stress

Although broad indices of allostatic load focus on the generalized consequences of stress, more organ- or function-specific effects may also be apparent with allostatic or allodynamic disturbances. Allostatic load has been conceptualized as an aggregate state of allostatic processes, but may be comprised of a number of more specific conditions or relations. The *metabolic syndrome* is a diagnostic classification based on a cluster of risk factors including hypertension, insulin resistance, and central adiposity, which forebodes an increased risk for cardiovascular morbidity and mortality and type II diabetes (Reaven, 2005). Measures of allostatic load include many markers of the metabolic syndrome, as well as additional parameters that expand the boundaries of the concept of allostatic load (e.g., see Seeman et al., 2001). That is, the concept of allostatic load is considerably broader than that of the metabolic syndrome, which raises an important question as to whether this represents a conceptual advantage or disadvantage. The generalized predictive abilities of the allostatic load construct may be due to a critical *interaction* among the systems, dimensions, and parameters which serve to measure and define it. Alternatively, allostatic load may provide a global predictor of health outcome because of the aggregate predictive relations among components with relatively independent risk factors. If the former is true, parsing allostatic load into component predictors may degrade the predictive power, whereas if the latter is the case, such a parsing may lead to more system- or function-specific predictors. This is an important distinction, because the two options have different implications for research strategies. If risk factors are independent, then they can be studied in relative isolation, although an aggregate measure may still have some utility in predicting health outcomes. If the risk factors interact, however, then the overall risk status cannot be adequately determined by isolated studies of individual risk factors, regardless of how many are included.

In this regard, Reaven (2005) has recently questioned the predictive utility of the concept of metabolic syndrome over its individual dimensions. If the metabolic syndrome is merely an aggregate of independent predictors, then the selective focus on specific relations between individual factors and allodynamic systems and health would be appropriate. That is, the appearance of insulin resistance alone, in the absence of other components of the metabolic syndrome, may be a sufficient indication for treatment and for the specific treatment strategy to resolve the insulin resistance (Raeven, 2005). The ongoing development of cardiovascular risk factor profiles is increasingly making an important contribution to risk stratification for cardiovascular disorders (Rosengren et al., 2004; Wood, 2001). If

this merely reflects the identification of a set of orthogonal dimensions that allow an aggregate risk assessment, then the individual dimensions can be studied independently, and a disturbance in a single dimension might suggest a treatment strategy focused on that specific anomaly. In contrast, if the risk factors are interacting, then isolated studies of the individual dimensions will never capture the full health implications of a group of risk factors. Moreover, if studies were limited to independent assessments, interactions between factors may never be known. Reality probably lies somewhere between these extremes. It will be important for future research to elucidate the manifestations of homeostatic or allostatic disorders that relate to specific physiological dimensions as well as those that entail more complex multi-system interactions. It is important that the latter not be disregarded, however, as a comprehensive understanding of an organism and its adaptation can only be achieved by the interactions of its parts and its transactions within the physical and social worlds (Cacioppo et al., 2000).

4.3.4. Allodynamic processes: protective and restorative functions

Although the discussion above has focused on physiological disturbances and negative health outcomes, homeostatic, allostatic, and allodynamic adjustments likely evolved because of their adaptive value and their positive benefit to health and survival. Autonomic, neuroendocrine and immune systems are orchestrated in part to buffer the organism against effects of internal and external changes by regulatory and restorative devices. Alterations from a constant homeostatic state may have highly beneficial effects in the short run, despite potential negative effects over longer periods of time (see Cacioppo & Berntson, 2006; McEwen & Seeman, 1999). Stress-related allostatic adjustments can improve wound healing and moderate stress may even enhance long-term immunological function and protective processes (Dhabhar, 2003; Dhabhar & Viswanathan, 2005). Alternative levels of regulation in allostasis, which may themselves be subject to change over time and circumstance, can be adaptive or maladaptive depending in part on the physical and social environment and the status of the organism. The focus of the above discussion of allostatic load has been on biological substrates and physical systems, but these systems are influenced powerfully by psychological states and the social world.

Although stress pathology is increasingly being elucidated, the neurobehavioral processes and transduction mechanisms that link stress to health outcomes are less well understood. What constitutes a stress and how the system reacts may differ from individual to individual. Individuals who approach active coping tasks with the belief that they can meet the task demands ("challenge appraisals") show primarily cardiac activation to the task, whereas those harboring a belief that they cannot meet task demands ("threat appraisals") show primarily vascu-

lar activation (Tomaka et al., 1997). These different reactions may have distinct health outcomes, and stressors may have positive as well as negative effects. For example, early stress can promote stress "immunization," entailing a genetic reprogramming that can lead to lower stress reactivity throughout life (Levine, Halmeyer, & Karas, 1967; Meaney, 2001). Autonomic, endocrine and immune reactions serve important regulatory and restorative functions that buffer adaptive challenges. This may be accomplished through homeostatic-like processes that defend the steady state or through allostatic adjustments that defy homeostasis. Generally adaptive, these processes in some circumstances may have negative outcomes. The design for a brain and stress physiology that worked well through early evolution may have maladaptive aspects, especially as longevity has increased well beyond the reproductive years. Even those reactions with negative dimensions often have positive effects on other dimensions, and the focus on positive, buffering, and restorative functions is an important emphasis in the recent literature (see Cacioppo & Berntson, 2006).

4.4. The allodynamic perspective

Homeostatic processes contribute importantly to adaptive function, but the simple feedback-controlled homeostatic model with its fixed operating set point does not adequately represent the complexity of psychophysiological regulation. Organ systems are complexly controlled and allostatically regulated by integrative neural, autonomic and endocrine systems. Regulatory levels and other operating characteristics are not rigidly fixed, but can be adaptively varied to face existing or anticipated demands. The allodynamic model affords a more comprehensive framework for psychophysiology than does the homeostatic construct. As considered above, the allodynamic model has substantive implications for psychophysiological measurement, constructs of physiological response, theories of psychophysiological relationships, and strategies for clinical intervention.

The neuropsychophysiological perspective is particularly important in studies of allodynamic regulation and dysregulation, as the links between psychological processes and physiological outcomes may be highly complex and dependant on central integrative systems. Studies of these intervening systems can both inform and be informed by psychophysiological relations. Because mappings between terms and concepts among closely related levels of analysis are likely to be simpler than those between more remote levels, the neuropsychophysiological perspective offers a viable bridging strategy for clarifying psychophysiological relations. This perspective does not challenge the importance of contributions from research limited to the psychological, psychophysiological, or neural levels of analysis. Rigorous independent research at each of these levels is crucial. The ultimate development of psychophysiology, however, will be

substantially enhanced by meaningful interdisciplinary multilevel analyses.

Developmental Psychophysiology: Conceptual and Methodological Issues

NATHAN A. FOX, LOUIS A. SCHMIDT, HEATHER A. HENDERSON, AND PETER J. MARSHALL

HISTORICAL PRECEDENT

Developmental psychophysiology is the study of behavior – physiology relations in infants and young children. Issues that are commonly studied by psychophysologists with adult populations such as cognitive processing, cognition-emotion interactions, or responses to stress, may be examined in populations of young children as well. For example, utilizing age appropriate paradigms, interested researchers have investigated infant visual attention through the measurement of cardiac orienting (Field, 1979; Sameroff, Cashmore, & Dykes, 1973); others have examined infant discrimination of human faces by recording event-related potentials (de Haan & Nelson, 1997; Nelson & Collins, 1991, 1992; Parker et al., 2005). Such research has been quite valuable in revealing the links between physiological responses and behavior in infants and children of different ages. When multiple ages are utilized, such studies have also revealed age-related differences in physiology-behavior linkages (Richards, 1985, 1989).

Developmental psychophysiology, however, may offer the greater promise of revealing the processes by which both physiology and behavior change together over time. Such an approach necessitates a three-tier investigation. First, there must be a description of age-related changes in behavioral performance and physiological response. Second, there must be an attempt to describe how the physiological system itself is developing and changing over time, often as a function of the stimuli that are being studied. Third, there should be some attempt at integration of physiology and behavior. An example of this approach may be seen in the study of infant memory for faces. Such research has utilized event-related potentials (ERPs), examining multiple age groups (Nelson & Collins, 1991, 1992). These studies find decreasing latency and increasing amplitude of particular components of the ERP with age (see Nelson, 1994; Nelson & Monk, 2001 for reviews). In several other areas of developmental study, decreasing latency and increasing amplitude of specific ERPs have further been linked to improved cognitive

performance including memory performance (Howard & Polich, 1985) and response monitoring (Segalowitz et al., 2004; Santesso, Segalowitz, & Schmidt, 2006a) across childhood. Together, these studies demonstrate the links between developmental changes in the characteristics of physiological measures and the underlying cognitive processes. While these findings are an important first step, the developmental psychophysicist should ask the next set of questions. Specifically, it seems critical when one studies a system that changes over time to understand what parameters of that system contribute to the response being measured. In the case of the increasing amplitude and decreasing latency of the ERP, we need to know what physical and physiological changes have occurred over developmental time, which may contribute to these changes in the ERP. For example, it is possible that changes in myelination of brain areas thought to be putatively involved in the behavior may affect the latency of the response. There may be changes in skull thickness or cortico-cortical connections that affect the pattern of the response. As well, there are clearly certain cognitive processes involved in the development of face recognition and discrimination, for example, which contribute to the behavioral response. Finally, while direct comparisons between adult and child behaviors may not be appropriate (i.e., each group may solve a particular problem with different strategies and perhaps with different underlying neural mechanisms), similarities in performance between age groups or deficits in one group may be useful for raising hypotheses about the underlying bases of the behavior. In a recent paper, Schacter, Kagan, and Leichtman (1995) reviewed studies of adult clinical populations who showed patterns of amnesia for episodic memory or confabulatory behaviors. Many of these adult subjects had injury to areas of the prefrontal region. Indeed, the clinical data on brain damaged adults seem to indicate that injury to certain areas of the prefrontal cortex may be associated with source memory deficits. Schacter, Kagan, and Leichtman (1995) drew a comparison between the responses of adult brain damaged patients to the behaviors that young children exhibit when tested for episodic or source memory. While they

did not suggest that the processes responsible for adult or child errors were similar, they do raise interesting hypotheses regarding the role of the prefrontal region in episodic memory.

Thus, developmental psychophysiology has the opportunity to study not only changes in response systems over age, but also the processes underlying this change. Not only must change in the response system be measured but it must be understood as a function of the physical and psychological maturation of the organism under study. These added elements of developmental change create a new level of complexity (Emde & Walker, 1976; Richards, 1989; Snidman et al., 1995) in contrast to the psychophysiological study of adult populations.

MODELS OF DEVELOPMENT

Developmental change has been modeled in many different ways and the model one adopts as well as the processes one examines will determine the questions that are asked. There are a number of different models of development, each of which emphasizes differentially the role of environment and biology in influencing behavior. Application of one of these models to a particular study will influence the manner in which questions are asked and variables are measured.

Biologically determined models of development. These models postulate that development is a function of the unfolding of predetermined biological processes. The underlying structures of the brain develop and connect with one another via predetermined processes, which have a great deal to do with the action and expression of certain genes (Edelman, 1987). Thus, neurons within the neuroblast migrate and generate particular layers of cortical and sub-cortical structures during embryonic development similarly for all individuals in the absence of toxic environments (e.g., in utero exposure to drugs, alcohol, or radiation) (Huttenlocher, 1979; Sidman & Rakic, 1973). Similarly, the formation of the nuclei responsible for cardio-respiratory control and vagal innervation of the heart occur in a standard developmental timetable except in the presence of toxic environmental effects. Of course, even in instances of well-programmed neural development, there are individual differences in the outcome of such growth, which may be the result of differences in intrauterine environments and the timing of particular stressors or intrauterine conditions upon development (Huttenlocher, 1979). Such differences reflect a critical variable, which must be taken into account in any developmental model. The timing with which certain environmental events impact upon pre-programmed biological growth is a critical area of study. Ultimately though, in biological models of development, the timing of neural development is thought to be pre-programmed and to occur in an orderly fashion in the absence of negative environmental events.

Critical period models of development. A second model of development is one that takes into account environmental input and emphasizes the criticality of the timing at which this input is presented. This model is best thought of as reflecting the concept of a critical period. The idea of a critical period is that there is a window of opportunity through which particular environmental input will have a major influence on the organization of behavior (Hubel & Wiesel, 1970). For example, there is some evidence that exposure to language during the early years of life is critical for the adequate formation of appropriate language ability (Lenneberg, 1967; Petitto, 1993). There are, in addition, other sensory modalities (e.g., audition, vision) that are thought to develop in human infants and children via critical period models (see Maurer, 2005 for a recent Special Issue on the topic). Such a notion implies that exposure prior to, or after, this window of opportunity will not have the same effect upon the neural organization underlying this behavior (however, see Mills, Coffey-Corina, & Neville, 1994). In addition, this model implies that appropriate exposure during the critical period will lead to the organization of structures in such a way that they will henceforth underlie the more mature behavioral pattern. The critical period model of development is akin to an "innoculation" model in that appropriate development necessitates input at a particular time. Neural reorganization occurs as a function of this input, which then underlies subsequent behavior. This reorganization of behavior is a second process, which plays an important role in our understanding of behavioral change. Once the infant has received the appropriate environmental input he/she is protected ("innoculated") from other competing environmental inputs.

Stage models of development. A third model of development is one in which development is explained as a series of different periods of reorganization of both physiology and behavior (Case, 1992; Fischer, 1983, 1987; Thatcher, 1991, 1994). Such a model is a derivative of Piaget's view of development. Piaget viewed development as comprising a continuous process of the organism accommodating and assimilating environmental information. At particular points in development, an individual's interpretation of the information changes qualitatively as he/she moves, for example, from a sensorimotor view to a more concrete operational one. For example, at a certain age, Piaget observed that young children were more influenced by the perceptual properties of objects than by rules of conservation. Once a child understands that the quantity of a liquid does not change if poured from a tall, thin to a low, round beaker they have mastered a new stage of understanding. At these transition moments, there are both behavioral and accompanying physiological reorganizations, which reflect changes in the manner in which the child operates on the world. There is interesting, though indirect physiological evidence to support this view. Thatcher, Walker, and Giudice (1987) examined changes in intra- and

inter-hemispheric coherence of the EEG across multiple age points. Thatcher et al. found what they described as lawful patterns of reorganization of coherence both within and between the left and right hemispheres. The ages at which these changes occurred seemed to correspond to periods of cognitive reorganization proposed by Piaget. A number of "stage" or re-organization models describe the transformation of existing behavioral/cognitive structures at particular periods of time into more sophisticated structures for the purpose of assimilating new and more complex information (Case, 1992; Fischer, 1980). Further, behavioral/cognitive re-organization is supposedly mimicked at the neural level (Fischer 1987; Fischer & Rose, 1994). For example, in a re-analysis of longitudinal EEG data collected by Matousek and Petersén (1973) John (1977) described distinct periods of reorganization of power in anterior to posterior scalp locations, which coincided with age periods thought to represent times of cognitive change. In a more discrete study of brain-behavior relations, Bell and Fox (1992) reported on changes in EEG power recorded from the frontal scalp leads in infants who had and had not mastered an object permanence task (A not B). This task is thought to involve the activity of the dorsolateral frontal cortex (Diamond & Goldman-Rakic, 1983, 1986, 1989). The timing of changes in behavior and EEG for successful infants was tightly locked so that reorganization of behavior and EEG (reflected not only in power but also coherence) was similar in scope.

Interactionist models of development. A fourth approach to the study of development is one that views the process as involving a continuous interaction between the genetic and biological disposition of the individual and environmental factors which impinge upon that individual (Gottlieb, 1976; Segalowitz & Schmidt, 2003). The goal of research is to understand the processes involved in gene-environment interactions. Accordingly, one must assess not only the biological/physiological status of the organism but also the manner in which various types of environmental contexts affect that status. Such an approach involves the study of individual differences and the role of the environment in affecting these differences. The study of individual differences is in fact a major topic in psychophysiology. Researchers have for some time recognized that individuals differ in their initial or baseline pattern of physiology and have attempted to take these differences into account when understanding subject response to stimulation (see Zahn, 1986, for a review). Indeed, a number of workers have given specific emphasis to the psychological meaning of these individual differences in physiology. For example, Davidson and colleagues have argued that resting patterns of asymmetrical frontal EEG activation reflects individual differences in the relative strength of approach versus withdrawal motivation tendencies (Davidson, 1984a, 1984b, 1995, 2000). Adults with greater relative right frontal EEG activation are more likely to respond to signs of impending danger or punish-

ment with a negative hedonic valence compared to adults exhibiting left frontal activation. Within the domain of autonomic activity, Porges has argued that individual levels of heart rate variability or vagal tone will affect the subject's reaction and subsequent recovery to a mild stressor (Porges, 1992). Individuals with low vagal tone are less likely to display significant cardiac orienting as compared to those with higher levels of vagal tone. Porges' work is unique in that he has extended these findings from adult to infant and child populations. Fox and colleagues have extended Davidson's model to examine temperamental differences among infants and young children. In a series of studies, Fox and his colleagues have shown that infants with resting right frontal EEG asymmetry are more likely to display distress and negative affect to unfamiliar stimuli as compared to infants with left frontal asymmetry (Calkins, Fox, & Marshall, 1996; Fox, Bell, & Jones, 1992). They have also shown that children displaying this pattern of right frontal asymmetry are more likely to show social withdrawal and reticence in a social situation with unfamiliar peers (Fox et al., 1995; Fox et al., 2001). Frontal EEG asymmetry has also been related to patterns of continuity and change in behavioral inhibition over time, with the best predictor of the tendency to be socially reticent with unfamiliar peers in the preschool years being the combination of temperamental negative affect and right frontal EEG asymmetry as assessed in infancy (Henderson, Fox, & Rubin, 2001).

While most developmental psychologists subscribe to the interactionist model to describe developmental processes, few studies actually capture the interactional component of the model (with some notable recent exceptions, see e.g., Fox et al., 2005). Most studies and researchers of individual differences are able to characterize the individual, and often the environment, but are less likely to describe the manner in which these factors mutually influence one another. Any understanding of development, however, must ultimately take into account such interaction. Such a model necessitates the integration of timing and reorganization of physiology as a function of experience and must take into account when exposure to certain events occurs and how this affects the organization of physiology and behavior.

Summary

Each of the four models described above provides important insight into developmental processes. There are clearly some changes that are primarily under "genetic" control (e.g., migration of nerve cells in the embryological development of the brain), other changes that necessitate environmental input at a particular point in time (e.g., the need for visual stimulation in the organization of the visual system), and still other changes that show transformations over time as a function of interaction with the environment (e.g., means-end ability). As such, the choice of a model will be a direct function of the processes under

study. At a macro-level, there must be some integration of these frameworks for understanding the complex manner in which development occurs in the central nervous system. In the [next section](#), we review two major psychophysiological systems (electrocortical and cardiovascular) and describe, where appropriate, how these systems have been examined in relation to the four models of development. We describe the historical precedent regarding each of these systems and review studies focusing on developmental issues.

PHYSICAL CONTEXT: SYSTEMS IN DEVELOPMENTAL PSYCHOPHYSIOLOGY

The electrocortical system: EEG and ERP measures

Overview. Like any system undergoing change, there are dramatic differences in activity of the EEG during the first two years of life. Changes in power and frequency of the EEG during this time period may be a function of certain developmental changes in specific brain parameters. For example, it is possible that changes in myelination of axons, changes in dendritic branching, and the sculpting of neuronal patterns (both in terms of cell proliferation and cell death) each affect the pattern of electrical energy recorded off the scalp. We know, however, precious little about the development of any of these physical parameters. The data on myelination of brain areas come from studies such as those conducted by Benes, Turtle, Khan, and Farol ([1994](#)) and Gilles, Shankle, and Dooling ([1983](#)). The data on dendritic changes and sculpting come from studies by Huttenlocher and colleagues (e.g., [Huttenlocher, 1984](#); [Huttenlocher & de Courten, 1987](#); [Huttenlocher et al., 1982](#)). None of these studies have directly linked anatomical changes to behavior.

The paucity of information regarding growth and development of the systems under study obviously makes interpretation of the pattern of responses being measured from these systems somewhat problematic. For example, adult alpha, recorded over the occipital cortex is defined as comprising the frequency band of 8 to 13 Hz. This frequency band seems to respond reliably to changes in visual attention (eyes-open versus eyes-closed produces alpha suppression). There is, however, little power in the 8 Hz to 13 Hz frequency band through late childhood. On the other hand, there is a reliable rhythm recorded over the occipital cortex, which is responsive in similar ways to visual input in the first year of life. The change in this frequency band may be of significance for understanding basic neural development as well as the relation between EEG and behavioral changes. That is, the increase in frequency of the “alpha rhythm” may tell us something about the development of the underlying neural generators in the thalamus, which are purportedly responsible for the generation of adult alpha rhythm ([Nunez, 1981](#)).

Developmental changes in psychophysiological measures may also reflect functional changes in the way the

brain processes information. It is possible that certain brain structures are present early on but do not come “on line” until later in development. Changes in psychophysiological responses may thus be the result of the appearance of new functional operations rather than the physical maturation of any structures. For example, some patterns of electrical activity are less a result of anatomical variations and more a reflection of functional changes. One example is the pattern of frontal EEG asymmetry reported in infant and adult studies. Individuals may show a predominant asymmetry pattern at rest (either left or right frontal EEG asymmetry). But there are also clear shifts in these same individuals as a function of affective state or cognitive activity. For example, individuals with a pattern of resting left frontal EEG asymmetry may display right frontal EEG asymmetry in response to an aversive film clip ([Jones & Fox, 1992](#); [Tomarken, Davidson, & Heniques, 1990](#)). These shifts seem to suggest that the pattern of changes in EEG asymmetry reflect functional changes in brain activation rather than anatomical differences. There may be, of course, developmental changes in the degree to which these functional differences emerge and are utilized. Nevertheless, individual differences in psychophysiological measures such as EEG asymmetry may reflect important functional rather than structural differences.

Historical background. Berger ([1929, 1932a, 1932b](#)) was the first to use the electroencephalogram (EEG) to assess human brain development. Berger found little brain electrical activity before one month of age, after which time EEG frequency and amplitude increased in the occipital region. Following Berger’s important work, a number of longitudinal studies on EEG development were conducted with full-term and premature infants, with a focus on distinguishing between sleep and wake states. Overall, the early studies found that EEG frequency and amplitude increased during the first year of life in the full-term infant, while brain electrical activity of the premature infant was similar to the *in utero* infant ([Dreyfus-Brisac & Monod, 1975](#)). More recent studies have also noted reduced EEG amplitude in pre-term compared with fullterm infants ([Duffy, Als, & McAnulty, 1990](#)).

The early EEG studies were, however, limited on several fronts ([Berger, 1932a, 1932b](#); [Smith, 1938a, b, c, 1939](#)). First, most of the studies were largely descriptive. They attempted to detail the development of various components of the EEG in the absence of any information regarding the physical development of the nervous system. Second, attempts at quantification of EEG frequency and amplitude were done by hand with a ruler, possibly limiting the precision of calculations; many of the early studies predated the use of computers and frequency analyzers. Third, adult parameters of state such as sleep staging were used to index EEG development in the infant. Fourth, the number of sites from which EEG was recorded were limited. A majority of studies only recorded from one or two

scalp sites, possibly precluding the contribution of brain maturation in other regions relative to the sites collected.

Both clinicians and basic researchers have used the EEG as an instrument to understand complex brain-behavior relations. Traditionally, the EEG has been used in clinical settings to diagnose neuropathology. In this setting, the neurologist primarily uses qualitative interpretation of the EEG signal to understand brain anomalies such as seizures or tumor. More recently, quantitative EEG (qEEG) has been used in basic research settings by investigators interested in understanding issues related to normal as well as atypical brain development. For example, some researchers have examined changes in EEG frequency (Hagena, 1968, 1972) and coherence (Thatcher, Krause, & Hrybyk, 1986) in relation to brain maturation. Still others have related regional EEG activation to the emergence of particular functions in the developing brain. For example, patterns of frontal EEG activation have been examined in relation to emotional (Dawson et al., 1992; see also Fox, 1991, 1994; Fox et al., 1992) and cognitive development (Bell & Fox, 1994) during infancy as well as the development of maladaptive patterns of social and emotional responding in early childhood (Fox et al., 1996; Fox et al., 2001; Shankman et al., in press).

With the advent of new computer technologies, the collecting of ongoing high density EEG at a high rate of speed is now a reality. Such advances allow for reliable temporal resolution of underlying neurophysiology processes. Furthermore, unlike the more intrusive brain imaging procedures such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), the EEG is a relatively noninvasive procedure, making it more tractable with pediatric populations. These methodological improvements and considerations, in combination with recent theoretical advances in the neurosciences, provide an exciting atmosphere for researchers interested in using the EEG to understand the developing human brain (Lewis & Stieben, 2004).

The use of EEG in understanding human brain development has been limited, however, largely because there have been relatively few longitudinal studies in which quantitative EEG has been used to assess brain maturation. In addition, the EEG suffers from poor spatial resolution. Neuroimaging techniques such as PET and fMRI have superior spatial resolution.

Studies relating EEG to early brain development. A number of longitudinal studies have been directed towards examining EEG frequency development during the first two years of life. Most of these studies examined posterior EEG frequency development and noted that a dominant EEG frequency emerged between 3 Hz to 5 Hz during the first 6 months of life and between 6 Hz to 8 Hz by the end of the first year. Smith (1938a, 1938b, 1938c, 1939) was one of the first researchers to examine EEG frequency development in the developing brain. Smith (1938b) noted that by age 3 to 4 months, a characteristic "alpha-like" rhythm

appeared in the occipital region in the human infant. The occipital rhythm increased to 6 Hz to 7 Hz by age 12 months (Smith 1938b, 1939, 1941). Smith (1938b) suggested that the onset of occipital activity at 3–4 months was linked to maturation of visual systems. Smith (1939, 1941) also noted a 7 Hz alpha-like frequency at age 3–4 months in the central region, which increased in frequency after 10 months. Smith (1941) speculated that this shift in pattern was linked to the emergence of reaching behavior in the infant. Lindsley (1939) also noted the development of an alpha-like rhythm between 3 Hz to 5 Hz in the occipital region at age 3–4 months, which increased to 6 Hz by age 12 months. Lindsley (1939) postulated that the development of this rhythm was related to the ontogeny of visual perception. Henry (1944) also reported a 3 Hz to 4 Hz rhythm in the occipital region at 3–4 months that increased to 7 Hz by age 12 months.

Following this early work, longitudinal studies of EEG frequency development waned for nearly three decades until the work of Hagena and her colleagues (Hagena, 1968, 1972; Hagena et al., 1973). Hagena's work is of particular importance for at least three reasons. First, unlike earlier studies, which calculated frequency data by hand, she performed frequency analyses using a fast Fourier transform. Second, Hagena recorded from multiple sites representing anterior and posterior regions of the brain. Third, Hagena was interested in relative power and peak frequency. Hagena (1968, 1972) reported that a delta (1.5 Hz to 3.5 Hz) to theta (3.5 Hz to 7.5 Hz) frequency ratio changed from 8 to 12 months, with increases in theta and decreases in delta. This pattern of change was a function of electrode location. Theta activity decreased in P3 and O1 between 8 and 10 months and increased between 10 and 12 months, while theta activity in C3 and Cz increased between 8 and 12 months. Still others (Mizuno et al., 1970) have examined relative power in the right occipital area using an alpha (7.17 Hz to 10.3 Hz)/delta (2.4 Hz to 3.46 Hz) quotient. Mizuno et al. (1970) found that this quotient increased from 1 to 12 months of age: There were increases in alpha activity and corresponding decreases in the delta band. Relative increases and decreases in band power have also been used as an index of EEG maturation, which in turn has been related to aspects of behavioral development. A relatively high level of low-frequency power (e.g., delta, theta) and a relative lack of higher-frequency power (e.g., alpha, beta) in the EEG has been associated with cognitive delays and attentional problems over a range of ages and contexts, including environmental adversity (Barry, Clarke, & Johnstone, 2003; Harmony et al., 1988; Marshall, Fox, & the BEIP Core Group, 2004; Satterfield, Cantwell, & Satterfield, 1974). There is some debate as to whether these deficits represent a maturational lag, or whether the EEG profile represents tonic hypoactivation (Barry, Clarke, & Johnstone, 2003).

We recently carried out an analysis of changes in EEG band power in a longitudinal sample from 5 months to 4 years of age (Marshall, Bar-Haim, & Fox, 2002). This

study replicated many of the above findings from previous researchers, and established guidelines for the use of a 6 to 9 Hz band to represent alpha power from late in the first year of life and into early childhood. Other researchers have employed similar bands to study alpha-range rhythms: For example, Orekhova, Stroganova, and Posikera (2001) used a frequency band of 6.4 Hz to 10.0 Hz in a sample of infants aged 7–12 months to represent both posterior alpha rhythms as well as sensorimotor rhythms such as the mu rhythm. The classical mu rhythm occurs in the 7 Hz to 13 Hz range in adults, and is maximal over central sensorimotor areas. The amplitude of the mu rhythm is attenuated by voluntary movement and somatosensory stimulation (Gastaut, Dongier, & Courtois, 1954), but is minimally affected by changes in visual stimulation and is considered to be a somatosensory alpha rhythm that is sensitive to somatic afferent input and is distinct from the alpha range rhythms in more posterior regions (Kuhlman, 1978). Very few studies have addressed the development of the mu rhythm, although we have noted the appearance in infancy of a rhythm in the 6 Hz to 9 Hz band in the EEG power spectra over the central region (Marshall, Bar-Haim, & Fox, 2002). In terms of its relative contribution to the overall power spectrum, this rhythm is particularly prominent in the second year of life. Other researchers who have documented this rhythm have suggested a functional relation between the oscillation observed at central sites in infancy and early childhood and the mu rhythm in adults (Galkina & Boravova, 1996; Stroganova, Orekhova, & Posikera, 1999). The salience of the central sensorimotor rhythm in the EEG power spectra may not be coincidental, given that the second year after birth is a time of such intense development of locomotor ability. An additional, intriguing possibility is related to the observation that the amplitude of the mu rhythm in adults is not only related to movement *per se*, but is also sensitive to subtle variations in observed movements (Muthukumaraswamy & Johnson, 2004). Given the importance of imitative learning in social contexts in the second year of life, it is also possible that the salience of the mu rhythm is related to this capacity, as well as to the developing locomotor capacities of the infant.

EEG coherence has also been used as a measure in the study of brain development. EEG coherence is a measure of the phase relation of two processes at a specific frequency band. Coherence values range from 0 (there is no phase relation) to 1 (the two signals are either completely in or out of phase with each other). A number of researchers have speculated on the interpretation of changes in EEG coherence. Nunez (1981) has suggested that coherence between two EEG electrode locations may reflect the activity of axonal connections between two regions. Others have postulated that coherence values may be related to the activity of short- and long-fiber networks of the axons (Thatcher, Krause, & Hrybyk, 1986; Thatcher, Walker, & Giudice, 1987). Thatcher postulated that development in the cortex involves processes of increasing communication between regionally distinct locations as well

as increased differentiation of regions across the cortex. Thatcher utilized a ratio score of long to short distance coherence to demonstrate this model. By examining the coherence of long-distance sites (and assuming increases to reflect increased long distance communication) and examining the coherence between short-distance sites (and assuming decreases to reflect regional specialization) Thatcher, Walker, and Giudice (1987) were able to model the growth of the cerebral hemispheres across the first ten years of life. Thatcher, Walker, and Giudice (1987) reported that periods of major change in short- and long-distance coherence coincided with what appear to be major stage transitions in cognitive growth. This, he argued, is an indirect confirmation of his model of neural change as reflected in the EEG measure of coherence. More recently, Barry and colleagues have focused on changes in EEG coherence over middle childhood and have argued for particular methodological modifications in the interpretation of coherence, such as correcting for inter-electrode distances (Barry et al., 2005; Barry et al., 2004).

If, in fact, coherence reflects the connectivity between different regions, then it may change as a function of the degree to which that connectivity increases or decreases. Studies of both human (Huttenlocher, 1979; Huttenlocher et al., 1982) and non-human primate cortical development (Greenough & Volkmar, 1973) report that during early development there is an over-population of neurons in the cortex which, also during early development seem to be selectively pruned. Bell and Fox (1996) wondered whether these processes may be reflected in measures of EEG coherence and took as their model the timing of self-produced locomotion during the first year of life. They recorded EEG from four groups of 8-month-old infants who varied in the degree of experience they had with self-produced locomotion (one group was not yet crawling; a second group crawled for one to two weeks; a third group from three to six weeks and a fourth group had been crawling for more than 7 weeks). Bell and Fox argued that coherence measures should differ as a function of the degree of experience that infants had with crawling. This model of experience dependent changes in neural patterning was first proposed by Greenough (Greenough & Black, 1992; Greenough, Black, & Wallace, 1987) who predicted an inverted U-shaped function in the number of connections (with an increase at the onset of particular expected experiences and a decrease as pruning occurred once a particular competency had been mastered). Bell and Fox (1996) found this same inverted U-shape function for intra-hemispheric coherence in the EEG among the four groups. Infants with no experience in crawling showed less coherence than those with only a short period of crawling experience. By seven weeks of experience the level of coherence had again dropped.

Studies relating ERP morphology to early brain development. Developmentalists who subscribe to early critical periods are interested in how environmental input can

affect brain development and the emergence of particular competencies during development. One such example is the acquisition of language. There seem to be critical periods around which particular components of language emerge. During the first half of the first year of post-natal life, all infants are capable of discriminating the sounds of any language across lexical boundaries. Thus, infants raised in an English-speaking environment in the United States are capable of discriminating across certain boundaries of Chinese or Japanese (Best, 1993). After six to eight months, this ability to discriminate any boundary seems to disappear and the child is only able to make these discriminations for their native language, the language to which they have been exposed. These changes clearly suggest the reorganization of neural centers as a function of language input and the critical period during which this reorganization is said to occur. ERP techniques have also been used to provide additional evidence of the neural changes underlying this reorganization (Cheour et al., 1998; Rivera-Gaxiola, Silva-Pereyra, & Kuhl, 2005). However, not all neural reorganization for language necessitates the input of oral communication. In a series of studies, Helen Neville and her colleagues have shown that congenitally deaf subjects differ from hearing subjects in the pattern of their ERP responses to language (Neville, Kutas, & Schmidt, 1982a, 1982b). Whereas hearing subjects displayed a prototypical left hemisphere distribution of the ERP in response to language stimuli, deaf subjects showed an opposite pattern (one of right hemisphere distribution). Neville reported that this pattern of right hemisphere activity in the ERP of deaf subjects might be a function of the type of language input that they receive. While hearing subjects receive oral auditory input, deaf subjects were more likely to receive visual-spatial input as communication. The type of language communication therefore reorganized the pattern of hemispheric dominance. These patterns of reorganization were reflected in the asymmetry of the ERP.

As with the EEG, particular characteristics of the ERP in early development have been related to certain aspects of brain maturation. For instance, the polarity of the mismatch negativity (MMN) in the auditory ERP has been found to relate to global maturational status in newborns (Leppanen et al., 2004). Characteristics of the auditory and visual ERP responses have also been used to document deviations from the typical maturational sequence in at-risk clinical populations of newborns and infants who suffered particular insults or deprivations in fetal development (Black et al., 2004; Siddappa et al., 2004). In older infants and young children living in institutions in Bucharest, Romania, the ERP responses recorded to facial expressions of emotion were significantly smaller in amplitude compared with a group of never-institutionalized infants and young children (Parker, Nelson, & the BEIP Core Group, 2005). In addition, the early negative components such as the Nc and N170 did not show age-related changes in the institutionalized children, whereas partic-

ular changes were seen in terms of latency and amplitude changes with age in the never-institutionalized children.

Still other more recent ERP studies have attempted to link particular ERP components to individual differences in personality in older children. For example, we have recently examined the error-related negativity (ERN) in children and adults. The ERN is an ERP waveform that occurs approximately 100 ms following an error response of the realization of having erred. The source of the ERN is thought to be the anterior cingulate cortex (ACC). The ACC is known to play an important role in error detection and response monitoring. We have found in a sample of non-clinical 10-year-olds attenuated ERN responses in children classified as undersocialized (Santesso, Segalowitz, & Schmidt, 2005) and exaggerated ERN responses in children classified as high on obsessive-compulsive behaviors (Santesso, Segalowitz, & Schmidt, 2006c).

While developmental ERP studies have long attempted to link certain ERP components to behavioral and psychological phenomena, there is increasing interest in the use of new techniques to localize these components in the brain. While localization of scalp-recorded brain potentials requires particular assumptions in order to overcome the "inverse problem" that is a fundamental constraint on such endeavors, recent advances have been made that allow researchers more accuracy in speculating about the possible origins of brain potentials in infants and children. Reynolds and Richards (*in press*) focused on the negative component known as the Nc, which is commonly observed in studies of visual recognition memory in infants (Nelson & Collins, 1992). Using spatial independent components analysis, the cortical source of the Nc was localized to specific areas of prefrontal cortex, including the medial and inferior parts of the frontal gyrus, as well as the anterior cingulate cortex. The study by Reynolds and Richards (*in press*) represents a particularly interesting application of combining novel statistical methods with new methods for recording EEG from high-density scalp arrays in infancy. The use of such techniques may prove very important in addressing some of the critical questions in the literature concerning the nature of early cortical development (de Haan, Johnson, & Halit, 2003; Gauthier & Nelson, 2001).

The cardiovascular system: Heart period and heart rate variability

Overview. The cardiovascular system is relatively well developed at birth and recording of the ECG is relatively easy even during the newborn period, thus providing researchers and clinicians with a useful and noninvasive means for assessing the developmental status of infants. Measures of heart period (the time interval between successive heart cycles, or the inter-beat interval) and heart rate variability (a general term used to refer to beat-to-beat changes in heart rate or heart period) serve as indices of autonomic nervous system regulatory activities and have

been related to individual differences in attention, cognition, and emotion in both child and adult populations. The interpretation of the autonomic origins of cardiovascular response patterns, whether in the context of intra-individual responses to discrete stimuli or inter-individual differences in "baseline" cardiovascular patterns, is complicated by the fact that the parasympathetic and sympathetic branches of the ANS dually innervate the heart. Methodological advances, such as the incorporation of spectral analytic techniques into the analysis of heart rate variability data, however, allow for the isolation and quantification of particular sources of heart rate variability (Mezzacappa et al., 1994).

The ability to empirically link basic cardiovascular measures such as heart period to higher order cognitive processes such as attention and information processing has been particularly useful in the field of child development where researchers are faced with the difficulty of gathering information from infants who have yet to acquire language or complex motor behaviors. Thus, cardiovascular measures have become a useful tool for the study and assessment of sensory, perceptual, and cognitive development in infants. Conversely, infant development provides a useful means for studying the development of autonomic functioning and its role in psychological processes.

Beyond infancy, cardiovascular functioning has been related to the development of emotional and behavioral disorders in childhood and adolescence. Theoretically, the cardiovascular system has been related to problem behaviors based on the assumption that cardiovascular functioning is related to higher order cognitive processes such as information processing. In older children and adults, information processing expands beyond simply attending to stimuli in the environment to allocating attention between internal (i.e., self-focused) and external (i.e., other-focused) events.

Historical background. There are excellent reviews of the historical development of the use of cardiovascular measures with adult populations in psychological research (e.g., Hassett & Danforth, 1982). Cardiovascular measures were originally used as an index of general arousal or emotion. Darrow (1929) first documented adults' physiologically distinct responses to classes of stimuli differing in the extent to which they were psychologically arousing. Specifically, when adults were presented with disturbing or arousing words, Darrow recorded a rise in blood pressure along with increases in heart rate. In contrast, there were little or very slight drops in blood pressure in response to benign sensory stimuli. In addition, Darrow found that heart rate and respiration were more tightly coupled or associated during the psychologically arousing conditions compared to the more benign conditions. Together, Darrow's findings demonstrated that stimuli with distinct characteristics and psychological meanings evoked physiologically unique responses. In addition, increased respiratory-cardiac coupling under psychologically arous-

ing conditions was attributed to increased autonomic arousal.

Ax (1953) extended Darrow's findings by demonstrating that specific emotions were associated with distinct physiological reaction patterns. During anger provocation in the laboratory, Ax found that adults responded with increased diastolic blood pressure and decreased heart rate. In contrast, there were fewer consistent reaction patterns during the induction of fear. Further, Ax noted that there was a greater coupling or association between physiological measures during anger induction. Ax interpreted these differences in the concordance of physiological measures as reflecting greater integration or organization during anger versus fear induction. From an evolutionary perspective, Ax related the increased physiological integration during anger reactions to a complete mobilization of resources, in contrast to a relative lack of integration or paralysis of bodily functions during fear reactions.

Lacey (1967) provided compelling ideas as well as empirical evidence to argue against general activation theories of emotion. Lacey argued that physiological activation could not simply be conceptualized as a uni-dimensional continuum in which the degree of physiological activation directly maps onto the intensity of emotion or behavior. Rather, Lacey proposed that activation is multidimensional and that physiological reaction patterns reflect not only the intensity but also the intended goal or aim of an emotion or behavior. In a series of experiments, Lacey reported that the direction of cardiovascular response was telling of a subject's intention (e.g., approach versus avoid/withdrawal) towards external stimuli. Through directional reactions, the cardiovascular system serves to meet the varying metabolic demands of the body. Cardiac decelerations in response to arousing stimuli were thought to reflect stimulus detection and active intake from the environment, while cardiac accelerations were thought to reflect active mental work, an internal focus, and the active filtering of irrelevant external stimuli.

The application of spectral analytic techniques to the study of both intra- and inter-individual differences in heart rate variability has allowed for more precise interpretations regarding the autonomic origins of these differences. Using power spectral analysis, heart rate signals are decomposed into a series of component frequencies, with each component contributing to the total variance in the signal. The distribution of the total variance across the frequency range studied is associated with particular sources of the heart rate variability and the related parasympathetic and sympathetic nervous system mediators (Akselrod et al., 1981, 1985). In adults, the majority of heart rate variability is contained within the frequency range of 0.0 Hz to 0.5 Hz, with the components ranging from 0.15 Hz to 0.5 Hz being referred to as high frequency (HF) and the components ranging from 0.04 Hz to 0.15 Hz being referred to as low frequency (LF). The HF band marks the component of heart rate variability associated with respiration or RSA (Hirsch & Bishop, 1981).

However, developmental changes in respiratory rate will affect the boundaries of this band. The influences of respiration on heart rate variability are mediated primarily by changes in parasympathetic control over the heart via the vagus nerve (Katona & Jih, 1975). Porges (1986) developed an algorithm to index cardiac vagal tone – a measure of heart rate variability due to respiration. Porges' work was based on early theoretical work of Eppinger and Hess (1915) on vagotonia and how the balance in sympathetic and parasympathetic tone was related to clinical phenomena and the empirical work of Katona and Jih (1975) some six decades later providing anatomical and functional evidence to this end in animals. The cardiac vagal tone metric is derived from spectral power in the HF band as a measure of the magnitude of Respiratory Sinus Arrhythmia, which in turn has been used as an index of vagal control over the heart. However, the predictive relations between RSA and cardiac vagal control are reduced by nonrespiratory parasympathetic contributions to heart rate variability and within-subject changes in respiratory parameters, making RSA an imperfect estimate of vagal cardiac control (see Berntson et al., 1997, for a review). Despite these limitations, RSA remains among the most selective noninvasive indices of parasympathetic cardiac control (Berntson, Cacioppo, & Quigley, 1993).

The neural origins of LF variability are more diffuse, being mediated by both the parasympathetic and sympathetic branches of the autonomic nervous system. Low frequency power varies with sympathetic control, but only under limited and very specific conditions (see Berntson et al., 1997 for a review). Measures of the LF/HF ratio have been used to index the balance between sympathetic and vagal cardiac control (e.g., Malliani et al., 1994). However, for several reasons including the fact that the PNS and SNS are not always reciprocally controlled, this method of estimating sympathovagal balance remains controversial (Berntson et al., 1997). Further, measurement of LF power requires HP data to be collected over a period of several minutes, with minimal motor movement and regular respiration (Snidman et al., 1995). These constraints are particularly challenging to overcome in work with infants and young children.

Sympathetic cardiac control has also been evaluated by measuring the duration of pre-ejection period (PEP); (Cacioppo et al., 1994). PEP is the period over which the left ventricle generates force, or the interval from the onset of ventricular depolarization to the beginning of ejection, and is inversely related to sympathetic inotropy (Binkley & Boudoulas, 1986). Systolic time intervals such as PEP can be derived from information provided by impedance cardiography, or from a combination of concurrent electrocardiographic, phonocardiographic, and pulse measurements. Although clearly more challenging to assess in children, PEP measures have recently been incorporated into studies of individual differences in young children (e.g., Buss et al., 2004).

In summary, advances in measurement techniques provide researchers with a means for empirically evaluating the specific relations between parasympathetic and sympathetic influences and a variety of cognitive, emotional, and behavioral measures (e.g., Mezzacappa et al., 1997). Due to the relative ease of isolating the parasympathetic influences on cardiac control, there have been more empirical studies relating psychological indices to vagal influences over the heart. Methods for non-invasively estimating sympathetic influences over the heart continue to be refined, however, as of yet there is no agreed upon measure (Berntson et al., 1997). Further, pragmatic constraints limit the extent to which methods for assessing sympathetic cardiac control can be applied to studies of infants and young children.

Cardiovascular psychophysiology is based, in part, on the premise that both the direction and magnitude of cardiovascular responses, are sensitive to stimulus characteristics and reflect not only the intensity of one's reaction but the intention as well. Cardiovascular measures can also serve as markers of individual differences in these reaction tendencies. The demonstration and articulation of these properties of the cardiovascular response system has triggered growing interest by developmental psychologists in cardiovascular development and in the development of ANS/CNS integration. As well, developmental psychologists have used cardiovascular measures and psychophysiological paradigms to index perceptual and cognitive processing abilities and risk status in preverbal infants. Finally, a good deal of developmental work has been completed on cardiovascular markers of individual differences in response tendencies in both cognitive and social domains.

SOCIAL, COGNITIVE, AND PSYCHOLOGICAL CONTEXTS

EEG and cognitive development: The case of the frontal lobes

There is a good deal of interest in the study of relations between maturation of specific brain areas and the development of cognitive processes (Bell & Fox, 1994; Diamond & Goldman-Rakic, 1989; Fox & Bell, 1990; Thatcher, 1994). One brain area that has held interest for both those interested in individual differences and those interested in cognitive-brain relations is the frontal region. The dorsolateral area of the frontal region is known to play a critical role in processes associated with working memory. Goldman-Rakic (Goldman-Rakic, 1987a, 1987b; Goldman-Rakic et al., 1983) and Diamond (Diamond & Goldman-Rakic, 1983, 1986, 1989; Diamond, Zola-Morgan, & Squire, 1989) have demonstrated how maturation of this area is critical in the performance of certain cognitive tasks which develop in the first and second years of life in the human infant. Diamond and colleagues (Diamond et al., 1997) have shown how variations in infant

diet could affect infants with PKU and ultimately compromise their frontal functioning. There is, in addition, a good deal of speculation on the role that the frontal lobes might play in inhibition, planning, and executive function behaviors (Chelune et al., 1986; Dennis, 1991; Welsh, Pennington, & Groisser, 1991). The frontal cortex is also directly involved in multiple behavioral components associated with emotion such as the motor facilitation of emotion expression, the organization and integration of cognitive processes underlying emotion, and the ability to regulate emotions (Dawson, 1994; Fox, 1994).

Although a large corpus of evidence exists on EEG frequency development in posterior regions as noted earlier, there has been little research directed towards frontal EEG development. Much of the hesitation in examining frontal EEG involved the belief that the frontal lobes did not develop until later childhood. Neuro-imaging studies, however, suggest otherwise. Chugani and Phelps (1986) found an increase in glucose metabolism in the frontal cortex in human infants between 8 and 12 months, providing evidence for changes in frontal activity during the first year of life.

Developmental research with non-clinical populations utilizing measures of brain electrical activity (whether via EEG or ERP) has examined changes in frontal lobe activity over the first years of life (c.f. Bell & Fox, 1994, 1996). There are also studies that have utilized measures of EEG or ERP as dependent variables examining frontal response as a function of cognitive challenge (Nelson, 1994). As well, there are studies that have attempted to link these measures to known developmental changes in specific brain structures and the behaviors which purportedly are subsumed by those structures.

An example of this work may be found in the intersection of the work of Diamond and Goldman-Rakic (1989) and Bell and Fox (1992, 1994). Diamond and Goldman-Rakic utilized infant non-human primates and were able to show by ablation of specific regions of frontal cortex that performance on paradigms such as the delayed response task or Piaget's A not B task both involved maturation and integrity of the dorsolateral frontal cortex. Bell and Fox (1992) followed up to this work, recording EEG monthly from infants aged 6 to 12 months. At each session, infants were assessed on the A not B task. Bell and Fox (1992) found a correlation between EEG recorded over the frontal region and performance on the A not B task in human infants. Bell and Fox suggested that the EEG recordings reflected activity generated from the dorsolateral frontal cortex. Such studies are suggestive of the manner in which EEG may inform knowledge of cognitive development.

Fox and his colleagues (Fox & Bell, 1990; Fox et al., 1992) explored frontal lobe maturation during the latter half of the first year of post-natal life using frontal EEG frequency measures. EEG was recorded from left and right frontal, parietal, and occipital scalp locations monthly in a group of 13 healthy full-term infants from 7 until 12 months of age. A measure of relative power for each region

using 6 Hz to 9 Hz/1 Hz to -4 Hz at each age was computed. The data revealed an increase in 6 Hz to 9 Hz power in the frontal region over age suggesting an increase in EEG power for the frontal region in the second half of the first year of life. These EEG data, in combination with the neuro-imaging findings mentioned earlier, suggest that the frontal lobes are active and developing during the latter half of the first year of postnatal life. Changes in EEG power in the frontal region during the latter half of the first year of postnatal life might reflect frontal lobe maturation.

Bell and Fox (1994) also examined EEG coherence values between anterior and posterior electrode locations in the same sample reported above. They found stronger coherence between the frontal and occipital sites across age compared with the frontal and parietal sites (see Bell & Fox, 1994). This pattern of long versus short distance coherence suggests the maturation of anterior and posterior connections over the second half of the first year of postnatal life which are necessary for the sequencing of complex behavior (Pribram, 1973).

Frontal EEG activation and the development of emotions

Based upon a series of studies completed with adults that indicated that the frontal region was involved in certain aspects of emotional behavior (Davidson, 1984a, 1984b), Fox and Davidson completed a series of papers in which they examined the relation between EEG asymmetry and the expression of emotion in human infants. Their first study (Davidson & Fox, 1982) investigated EEG in ten-month-old infants who viewed a videotape of an actress while the actress was smiling or crying. Davidson and Fox (1982) found, in two independent studies, that infants exhibited greater relative left frontal EEG activity when viewing the smiling face compared to when they viewed the crying face. Fox and Davidson (1984) interpreted these results as suggesting that the frontal region was specialized for the control of the expression of behaviors involved in approach and withdrawal. Emotions were one class of behaviors and that could be parsed into those associated with approach (such as joy or interest) or withdrawal (disgust, fear, distress) (see Fox, 1991).

In a subsequent test of this model, Fox and Davidson presented one- and two-day-old infants with different liquid tastes (sugar water, citric acid, and plain water) (Fox & Davidson, 1986a). They recorded EEG in response to the presentation of the tastes and found differences in asymmetry along the approach-withdrawal dimension. Further studies with ten-month-old infants who were responding to the approach of an unfamiliar adult (Fox & Davidson, 1987) or maternal separation (Fox & Davidson, 1988) confirmed the role of behaviors associated with either approach or withdrawal as being associated with left or right frontal EEG asymmetry. More recent studies on the issue of frontal EEG activity and the development of emotion have used other sensory modalities to induce emotion

and examine corresponding changes in physiology. The auditory modality is one such example to which we now turn.

Studies of musical/auditory emotions. Santesso, Schmidt, and Trainor (2006b) recently examined infants' psychophysiological responses to emotional infant direct (ID) speech and music. Although behavioral studies suggest that ID speech elicits appropriate emotional responses in infants (Fernald, 1993; Santesso, et al., 2006b) were interested in whether infants could differentiate the emotional content of ID speech using regional continuous EEG measures.

Nine-month-old infants were presented with pre-recorded samples of mothers saying, "Hey honey, come over here," that varied in both emotional intensity (e.g., intense versus calm) and valence (e.g., pleasant versus unpleasant). For example, comforting (low intensity, positive valence), surprised (high intensity, positive valence), and fearful (high intensity, negative valence) voices were used and presented while infants' regional EEG and heart rate measures were continuously recorded. Santesso et al. (2006b) found that the emotional intensity of the ID speech was directly related to the overall frontal EEG power, such that greater power was related to greater emotional intensity. The fearful ID speech elicited the greatest absolute frontal EEG power, followed by the surprised and finally the comforting ID speech. These authors speculated that infants were responding to the *cognitive* aspects of ID speech, as increased EEG power during the first year of postnatal life is related to the cognitive/attentional properties of the stimuli (see Bell, 2002, for a review). Increasing the intensity of the ID speech (e.g., surprise/fearful ID speech) amplifies its emotional and attentional properties, thereby increasing the infants' external attention and interest. This corresponds to an increase in overall frontal EEG power (e.g., decreased activation). The comforting ID speech may encourage a decrease in EEG power (e.g., greater activation) and, therefore, more synchronous electrocortical activity, promoting emotional regulation. This interpretation was corroborated by the autonomic responses to the ID speech. Significant decelerations in heart rate were seen in response to both the positively and negatively valenced ID speech, which may signify either the infants' interest or their attentional engagement with speech stimuli. Thus, both central and autonomic measures suggest that infants are responding primarily to cognitive or attentional properties of ID speech, rather than emotional properties.

Similar to ID speech, ID music is a form of emotional communication between parents and infants. These musical registers facilitate both the creation of an emotional bond between parent and child, and the regulation of infants' emotional states (Rock, Trainor, & Addison, 1999; Trainor, 1996). As with ID speech, caregivers tend to make universal modifications to their singing directed toward infants (Rock, Trainor, & Addison, 1999; Trehub & Trainor, 1998; Trainor et al., 1997) that distinguish it from

adult-directed (AD) music (Trainor, 1996; Trehub, Unyk, & Trainor, 1993). Furthermore, infants are responsive to music, with innate (Masataka, 1999) preferences for ID to AD music (Trainor, 1996), and distinctive behavioral responses to the emotional content of the ID music (Rock, Trainor, & Addison, 1999). Although older children are able to extract emotional meaning and make emotional judgments about music (Scherer & Zentner, 2001; Trainor & Trehub, 1992), little is known about the basis for infants' reactions to musical emotions. Are infants' reactions based on the emotional quality of the songs, or are they rooted primarily in the attentional properties of the children's music, as appears to be the case with ID speech?

We (Hodgson-Minnie et al., 2006) next presented 9-month-old infants with 60-second excerpts of children's music varying in emotional valence and intensity while continuously recording their regional EEG and heart rate responses. The musical stimuli resembled either songs that infants would typically be exposed to in their natural environment (e.g., play-songs and lullabies) or unfamiliar, fearful music to which most infants of this age would not have been exposed. Infants, then, listened to three types of children's songs: familiar, joyful, play-song-like music (intense, pleasant emotion); fearful, unfamiliar style of children's music (intense, unpleasant emotion); and familiar, soothing, lullaby-like music (calm, pleasant emotion). It appears that the processing of children's musical emotions may tap into right frontal processes, rather than recruiting the differential left and right hemispheric activities noted with other stimulus modalities at this age and with older children and adults (e.g., Davidson, 1984, 1992, 2000; Fox, 1991, 1994). Greater relative right frontal EEG activity (e.g., less frontal EEG power) resulted from the presentation of both positively- and negatively-valenced children's musical emotions. Although this finding coincides with the idea that the right hemisphere dominates the processing of emotion (e.g., Heller, 1993; Gainotti, Caltagirone, & Zoccolotti, 1993), it is also important to note that the emotional prosody contained in the children's music is a salient feature for infants, and its detection has been linked to increased right hemispheric activity (Buchanan et al., 2000; Pihan, Altenmuller, & Ackermann, 1997). Perhaps infants of this age are focusing exclusively on the prosodic features of the children's music, resulting in a right hemispheric bias. In contrast to earlier findings with ID speech (Santesso et al., 2006b), overall frontal EEG power was linearly related to the affective *valence* of the children's music, such that greater relative EEG power corresponded to increases in the *positive* valence of the music. Again, the pattern of overall EEG power may reflect the cognitive aspects of emotion (Bell, 2002). For example, infants tend to respond behaviorally to play-songs with increased external awareness and attention, whereas they respond to lullabies with a greater internal focus (Rock, Trainor, & Addison 1999). Similar to the surprised ID speech, joyful children's songs may result in greater EEG power (e.g., decreased activation) due to the attentional properties of the music that promote greater social interactions. In

contrast, the soothing, lullaby-like children's songs (resembling comforting ID speech) may promote emotional regulation through a decrease in overall frontal EEG power. One might expect the fearful children's music to encourage increased external attention and therefore greater frontal EEG power, as was seen with the fearful ID speech; however, in this case, this unfamiliar stimulus corresponded to the least relative frontal EEG power. Perhaps the fearful music activates more primitive, subconscious brain structures due to its negative quality. Conversely, perhaps the infants are unable to process the emotional quality of this unfamiliar, fearful music on a cognitive level due to their inexperience with this emotion in a musical context. Fear is one of the hardest emotions to express by music (Terwogt & van Grinsven, 1991) and is rarely included in children's songs. On the autonomic level, infants responded with heart rate decelerations to increasing attentional demands associated with the emotional stimuli. Infants' heart rate was inversely related to the intensity of the musical emotions, with more intense children's musical emotions (joyful, play-song-like and fearful music) eliciting heart rate decelerations, relative to the less intense stimuli (soothing, lullaby-like music). Infants exhibited a low heart rate in response to the intense, fearful stimulus, corresponding to external attention and interest (Berntson & Boysen, 1990), which would be required to assess any potential threats or dangers. Moreover, there was an association between the cognitive and autonomic attentional processes during the processing of the joyful and soothing children's music. Specifically, the joyful, play-song-like children's music promoted greater EEG power and heart rate decelerations, both of which are associated with external attention and emotional engagement. In contrast, soothing, lullaby-like music may promote self-regulation through the combination of heart rate accelerations associated with an internal attentional focus (Berntson & Boysen, 1990) and attenuated overall frontal EEG power. It appears that infants respond to the cognitive or attentional properties of the musical, auditory stimuli. However, both ID speech and ID music have relatively simplistic structural properties. It is unclear if this apparently attentional response would continue if the complexity of the music is increased to include orchestral, rather than ID, pieces.

Schmidt, Trainor, and Santesso (2003) addressed this question in a series of cross-sectional studies that examined infants' psychophysiological responses to orchestral music at 3, 6, 9, and 12 months of age. Infants were presented with a series of three 30-second orchestra excerpts varying in emotional valence and intensity (fear, sadness, and happy) while their regional EEG and heart rate responses were continuously recorded. With these increasingly complex pieces, infants were neither able to differentiate the valence nor the intensity of the emotional music on a psychophysiological level. However, clear developmental changes were observed in response to the emotion-laden orchestral music. First, while each excerpt served to increase overall brain activity in 3-month-old infants,

by 12 months of age, each of the affective pieces attenuated overall brain activity, perhaps exerting a "calming" influence and reflecting infants' interest and attention to the musical stimuli. Specifically, both frontal and parietal regions shifted from exhibiting a decrease in EEG power to an increase in EEG power in response to the orchestral pieces (collapsed across condition) with increasing age. The distribution of EEG activity also changed with age. The musical emotions exerted a more global influence during early development, resulting in equivalent measured EEG activation in frontal and parietal scalp regions at 3 and 6 months of age, and later shifted to a more localized effect on the frontal scalp region by 12 months of age. This change likely reflects the maturation of frontal lobe functioning. Finally, infants failed to show differential hemispheric responses to the music (collapsed across condition) until 12 months, at which time they displayed increased left hemispheric EEG activity (greater relative right hemispheric EEG power) in response to both the orchestral stimuli and baseline conditions. The authors believe that this pattern of hemispheric EEG asymmetry may reflect the development of emotional regulatory processes, involving the maturation of frontal lobe functioning between 9 and 12 months and the relative attenuation of frontal activity by 12 months. On an autonomic level, heart rate was attenuated in response to the music (collapsed across condition) early in development (e.g., at 3 and 6 months), perhaps reflecting interest in the novel musical stimuli. By 9 months, infants' heart rate accelerated in response to the music, suggesting an internal focus (Berntson & Boysen, 1990) and possibly the emergence of self-regulatory processes. By 12 months, however, there were no significant differences between resting and music conditions on heart rate, opening the possibility that either infants were able to self-regulate their emotional responses and arousal or that the orchestral music was too complex for them to extract any emotional significance. Unlike its structurally simpler musical counterparts, then, orchestral music was seemingly too complex for infants to process its emotional valence or intensity. It did, however, promote developmentally distinct psychophysiological reactions in infants across the first year of post-natal life, possibly reflecting the development of emotion regulatory processes crucial for successful social and emotional development.

FRONTAL EEG ACTIVATION AND THE DEVELOPMENT OF INDIVIDUAL DIFFERENCES IN TEMPERAMENT AND AFFECTIVE STYLE

Recent studies have shown that the pattern of resting frontal EEG alpha asymmetry reflects a predisposition to experience positive and negative emotion and is predictive of individual differences in affective style in healthy adults (see Davidson, 1993, 2000; Coan & Allen, 2004, for reviews) and children (Fox, 1991, 1994; Fox et al., 2001). Individuals who exhibit stable right frontal EEG asymmetry at

rest are easily distressed, fearful, and shy, whereas those who exhibit stable left frontal EEG asymmetry at rest are socially outgoing and extraverted.

Individual differences in approach/withdrawal. Both Davidson (1995; Wheeler, Davidson, & Tomarken, 1993) and Fox (1991) found that the pattern of resting or baseline frontal EEG asymmetry was itself a marker for the disposition of the subject to express affects associated with either approach or withdrawal. For example, Davidson and Fox (1989) reported that differences in tonic frontal EEG arousal predicted infants' emotional responses. Infants who displayed a pattern of greater relative right frontal EEG activation exhibited a shorter latency to cry to maternal separation at age 10 months compared with infants who display left frontal asymmetry. Together, these studies suggest that stable individual differences in frontal EEG (e.g., Fox et al., 1992) may reflect individual differences in temperamental characteristics of the individual. Additional work from Fox's laboratory with behaviorally inhibited toddlers and preschool children would seem to confirm this notion (Fox et al., 1995; Fox et al., 2001).

Studies of behaviorally inhibited and socially withdrawn children. Behavioral inhibition reflects a tendency to display fear and wariness in response to novel stimuli (Kagan, Reznick, & Snidman, 1987). Behaviorally inhibited children display long latencies to approach novel stimuli, exhibit a high frequency of negative affect, and remain in close proximity to their mothers in response to the presentation of novel stimuli. Children who display this pattern of behavior towards novel social stimuli have been characterized as shy and timid. In addition, children who remain inhibited during the first few years of life are at risk for anxiety disorders in later childhood (Hirshfeld et al., 1992).

Calkins et al. (1996) examined frontal lobe development in a group of infants selected at 4 months of age for temperamental constellations thought to predict behavioral inhibition and shyness in early childhood. Eighty-one healthy infants were selected at 4 months of age from a larger sample of 207 using procedures similar to those reported by Kagan and Snidman (1991). Infants were observed in their homes at 4 months of age and videotaped as they responded to novel auditory and visual stimuli. The 81 infants were selected based upon their frequency of motor activity, and degree of positive and negative affect displayed in response to these novel stimuli. Three groups were formed on the basis of the infant's behavior at 4 months of age. The Negative group comprised infants who responded to the stimuli with high motor activity, high negative affect, and low positive affect. Kagan and Snidman (1991) found that this temperamental group of infants was behaviorally inhibited at 14 months of age. The Positive group comprised infants who responded with both high amounts of motor activity and positive affect, but low amounts of negative affect. A third group of infants, referred to as the Low responders, were characterized by

their low levels activity, including motor activity and both positive and negative affect.

The infants were seen again in the laboratory at 9, 14, and 24 months, at which time EEG was recorded. At 14 months, each infant was observed interacting during a freeplay situation, and with a series of unfamiliar stimuli designed to elicit his or her response to novelty. The data revealed that infants who were easily distressed to novelty at 4 months of age exhibited greater relative right frontal EEG activation at 9 months as well as at 24 months compared with infants in the other two groups. These same infants displayed a greater number of behaviors reflecting inhibition at both 14 and 24 months of age compared to infants in either of the two other groups. It is also important to note that infants who displayed a pattern of stable right frontal EEG activity across the first two years of postnatal life tended to be more inhibited at both 14 and 24 months compared with infants who exhibited a pattern of stable left frontal EEG during this time (Fox, Calkins, & Bell, 1994).

These data suggest that greater activity in the right versus left frontal region may serve as a marker for infants' temperamental wariness in response to novelty. Infants who display a pattern of greater relative right frontal EEG activation appear less able to successfully regulate the arousal of negative affect, perhaps serving as a marker of subsequent behavioral inhibition in toddlers.

This pattern of frontal EEG asymmetry and inhibition is critical for understanding the development of social withdrawal in the school years. The preschool years coincide with the development of social skills and peer interactions, both of which are determinants of the child's subsequent social development. Children who are shy and socially reticent often fail to develop such skills, and as a result are at risk for social withdrawal, social anxiety, and internalizing problems during the early school years (Rubin, Stewart, & Coplan, 1995). Conversely, children who are aggressive and intrusive with other children often fail to develop social skills and peer relationships. This group of children may be at risk for externalizing problems during the early school years. The origins of both forms of maladaptive social behavior may be linked to emotion regulatory problems and frontal dysfunction.

In an attempt to examine this very issue, Fox et al. (1995) observed 48 4-year-old children during play in groups of four. These groups were comprised of children who were unfamiliar to one another, but of the same age and same sex. The play session consisted of five parts: (1) unstructured freeplay, (2) clean-up, (3) birthday speeches, (4) cooperation task, and (5) unstructured freeplay. The children were unobtrusively observed during this time and their social behaviors were subsequently coded for measures of social participation.

A composite measure of social reticence was computed from behaviors displayed during the play session. This composite included the following standardized measures: (1) proportion of anxious behavior, latency to first

spontaneous utterance, proportion of reticent behavior (unoccupied and onlooking behavior) during freeplay, (2) proportion of unoccupied behavior during cleanup and cooperation task, (3) the inverse of duration of speech episode, and the inverse of total time talking during the speech episode.

Each child was seen individually some two weeks after the group visit at which time EEG was recorded for 3 minutes while the child was seated and attending to a visual stimulus. The data revealed that children who displayed a high proportion of anxious behavior and wariness in response to their peers during the play session exhibited greater relative right frontal EEG activation that was a function of less power (more activation) in the right frontal site relative to the left frontal site compared with their more sociable and less anxious peers.

Measures of frontal EEG activation have also been used in conjunction with behavioral measures to help elucidate the underlying motivations for different social behaviors in young children. We recently examined patterns of frontal EEG activation in relation to different forms of nonsocial behavior in preschoolers during a play session with unfamiliar peers: social reticence and solitary-passive behavior (Henderson et al., 2004). In contrast to solitary-passive children who occupy themselves with exploratory and constructive activities such as drawing and working on puzzles while in the company of unfamiliar peers, reticent children remain visually focused and oriented toward other children, yet do not join them in their activities. Both reticent and solitary-passive children showed a pattern of resting right frontal EEG asymmetry, which suggests that these different forms of solitude may share a common withdrawal motivation. However, reticent children also showed a pattern of increased generalized EEG activation (or decreased alpha power) across the scalp. This pattern of activation is consistent with animal studies demonstrating that generalized cortical activation can reflect activity in the central nucleus of the amygdala (e.g., Kapp, Supple, & Whalen 1994).

Measures of frontal EEG activation have also been used to examine the regulation of children's social behaviors. Fox et al. (1996) examined the interactions between resting frontal EEG asymmetry and social behavior during peer play in the prediction of behavior problems in preschoolers. Highly sociable children who were right frontally activated at rest were more likely to exhibit externalizing problems compared with sociable children who were left frontal. In addition, shy children who displayed greater relative right frontal EEG activity were more likely to exhibit internalizing problems compared with shy children who displayed greater relative left frontal EEG activity at rest. These findings suggest that individual differences in frontal EEG activation may play an important role in the development of maladaptive social behavior during the preschool years. Children who display greater relative right frontal EEG activation may not have the competencies such as verbal mediation skills and analytic abilities –

thought to be subserved by the left frontal region – which are necessary to successfully regulate affective arousal. Children who display a pattern of right frontal EEG activation and extreme social reticence or sociability may be at risk for subsequent affective and behavioral problems. Indeed, frontal dysregulation has been implicated in conduct disorders by others (Moffit & Henry, 1989).

Theall-Honey and Schmidt (2006) recently reported that the frontal EEG asymmetry measure was related to the processing of emotion in shy preschoolers. Shy preschoolers who exhibited greater relatively right frontal EEG activity had problems regulating emotion, particularly negative emotion compared with their non-shy counterparts. When presented with affective video-clips that induced fear and sadness or when asked to give a speech about an embarrassing moment, shy children who exhibited greater relative right frontal EEG activity displayed more nonverbal signs of anxiety during the presentation of these stimuli compared with nonshy children or those exhibiting greater relative left frontal EEG activity.

Similarly, in older children, Schmidt et al. (1999) found that frontal EEG measures were related to the processing of social stress in older children who were shy. Seven-year-olds who were shy exhibited significantly greater increases in right, but not left, frontal EEG activity in anticipation of giving a speech about an embarrassing moment. The findings from these latter two studies demonstrate that the frontal EEG measures may be used to index, in addition to trait-like measures, state or phasic changes related to the processing and regulation of emotion in shy children.

Studies of shy and socially anxious adults. Individual differences in frontal EEG were also shown to predict affective style and personality in young adults. Adults who displayed a pattern of greater relative right frontal EEG activation are likely score high on psychometric measures indexing behavioral inhibition (Sutton & Davidson, 1997) and to rate film clips more negatively (Tomarken et al., 1990) than those individuals display greater relative left frontal EEG activation. As well, young adults who are shy (Schmidt, 1999) and unsocial in a dyadic social interaction (Schmidt & Fox, 1994) are more likely to exhibit greater relative right frontal EEG activity compared with sociable adults.

EEG and the development of behavior problems in older children and adults

Psychophysologists have long been interested in psychopathology. There is a long and rich history of research investigating the CNS responses via EEG and ERPs of clinical populations including patients diagnosed with schizophrenia, depression, and psychosis (Lahmeyer, Reynolds, Kupfer, & King, 1989; Miller & Lesser, 1988; Niznikiewicz et al., 1997; Pollock & Schneider, 1990; Pritchard, 1986). There have been also a number of studies of CNS responding with children who have been diagnosed

with specific psychiatric disorders such as hyperactivity, attention deficit disorder, and conduct disorder (e.g., Chelune et al., 1986; Raine & Venables, 1987; Raine, Venables, & Williams, 1990a). These studies have, by and large, attempted to outline the physiological mechanisms that are associated with the cognitive or affective deficits seen in these child clinical populations.

The use of resting frontal EEG measures and individual differences in the patterning of resting frontal EEG asymmetry can shed light on some behavioral problems in older children. For example, we (Santesso et al., 2006a) have most recently found a pattern of greater relative resting right frontal EEG activity at rest in a group of non-clinical 10-year-olds who were reported to have more CBCL aggression than those displaying greater relative left frontal EEG activity at rest.

Over the past ten years, there has been an increased interest in processes associated with the development of psychopathology in children, along with a re-thinking of the manner in which these issues ought to be approached. In particular, the questions arise as to the origins and factors which predispose some children to certain conditions, or the environmental factors which contribute to these conditions, and ultimately, to the nature of the interaction between dispositions and environments which may be the ultimate cause of certain types of psychopathology in children (Cicchetti, 1993). Researchers have recognized that certain forms of child psychopathology (particularly internalizing or externalizing disorders) do not arise de novo but rather are the end product of multiple factors including infant or child temperament, parenting style, and certain environmental correlates (e.g., Cicchetti & Richters, 1993). Such an approach is analogous to the interactionist model detailed above and necessitates for the psychophysiological an analysis at the level of individual differences in child or infant disposition and the effects of environments (or parenting) on these initial dispositions.

Studies of infants and children of depressed mothers. An example of this approach would be the work currently being completed on the effects of maternal depression on infant physiology and ultimately on child behavioral outcome. Recent studies have begun to examine the effects of maternal depression on infant physiology (Dawson et al., 1992; Field et al., 1995). It is widely known that adults who are depressed display less positive affect and more anxiousness compared to their nondepressed counterparts. Depressed adults are also known to exhibit reduced left frontal EEG activation (Henriques & Davidson, 1991) and greater right frontal EEG activation (Schaffer, Davidson, & Saron, 1983; Henriques & Davidson, 1990) than nondepressed adults. Women who are depressed are known to display less positive affect and reduced levels of stimulation when interacting with their infants (Cohn & Tronick, 1989; Cohn et al., 1986; Field, 1986; Field et al., 1988). Infants of depressed mothers display less positive affect and increased irritability (Cohn et al., 1986; Field, 1986,

Field et al., 1985) and greater frontal EEG activation than infants of nonsymptomatic mothers (Dawson et al., 1992). The findings reported by Dawson and her colleagues were with infants who ranged in age from 11–17 months. A similar pattern of frontal EEG asymmetry has recently been documented in infants as early as the first six months of life (Field et al., 1995).

Field et al. (1995) recorded baseline EEG in infants of depressed and nondepressed adolescent mothers. Infants ranged in age from 3 to 6 months. EEG was recorded during an alert state of attention. Infants of depressed mothers exhibited greater right frontal activation compared to infants of nondepressed mothers. Collectively, these studies suggest that maternal depression may affect infant physiology in the first two years of life. The fact that maternal depression affects brain electrical activity is consistent with an interactionist approach to development. It is also possible that the pattern of frontal EEG asymmetry in infants of depressed mothers may reflect a heritable component of the mothers' depression. There have been relatively few studies in which the genetic basis of EEG patterns has been examined. Further, it remains unknown whether these patterns of EEG asymmetry as observed in infancy remain stable over time (given certain types of parenting and environments) or whether they change, and whether children who as infants displayed these EEG patterns present with behavioral difficulties as they get older. The answers to these questions, however, will require longitudinal study, which operationalize and assess the interactive processes involved in development.

Studies of adults with depression, anxiety, and psychosis. A number of other studies have shown that the pattern of resting frontal EEG alpha (8 to 13 Hz) asymmetry is predictive of individual differences in affective style in some clinically depressed and anxious populations even when their symptoms are in remission. Individuals who exhibit stable patterns of greater relative right frontal EEG activity at rest are known to be at risk for depression (Henriques & Davidson, 1990, 1991) and anxiety-related disorders. Recent studies have also shown that adolescent females at familial risk for major depressive disorder (Miller et al., 2002) exhibit greater relative right frontal EEG activity at rest.

Still other studies have examined the relation between frontal EEG activity and affective style in populations characterized by clinical phenomena other than mood and anxiety disorders. For example, we (Jetha, Schmidt, & Goldberg, 2005) recently examined the pattern of resting frontal EEG alpha activity in relation to personality in a group of adults with major psychosis. Using recent frontal EEG activation/affective style models as a theoretical platform, we attempted to extend these findings to adults with schizophrenia. The relations among the pattern of resting (eyes open, eyes closed) regional EEG alpha activity and trait shyness and sociability were examined in 20 adults with schizophrenia (outpatients who attend a community-based treatment and rehabilitation center and

who were classified as having low positive and negative symptoms). Interestingly, we found the predicted relation between high trait shyness and greater relative resting right frontal EEG activity, and high trait sociability and greater relative resting left frontal EEG activity only in adults with schizophrenia whose positive symptoms of the disorder were reduced. In other words, once the symptoms of the disorder were controlled, then and only then, did the predicted relations emerge. This provides further evidence for the notion that the pattern of frontal EEG activity may reflect a basic property of personality even in the disordered brain.

Other issues: Psychometric considerations of the frontal EEG asymmetry metric

Inherent in the definition that the frontal EEG asymmetry metric is trait-like is the notion that it is stable across time and context. There is growing support for this idea in both adults and children. For example, Davidson and his group (Tomarken et al., 1992) have found modest to good stability across 3 months on frontal EEG asymmetry measures. We have recently noted modest to good stability of frontal EEG alpha activity in another context, across different stages of sleep in non-clinical young adults (Schmidt et al., 2003). We have also examined short-term stability (i.e., second-by-second stability) on frontal EEG asymmetry measures in 9 month-infants (Schmidt, 2006) and 7-year-old children (Schmidt, 1996) and found that stable patterns of greater relative right frontal EEG activity were related to individual differences in temperament. Taken together, the frontal EEG asymmetry metric is stable across time, situation, and development.

Cardiovascular measures and the study of cognitive development

Berg and Berg (1979) emphasized the utility of cardiovascular and other autonomic measures in the study of developmental psychology due to the fact that these systems are relatively well-developed at birth and during infancy relative to the limited behavioral repertoire of same-aged infants. For example, the heart begins to beat by the fourth week post-conception and with the development of central control mechanisms, the heart becomes responsive to state changes (e.g., Groome et al., 1997). By 30 weeks post-conception heart rate changes are reliably associated with changes in internal states, such as changes in sleep cycles.

As with adults, infants demonstrate directional cardiac responses to external stimuli. The direction of change is directly related to the development of neural control over the heart. In both humans and rats, Porges reports monotonic increases in the extent of vagal control over the heart across gestational age (e.g., Porges, McCabe, & Yongue, 1982; Porges, 1983). At birth, infants show reliable heart rate accelerations in response to stimulation (airstreams), however, by 2.5 months of age infants show consistent

heart rate decelerations in response to the same stimulus (Berg & Berg, 1979). Others have noted significant shifts in baseline levels of heart rate variability around 2 to 4 months of age (e.g., Attuel et al., 1986; Lewis et al., 1970). These shifts in baseline and reactive cardiac patterns may reflect a general physiological reorganization of the CNS reflecting increasing cortical control. By 3 to 4 months of age, infants show consistent heart rate decelerations in response to stimulation regardless of modality (i.e., visual, acoustic, and tactile stimuli). These decelerative responses are interpreted as reflecting infants' active processing of sensory events.

Infants do not simply respond indiscriminately to the environment, rather their orienting responses are sensitive to stimulus parameters. Even newborns show visual preferences for horizontal versus vertical gratings, curved versus straight contours, and novel versus repeated stimuli (Slater & Morison, 1991). These visual preferences are accompanied by larger and longer decelerative heart rate responses (e.g., Lewis et al., 1966; McCall & Kagan, 1967). The fact that infants can discriminate among such stimuli and that these discriminations are reflected in different patterns of heart rate change gave rise to important developments in experimental paradigms for work with infants. For example, the habituation/dishabituation paradigm (Graham & Clifton, 1966) provides a means for indexing fundamental cognitive processes such as attention, memory, and responsiveness to novelty, and continues to be used as an index of basic sensory capacities. Specifically, with repeated exposure to the same stimulus, behaviors (i.e., visual attention) and physiological responses (i.e., heart rate decelerations) become habituated, or less pronounced, reflecting an infant's waning attention. During dishabituation trials, a novel stimulus is presented and stimulus detection is marked by an increase in responding such as renewed visual attention or cardiac decelerations.

Differences in tonic and reactive cardiac responses can also serve as markers of individual differences in physical and/or cognitive status. For example, differences in parasympathetic tone have been related to levels of infant attentiveness and reactivity (Richards, 1987). Perinatal events (e.g., physical stress and recovery from maternal medication) have been reported to temporarily block the decelerative response (Adkinson & Berg, 1976) and more enduring conditions such as malnourishment have longer-term effects on cardiac reactivity (Lester, 1975). Thus, cardiovascular responses can serve as a means or apparatus for the study of development within particular domains of psychology including cognitive, sensory, and perceptual development, and in addition, as a means of assessing individual differences in the neurally mediated capacity to respond within these domains.

In order to serve as a marker of enduring individual differences, as opposed to simply differences in state, cardiac measures must show stability over time and over shifts in development and maturation (Porges, Doussard-Roosevelt, Portales, & Suess, 1994). Individual differences

in cardiovascular measures including heart period and heart rate variability show little stability from birth until at least 3 months of age (Fracasso et al., 1994; Snidman et al., 1995; Stifter & Fox, 1990). For example Stifter and Fox (1990) found little stability from birth to 5 months of age on measures of heart period, heart rate variance and vagal tone, but moderate stability from 5 to 14 months of age. Similarly, Fracasso et al. (1994) assessed vagal tone and mean heart period during baseline and following the presentation of emotion-eliciting stimuli at four time points between 5 and 13 months of age. These measures were significantly related at all ages, with the magnitude of the correlations increasing with age. With older children, Fox and Field (1989) reported moderate stability in vagal tone and heart rate variability across a six-month period in a sample of preschool-aged children. Longer-term stabilities, from infancy into early childhood, were reported for both heart period and vagal tone by Porges et al. (1994). From 9 months until 3 years of age, heart period and vagal tone increased across the entire group, but children maintained their rankings relative to the group across the same time interval. Porges et al. (1994) further reported that the stability of heart period and vagal tone was similar in magnitude to the stability of maternal reports of temperament over the same time period. Baseline measures of RSA also show a good deal of stability in later childhood. For example, El-Sheikh (2005) recently reported a moderate level of temporal stability in baseline RSA over a two year period in children between the ages of 9 and 11 years.

Cardiovascular measures as indices of risk status

Premature neonates demonstrate different patterns of both tonic and reactive cardiovascular activity compared to full-term newborns. For example, premature infants, both those who are healthy and those who are at greater risk due to various medical complications, tend to have higher heart rates (e.g., Krafchuk, Tronick, & Clifton, 1983) and greater heart rate variability compared to full-term infants. Premature infants also demonstrate markedly different patterns of cardiovascular responding to environmental stimuli compared to full-term infants. Rose, Schmidt, and Bridger (1976) reported that sleeping preterm infants exhibited depressed cardiac responses to various tactile stimuli in comparison to full-term infants. Further, Krafchuk, Tronick, and Clifton (1983) found that in comparison to full-term infants, high-risk premature infants showed slower and smaller magnitude cardiac changes in response to auditory stimuli and in response to a dishabituation trial in which the head end of the infant's basinet was raised 2–3 inches and then released. Once the high risk group reacted to the stimuli, particularly the dishabituation stimulus, however, they took longer to habituate their cardiac response. This mix of hypo- and hyper-responsiveness was interpreted as reflecting the relative immaturity of the CNS. This pattern of

reacting provides an infant with less control and flexibility with which to regulate his/her responses to the environment.

Global cardiac measures (i.e., heart period, heart period variability) have been used as a means for detecting gross dysfunction (i.e., severe brain damage versus all other infants) among neonates with a variety of clinical pathologies (e.g., Porges, 1983). Porges (1983) used vagal tone, thought to provide a more sensitive index of CNS functioning, to classify the same group of neonates along a continuum reflecting the severity of neuropathology. Higher vagal tone was associated with lower risk status. Higher vagal tone has also been associated with better cognitive outcomes by the end of the first year of life. For example, infants with higher vagal tone at birth had higher Bayley MDI scores at both 8 and 12 months compared to infants with lower vagal tone (Fox & Porges, 1985). Although children in the extremes of the distribution of vagal tone had consistent outcomes, there was not a perfect linear relationship. That is, not all children with low vagal tone performed poorly on the Bayley MDI. These findings raise the more general issue of how different patterns of early reactivity, as reflected in cardiovascular measures, affect, and are affected by, the nature of interactions with their surrounding environment, in particular, interactions with caregivers to promote development.

Cardiovascular measures and emotional development

In general, greater heart rate variability during the first year of life is associated with greater reactivity, both cardiovascular and behavioral, to environmental stimulation. These differences apply not only to sensory stimuli but to social stimuli which for young infants consists primarily of interactions with caregivers. Work by Fox (1989) suggests that these differences in global reactivity are associated with differences in self-regulation and the development of particular social behaviors.

In infants, differences in heart period variability have been associated with differences in facial expressivity. Specifically, 3-month-old infants with greater heart rate variability displayed longer duration interest expressions during face-to-face interactions with their mothers (Fox & Gelles, 1984). Stifter and Fox (1990) found that at five months of age, infants with greater heart rate variability displayed more negative expressions in response to an arm-restraint procedure used to elicit distress or anger in the laboratory. Stifter, Fox, and Porges (1989) further reported that 5 month olds with higher levels of heart rate variability expressed a greater number of positive emotional expressions especially in response to an approaching stranger. Thus, heart rate variability appears to be related to global reactivity or responsivity (both positive and negative) in early infancy.

Heart rate variability is also associated with infants' capacities to flexibly regulate their own reactions. Infants

with greater heart rate variability at birth displayed more self-regulatory behaviors in response to an arm-restraint procedure at 5 months of age (Fox, 1989). Behaviors such as looks to mother, looks at self in the mirror, arm and leg thrusts, and vocalizations were coded as self-regulatory. Heart rate variability is likely related to self-regulatory behaviors via the common relations with infants' capacities to flexibly implement strategies for managing interactions with the environment. By the second year of life, differences in reactivity and regulation are apparent in children's behaviors in social contexts. At 14 months of age, children with high vagal tone approached an adult stranger more readily and spent less time in close proximity to mother during a laboratory visit. Vagal tone measured at 14 months of age related to the same infants' reactions and use of self-regulatory behaviors during their 5-month visit. Specifically, children with high vagal tone at 14 months of age expressed more negative affect during the 5 month visit and were more likely to have cried during the arm restraint procedure at 5 months, in comparison to children with low vagal tone.

Cardiovascular measures, as assessed during infancy, have concurrent relations to temperament and also predictive relations to temperament at later ages. For example, Porges, Doussard-Roosevelt, Portales, and Suess (1994) found that high vagal tone was related to maternal reports of difficult temperament at 9 months of age. Interestingly, while there were no concurrent relations between vagal tone and temperament ratings at the 3-year assessment, higher vagal tone as assessed at 9 months of age was predictive of maternal reports of less difficult temperament when the same children were 3 years old. Nine month vagal tone predicted 3-year temperament reports over-and-above, or independent of, the relations between 9-month and 3-year temperament reports. This apparent switch in the direction of relation between vagal tone and temperament is probably best explained by considering the influences of early temperament on infants' interactions with their environment and particularly their interactions with caregivers. High vagal tone during early infancy appears to be associated with greater global reactivity, which is likely interpreted by caregivers as "difficult." Vagal tone, however, is also related to infants' abilities to self-regulate their reactions. Thus, the capacity to self-regulate at 3 years of age is likely interpreted by caregivers as reflecting a relatively easy temperament. It may be that infants who are reactive to their environments from birth, in a sense, create more opportunities for learning how to flexibly regulate their own arousal. Reactivity likely leads to more contact with caregivers, leading to more socialization experiences surrounding issues of regulating reactivity. In contrast, less reactive infants may have fewer learning experiences surrounding issues of self-regulation. However, hypotheses regarding the ways in which reactivity, regulation, and socialization experiences interact to promote development have yet to be empirically examined.

Cardiovascular measures and the development of behavior problems in older children and adolescents

Individual differences in the tonic level of activation and in the degree of reactivity of the ANS have been related to the development of specific behavior problems. There have been mixed results relating tonic levels of autonomic activity to behavior problems. For example, in a prospective study of criminal behavior, Raine, Venables, and Williams (1990a) found that lower resting heart rate and fewer non-specific skin conductance responses as assessed in a sample of 15-year-old boys were associated with an increased likelihood of criminal behavior at 24 years of age. These findings suggest that ANS underarousal may be associated with, and perhaps even causally, criminal behavior. This global pattern of underarousal may lead individuals to seek out stimulation, for example, by engaging in anti-social or criminal behaviors. In the studies by Raine and his colleagues, ANS underarousal has been hypothesized to be attributable to both reduced sympathetic modulation (Raine et al., 1990a, 1990b) and enhanced vagal modulation (Raine & Jones, 1987; Raine & Venables, 1984). In contrast, however, Zahn and Kruesi (1993) concluded that there were no consistent differences in tonic levels of arousal or generalized ANS activity between boys with behavior disorders and their same-aged peers. Indeed, in a recent review of studies Raine (1993) reported on the inconsistencies of the findings relating global underarousal to antisocial behaviors.

Using spectral analytic techniques, Mezzacappa et al. (1997) more directly examined the relations between adolescent boys' self-reports of antisocial behavior and autonomic regulatory influences over the heart. Mezzacappa et al. (1997) analyzed the transfer of respiratory variability to heart rate variability. This transfer can essentially be thought of as the heart rate response to quantified changes in respiration, with individual differences in the transfer dynamics implying differences in the central processing of cardiorespiratory interactions. Using this logic, the findings indicated that the central processing of respiratory-heart rate relations was disrupted in antisocial individuals, which would support the literature relating parasympathetic control to the integrity of regulatory processes (Porges, Doussard-Roosevelt, & Maiti, 1994).

In addition to tonic levels of autonomic arousal, anti-social behaviors have been related to unique patterns of autonomic reactions to various environmental stimuli. Autonomic reactivity has been related to the development of behavior problems through their common relations to orienting responses and orienting deficits. Cardiovascular reactivity can serve as an index of the orienting reflex which assesses the extent to which a subject attends to and processes an eliciting stimulus. Raine et al. (1990b) found that criminal behavior at 24 years of age was predicted by hyporeactive heart rate responses to auditory stimuli as

assessed at 15 years of age. This pattern of hyporesponsivity was predictive of criminal behavior over-and-above the predictive effects of tonic heart rate, suggesting that the response deficit was not simply a function of lower overall physiological arousal, and that the deficit may be a risk factor for later criminal behavior.

Raine and his colleagues have recently expanded their work to explore patterns of psychophysiological responding which may serve to protect antisocial adolescents from continuing on to commit crimes in early adulthood. Specifically, they hypothesized that adolescents who engage in antisocial behaviors but who do not go on to commit crimes in adulthood, may have distinctly "hyper-reactive" patterns of physiological responding in comparison to both normals and those antisocial adolescents who go on to commit crimes in early adulthood (Raine, Venables, & Williams, 1995). Such a model goes against previous theories in which "adolescent-limited" antisocial individuals are seen as falling between their more resistant antisocial peers and their normal peers on a continuum of antisocial behavior. Indeed, Raine, Venables, and Williams (1995) reported that adolescent-limited antisocial individuals had higher resting heart rates and greater electrodermal orienting responses compared to their resistant antisocial peers. Raine, Venables, and Williams (1995) further reported that the adolescent-limited antisocial individuals had higher heart rates and greater electrodermal orienting responses compared to a sample of normal adolescents, however, these differences did not reach statistical significance. It is, therefore, difficult to deduce whether this pattern of greater autonomic arousal indeed reflects a unique protective mechanism against committing crime, or whether the adolescent-limited antisocial individuals simply respond autonomically like their non-antisocial peers. Regardless, the work of Raine and his colleagues, highlight the relation between both tonic and reactive patterns of autonomic responding and antisocial behaviors.

The direction of heart rate change in response to environmental stimuli has further been interpreted in the context of social information processing. Cardiac decelerations, as in work with infants, are interpreted as reflecting the active intake of information from the environment. This style of responding may serve as a marker of other-oriented-focused attention such as the experiences of empathy and sympathy. In contrast, cardiac accelerations are interpreted as reflecting the rejection of environmental inputs and may serve as a marker of a person's attempt to actively cope with personal distress or anxiety (e.g., Zahn-Waxler et al., 1995). For example, preschoolers who responded with cardiac decelerations to a videotape designed to induce sadness, were observed displaying more prosocial behavior and greater empathic concern in response to others' distress compared to children who responded with little or no cardiac deceleration. In contrast, children with lower tonic heart rates while viewing the sadness induction tape were observed demon-

strating more avoidance and joy reactions during others' distress.

In contrast to the findings linking cardiac hypo-activation to conduct problems, cardiac hyper-activation, may be related to behavior problems of an internalizing nature. Children who expressed few emotions while viewing a mood induction tape were found to have higher, more stable heart rates, lower vagal tone and to display less change in heart rate from baseline to the mood induction tape (Cole et al., 1996). This pattern of cardiovascular responding was interpreted as reflecting a resistance to external input and an increased focus on internal state. This pattern of high, stable heart rate is similar to that reported by Kagan and his colleagues relating cardiovascular measures to behavioral inhibition in children (e.g., Kagan, Reznick, & Snidman, 1987, 1988). In an examination of the changes in the frequency components of heart rate variability during cognitive challenge, Kagan, Reznick, and Snidman (1987, 1988) found that behaviorally inhibited children displayed greater shifts in the distribution of heart rate variability towards the LF band of the distribution. Kagan and colleagues interpreted this shift as reflecting an increase in sympathetic influences over the heart during the cognitive challenge. In a more direct examination of the associations between anxiety and sympathetic cardiac influences, Mezzacappa et al. (1997) used the change in LF heart rate variability with postural manipulations (supine to standing) as an indicator of sympathetic cardiac influences on heart rate. Sympathetic influences were positively correlated with adolescent boys' self-reports of anxiety.

INFERENTIAL CONTEXT: METHODOLOGICAL ISSUES IN THE PSYCHOPHYSIOLOGICAL STUDY OF INFANTS AND CHILDREN

There are obvious methodological issues involved in the recording of EEG, ERPs, or ECG in adult populations. These have been discussed in detail elsewhere, and there are published recommendations regarding standards of methods for each measure (Berntson et al., 1997; Pivik et al., 1993; Task Force, 1996). Additionally, there are unique methodological problems when using these measures with infants and young children. These include movement and muscle artifact, placement of electrodes, state changes of the infant or young child, definition of a "baseline" and the need to link physiology to behavioral response. It should be noted that these methodological issues are not specific to either EEG, ERPs, or ECG response acquisition but are common to the recording of all psychophysiological responses.

Movement and muscle artifact. Obviously, one cannot instruct infants or young children to sit still so as to record resting levels of physiology. As well, when presenting either auditory or visual stimuli it is not possible with infants

or young children to issue instructions to pay attention to the stimulus or not to move. Therefore, recording of either autonomic or brain electrical activity is fraught with the possibility of confounding with unwarranted movement artifact. Researchers have attempted to design studies, which capture the young subject's attention for long enough periods of time so as to provide data for analysis. Further, developmental psychophysicists have usually designed systems, which allow them the ability and flexibility to edit their physiological records for period of artifact. Nevertheless, the problem is a critical one for investigators wishing to study these populations. Studies, which do not report how they edited or artifact scored data or which do not report the ratio of artifact rejected to "good" data may be including points which are unwarranted.

Electrode placement. Prior to the advent of neuroimaging techniques such as MRI, the placement of electrodes was accomplished by the examination of brain geometry and topography via autopsy, and these findings were generalized to create a set of standard placement sites (Jasper, 1958). Jasper mapped what became accepted as an international set of placements of 20 electrodes over the scalp reflecting the major cortical divisions as well as the various sulci of the cortex. Unique sets of problems arise in the application of the 10–20 system for use with infants and young children. In the Jasper system, the placement of electrodes relies on a ratio of distances between anterior and posterior sites. It is unclear whether this same ratio exists across development or whether different regions of the brain mature, physically, at different rates, leading to differences in the relation between anterior to posterior growth. A number of researchers (e.g., Myslobodsky et al., 1990) have examined this problem, primarily again through autopsy, and have found that the 10–20 system does an adequate job in defining placement of electrodes across key cortical regions. With the advent of MRI, a number of studies have begun to examine the accuracy of electrode placement with respect to actual physical landmarks of cortical topography (Lagerlund et al., 1993). Overall, these studies have found that by and large the 10–20 system does a good job in defining the location of electrodes over significant cortical landmarks in adult populations. Less is known, however, about the adequacy of this system for use with infants and children. The issue of electrode placement is becoming less of a problem with the recent advent of dense arrays of EEG electrodes on some caps that include 128 and 256 sites.

State change. A third methodological issue involves the need to attend to the state of the subject, particularly when subjects are infants or young children. Again, it is not possible to issue instructions regarding level of attention to a task to these populations, nor is it always possible to time laboratory visits so that they are optimal for the level of attention that is necessary for the task. These issues are particularly salient for infants whose ability to main-

tain a particular state of attention may be fragile. Often researchers working with infants will time their assessments with the sleep wake and eating cycle of the child. Subjects are often seen prior to a feeding when they are awake and alert – or after a feeding and a sleep cycle. Aside from concern regarding the timing of the assessment, it is incumbent upon the researcher to monitor behavioral state so as to insure that the physiological responses that are recorded across subjects are done so consistently from the identical state.

Definition of a baseline. Very often psychophysicists are interested in the change in response of a measure from a "resting baseline" to some other state, which has been elicited as a function of cognitive or affective challenge. Or, researchers are interested in individual differences in the level of resting state of a group of individuals (for measures of EEG, blood pressure, or heart rate). In all instances, the assumption underlying measurement of a resting baseline or a pre-challenge condition is that subjects are all in the same affective and cognitive state. While it is not always clear that this assumption is being met with adult populations, it is even more difficult with infant and child populations. It is sometimes impossible to instruct subjects to remain in a particular state for a period of time. As well, state variability is great for very young infants. Researchers have met this challenge by presenting infants with certain types of stimuli which have a general appeal and create conditions of quiet attention across large groups of subjects. So, for example, Fox and colleagues present infants with a rotating bingo wheel which contains multi-colored bingo balls. This display captivates most infants' attention and EEG can be collected during these times as it remains relatively artifact free from movement. This event and the state it elicits from infants is one of focused attention, however, and is obviously different from the "resting baseline" collected in some adult studies. State control and equivalence of baseline are thus critical issues as you go up the developmental ladder.

Linking physiological responses to behavior. Monitoring behavior during the experiment leads to an additional critical methodological issue for studies with infant and young child populations. In the absence of self-report, it is necessary that infant or young child psychophysiological responses be anchored to behavior. If the researcher does not have this anchor, it will be difficult to interpret the physiological response that is being recorded. For example, in studies of infant face discrimination Nelson and his colleagues (e.g., Nelson & Collins, 1992) routinely test infants in behavioral paradigms to insure that they are able to make the types of discriminations that are being presented in the ERP study. The coordination of behavioral testing and ERP testing lends support to any interpretation these workers may have about neural processing of face discrimination. Fox (Fox, 1994; Fox & Davidson, 1986b) has argued that inference about physiological correlates

of emotion response should only be made in the presence of observable behavioral measures such as facial or vocal expressions. In his work, there is a link between report of EEG activity during the expression of certain emotions and behavioral signs of these emotions. Obviously, as children develop and are able to provide self-report measures or appropriate motor responses these should be utilized in linking physiology to behavior. In general, however, physiological reactivity should be reported in infants or young children only in the presence of observable behavioral response.

Signal localization. Aside from these unique methodological issues, recording EEG and ERPs from infants and young children poses additional issues to researchers interested in the localization of these signals. These issues are, in some sense, above the very real concerns about localization that researchers have for the signals as recorded in adults. The morphological changes, which occur over development during the first years of postnatal life may influence the localization of the electrical activity emanating from the brain. These changes include myelination of certain brain areas as well as dendritic arborization (Greenough et al., 1987; Greenough & Volkmar, 1973). The little we know about neural development compounds the problem of accurate localization of source activity in the young infant. In addition, the fontanelle does not close in most infants until the second half of the first year of postnatal life. The fontanelle may in fact create an electrical "sink hole" around which there would be current flow. This might change the nature of the signals that are being transduced off the scalp. The use of today's systems and EEG caps with more dense array of electrodes to record brain electrical activity now permit current source density mapping to localize signals.

THOUGHTS ON THE STUDY OF DEVELOPMENTAL PSYCHOPHYSIOLOGY

Psychophysiology has lagged behind other branches of psychology in integrating knowledge of developmental processes into its approach to research. A survey of papers or posters presented over the past ten years at Psychophysiology conferences finds only a handful of presentations in which children are studied and fewer yet in which developmental questions are asked. Too often, when infants or children are studied, their responses are treated similarly to adult data. These populations have often been approached as if they are "little adults" and the measurements and interpretations of their responses are viewed against the background of group differences (infant, child, adult) attributed to "age." To some extent the lack of interest in developmental processes is changing within the Psychophysiological community. There is increased interest within cognitive neuroscience in the development of processes, such as memory or attention, which have been studied intensively within Psychophysiology. This renewed

interest is coupled at a time with improved technology, which makes the psychophysiological study of developmental populations more accessible.

Through the integration of research in the areas of developmental psychology and psychophysiology, advances have been made in understanding the structural and functional developments of the autonomic and central nervous systems in infancy and childhood. Substantial progress has been made towards unraveling the intricate processes underlying development in these systems, and the relations these developments have to changes in cognition and behavior during childhood. The fact that children and adults differ in the organization of physiological systems, highlights the need to investigate the development of these systems in detail. As these systems become better understood, as they exist and develop in children, they contribute both conceptually and methodologically to our understanding of the development of basic psychological processes including cognition, perception, and emotion. Further, stable individual differences in the activity and reactivity of these systems provide insight into the basic processes involved in the development of both normal and problem behaviors.

21 Interoception

BARRY R. DWORKIN

The focus of this chapter is the basic physiological properties of those sensory receptors that monitor the internal state of the body, and on the methods that are used to study them. Its content is intended to provide an appreciation of the range of biological phenomena that involve interoceptors, to explain the goals and procedures of interoception research, and to offer to researchers some practical suggestions and theoretical guidelines for interoception experiments.¹ The scope of the chapter is well characterized in the following quotation from an 1894 lecture by Pavlov.

...in the life of a complex organism the reflex is the most essential and frequent neural phenomenon. With its help a constant, correct, and precise correlation becomes established among the parts of an organism, and among the relationships between the organism as a whole and the surrounding conditions. And the starting point of the reflex is the irritation of the peripheral endings of centripetal nerves. These endings pervade all organs and all tissues. These endings must be visualized as extremely diverse, specific ones, each individually adapted, like the nerve endings of sense organs, to its own specific irritant of mechanical, physical, or chemical nature. Their effectiveness determines at each given moment the magnitude of, and fluctuations in, the activity of the organism. (Pavlov, 1940, p. 142)

SENSORY RECEPTORS

There are three generally recognized classes of sensory transducers:

(1) Exteroceptors, such as the photoreceptors of the eye, the hair cells of the cochlea, or the mechanoreceptors

¹ Thus, the emphasis is on the physiological implications of visceral sensory mechanisms, not the psychological implications of visceral perception. Excluded are certain subjects dealing with specialized perceptions, for example, the awareness of heart beat (see next note) and a detailed discussion hunger and satiety. For a recent review of the role of the perception of visceral sensation in the control of food intake see (McHugh & Moran, 1985; Schwartz & Moran, 1996). Nociception is discussed in relation to interoceptor properties, but visceral pain and its mechanism is an extensive and separate subject.

of the skin. These are located at or near the body surface, and are the basis of exteroception, the perception of mechanical and electromagnetic energy fields in surrounding space.

(2) Proprioceptors, such as skeletal muscle spindles, Golgi tendon organs, and joint strain receptors. These sense the velocity, orientation, and mechanical tension of the skeleton. They are the basis of proprioception: the control of skeletal reflexes, complex movement, and the perception of the orientation and action of the body in space.

(3) Interoceptors, such as mechano, thermo, and chemoreceptors, of the gut; stretch receptors of the atria, carotid arteries, and aorta; chemoreceptors of the carotid sinus, lipid receptors in the portal circulation, and metaboreceptors in the skeletal muscles. These are situated within the body cavities, and are the basis of visceral reflexes; and of interoception, the central neural representation of the blood vessels and visceral organs. They are the sensory radix of the vegetative infrastructure of higher animals.

Among the receptors, the first two classes are most readily accessible to stimulation and electrophysiological recording. As a consequence, their microanatomy and biophysical transduction mechanisms are well described, and to a large extent, modal selectivity, dynamic response characteristics and central connections have been analyzed. In contrast, the receptive field, generator structure, and pseudo-dendrite of a typical interoceptor are deep within a body cavity, and comparatively inaccessible.

It is much more difficult to stimulate the, comparatively inaccessible, receptive field of an interoceptor, and simultaneously record from its small, often unmyelinated, fiber. Consequently, the detailed properties and functions of interoceptors are less known than those of exteroceptors and proprioceptors. Nonetheless, anatomically, nearly ninety percent of the fibers of the vagus and more than fifty percent of the fibers of all autonomic nerves are afferent (Norgren, 1985, p. 145), and these fibers convey extensive information from interoceptors to the brain.

INTEROCEPTOR TAXONOMY

The term “interoceptors” includes visceral receptors, but, is broader: “Visceral” is from “viscus,” meaning an internal organ of the body; especially: one (as the heart, liver, or intestine) located in the great cavities of the trunk. For example, the entire small intestine or bladder is considered visceral; whereas, the skeletal muscles are not. Thus defined, the stretch receptors of the gut are all interoceptors; whereas, the nearly homologous, spindles, which regulate the mechanical function of the skeletal muscles, are not. The spindles and other skeletal mechanoreceptors are instead called proprioceptors. This distinction is logically consistent and reasonably clear, but adjacent to proprioceptors, the skeletal muscles also have other receptors, which respond to the metabolic state of the muscle tissue itself. These metaboreceptors fire with elevated lactic acid and diprotonated phosphate ($H_2PO_4^-$) concentrations in the surrounding tissue; their activation augments muscle sympathetic nerve activity and partially opposes the local vasodilatory effects of metabolic products; they, thus, regulate the circulation, and ensure that each muscle receives the cardiac output fraction that fits its activity (Batman et al., 1994; Sinoway & Prophet, 1990). Metaboreceptors are neither proprioceptors or exteroceptors; they have many properties in common with interoceptors, but are not part of the “viscera” by the usual definition.

The metaboreceptor example points up that, in addition to its anatomy, the function of a receptor also must be accounted into the taxonomy: In general, within an organ or tissue there are (1) those sensory elements that serve a special host organ function, such as photoreceptors of the eye, the hair cells of the cochlea, the spindles of the skeletal muscles, or the stretch and mucosal chemoreceptors of the intestine; and (2) those that subserve more general tissue maintenance functions, such as do, the various metaboreceptors. Hence, a distinction can be appropriately drawn between receptors serving vegetative and those serving special organ functions.

Thus, to be complete, interoceptors should include all sensory receptors in visceral organs, plus other receptors, wherever located, that subserve local tissue metabolic functions. In addition, it is necessary to consider separately certain other cases where the anatomical position of a sensory ending and its effective receptive field do not obviously coincide. For example, some stretch receptors in the mesentery are activated with strong contraction of the muscular layers of adjacent intestine. Although, these are indisputably interoceptors, and their function seems obvious, there are other more subtle or ambiguous cases: For example, at least in part, the conscious perception of the heart beat, particularly in arrhythmia, depends on receptors situated in the chest wall and/or overlying skin.² Because their receptive field includes visceral structures,

should these striate muscle and/or cutaneous receptors appropriately be considered to be interoceptors? The general answer probably is no; but in a specific case, it may depend on the implications that are to be drawn from the observed effects. (And suppose, for argument, that the receptors in question were located on the pleural membrane instead of the chest wall, Would their classification be the same?)

Finally, certain authors have objected to the tacit identification of sensory receptors with one or the other branches of the autonomic nervous system (Jänig & Häbler, 1995). This concern is appropriate, and it should be yet further noted that the peripheral nervous pathway of a receptor cell's afferent process is not always a reliable basis for characterizing a receptor or receptor population: For example, the vagus is mostly composed of visceral afferents, but the vagus is, in fact, not a pure visceral nerve. Fibers from the larynx, via the recurrent laryngeal nerve, enter the vagus at the aortic arch; thence, course the full extent of the cervical vagus. Some of these fibers are afferent, and project to striate muscle spindles. In addition to these somatic proprioceptive afferents, the vagus also contains a population of general cutaneous sensory fibers, which are derived from its auricular ramus (Brodal, 1969). Thus, electrical stimulation of the cervical vagus can not be assumed to emulate a pure visceral afferent effect, and electrical activity that is recorded from the vagus may be partially somatic.

In biology, we *classify* things so that we can make observations on a few members of a class, and then use the result to make useful inferences to the other members of the same class. Definitions constrain conclusions: If a question concerns, for example, specific hemodynamic effects of low pressure atrial baroreceptors, the receptor population for study can be readily defined in terms of physiological and anatomical criteria, and the conclusions confidently applied back to the appropriate population. However, when more general questions are addressed, such as, “Is there conscious perception of moderate intestinal dilation?”, the criteria are less pat.

More important than post hoc justification of inferences, definitions guide the design of a convincing experiment. For example, an intestinal perception hypothesis could be tested by applying a signal detection procedure to a balloon in the lumen. But, in parts of the intestine, in addition to the stretch receptors of the gut wall, balloon inflation might also distend the overlying abdominal skin. Suppose, in such an experiment, detection is found to be reliable, but that activation of the skin receptors has not been ruled out as a source of the sensory input, Is it reasonable to infer that, in general, intestinal dilation can be perceived? Probably not, But why? The ready answer is: Because the sensation is obviously from the skin, not the intestine! But, why are skin receptors not considered to be a legitimate source of visceral sensory input?

² See for example (Brenner & Jones, 1974; Paintal, 1972). For an excellent and extensive review of heart beat perception see (Jones,

1994); for a discussion of probable sources of mediation op. cit. pp. 156–160.

To overcome the limitation (on the target inference class) the intestinal perception experiment would need to incorporate appropriate controls. These could be achieved in two ways: (1) With a differential experiment in which the skin artifact is deliberately included in both the control and experimental stimulations, or (2) by refining the intraluminal stimulation technique to entirely exclude any skin artifact. In an animal study, inflation of an intraluminal balloon could be compared to "control" inflation of an adjacent extraluminal balloon. The control inflation would stimulate the skin, but not the luminal stretch receptors; the intraluminal inflation would stimulate both, and the difference would specifically measure the luminal stretch contribution. This design is satisfactory but requires surgical placement of the control balloon in the abdominal cavity; something which is obviously not appropriate in humans.

It is difficult to dilate an intestinal segment without some effect on overlying skin, but sometimes a more stringent experiment can be used to show that an observation also holds in a less stringent sense. For example, a relatively non-invasive procedure can be used to study differential detection in two adjacent intestinal segments: A catheter with two separately inflatable balloons spaced several centimeters apart (a Barthelheimer tube) can be passed per os into the intestine, with the subject instructed to attempt to respond to one and only one of the two balloons as the signal, and the balloons inflated in a controlled quasi-random pattern. If the experiment shows that the separate inflations can be discriminated, the result would go beyond, but would definitely include, solid evidence of simple detection by intestinal distension. In fact, procedure of this kind has been successfully used (Adam, 1967, pp. 127–128) to study the sensory capability of the human duodenum.

It should be noted, here, that a hazard of using discrimination as the criterion of simple detection is the increased chance of the Type II error (the null hypothesis is inappropriately accepted). In general, experiments should be designed so as to minimize systematic error, but a draconian standard of evidence can obscure an important phenomenon; hence, in stating the conclusions of a highly differential experiment, negative outcomes should be interpreted with the same degree of caution as a positive ones.

Ultimately, any acceptable definition depends on the question that it serves, and the question devolves to the relationship between the experimental preparation and the target inference class. Every scientist appreciates that randomization is the crux of statistical inference; a valid proband always must be drawn at random from the applicable universe; in fact, a similar, but more general "sampling" principle governs any inference. It demands that an experimental preparation be, as nearly as possible, a *generic* example drawn from the target class: in other words, the properties of the preparation – at least, those properties that, arguably, are relevant to the putative effect – must be the same for all members of the inference

class. For example, consider again the enteric perception experiment, if all intestinal segments were situated such that the overlying skin was stimulated by balloon dilation, the result would be convincingly applicable to all intestinal segments, and generally valid; however, because this is almost certainly not true, the inference only applies to those segments where the condition holds. Furthermore, general properties of the physiology and anatomy of the gut dictate that skin stimulation would not likely be a reliable sensory pathway for intestinal distention; thus, in experiments of this kind, an effect that depends on sensation in the overlying skin is appropriately considered an experimental artifact.

THE GENERAL BIOPHYSICAL PROPERTIES OF INTEROCEPTORS

Stimuli have the qualities of anatomical location, physical mode, intensity and its derivatives of time; but, although a particular receptor may be more efficiently activated by certain combinations of these qualities, most interoceptors are anatomically diffuse, polymodal, and simultaneously affected by both the level and rate of change of the stimulus.

Selectivity: For any sensory system, stimulus discriminability ultimately is determined by the properties of individual receptors. Studies of skin sensations of awake humans indicate that individual receptors can code a range of stimulus qualities. Intraneuronal micro-stimulation of individual afferent units can evoke sensations of intermittent tapping, vibration or tickle, or a perception of distinctly localized pressure: Quantitatively, depending on the unit stimulated, afferent impulse frequency may determine the magnitude of perceived pressure, or the frequency of perceived vibration (Ochoa & Torebjork, 1983).

In addition to unit properties, modern sensory physiology, kindled by the work of Adrian, Hartline, and Hubel and Weisel, has confirmed that comparatively simple assemblages of appropriately connected receptors can encode many additional stimulus properties; thus, in the central visual areas, there are cells that fire differentially to edges moving in a particular direction, even though, the retina itself, has no actual edge detecting cells. Due to the comparative inaccessibility of the visceral receptive fields, and visceral afferent nerve tracts, there are no direct observations of the sensory capabilities of functional interoceptor arrays, but most likely the organization is similar: We know for example, that the anal canal has "shearing" sensitive regions (Jänig & Häbler, 1995), and that probably similar shear sensitivity occurs in the upper gastrointestinal tract; and that these perceptions probably derive from spatially organized receptive fields composed of simple stretch (pressure) receptors. The regulatory implications of temporal convergence of activity from different receptors is not addressed by conventional systems analyses: the electrical activity from a visceral nerve is typically treated as a scalar quantity, represented by the rectified and integrated

neurogram. Consider by analogy, trying to explain pattern detection or color vision from fluctuations in the averaged activity of the optic nerve.

For almost all receptors certain key steps in transduction are common: in particular, although some visual and auditory receptors hyperpolarize to certain stimuli, an adequate stimulus usually displaces the membrane potential toward zero. Because maintenance of the resting membrane potential depends on metabolically sensitive active processes, ionic selectivity of the plasma membrane, and the composition of the extracellular environment, depolarization is also a consequence of any cellular damage or extra-cellular change that is sufficient to disrupt either metabolism or structure, or affect the Nernst potential of a key ion. Hence, large parametric excursions, or moderate non-specific injury of the surrounding tissue will cause most receptors to begin firing, often rapidly, and to continue to fire, until the cell is actually devastated. For similar common biophysical reasons, all receptors are sensitive to ambient electrical currents, and most will also fire with application of mechanical pressure sufficient to produce significant membrane distortion. Beyond these ubiquitous membrane processes, transduction processes initiated by trans-membrane receptor molecules, may be multi-modal or non-specific. For example, chemoreceptors respond to both CO₂ and pH, and many gustatory receptors respond to several of the basic stimuli, and some vagal afferent fibers respond to both cholecystokinin and distention. In addition, the broad and overlapping sensitivity of many “pharmacological” receptor molecules is well documented.

Temporal properties: Receptors can be broadly characterized by their firing rate as a function of a step change of the stimulus in time. In a qualitative sense there are two separable aspects of this “step response”: the accuracy or speed with which the receptor follows the rising edge of the step, and the stability of the asymptotic firing rate to the steady level of the plateau. In the somatomotor, the visual, and the auditory systems, receptor response speed is important, because it is often the limiting factor in system performance, but for the regulation of visceral function this is rarely the case: For most autonomic reflexes the sensory receptor mechanism is relatively fast, compared to the cumulative lag of the proximal stimulus dynamics, central processing and efferent mechanisms (Dworkin et al., 2000); thus, *interoceptor response speed is ordinarily not the limiting factor in determining autonomic control properties*.

However, in contrast to somatosensory, visual and auditory processes, which mostly engage phasic reflexes acting within seconds, many interoceptors are involved the feedback controlled steady state regulation of the basal value of physiological variables. Consequently, for interoceptors, the stability of the asymptotic firing rate to a constant stimulus is an extremely important issue. In fact, the steady state response properties of interoceptors, which are described and analyzed below, are difficult to reconcile with their putative function within a conventional negative feedback regulatory framework, and exactly how the sys-

tem actually works remains an open question (Dworkin, 1993).

Adaptation is the gradual decline in receptor firing to constant stimulation. Adaptation can be a striking and obvious effect: In the 1950s there were experiments in humans that employed stabilized retinal images, produced by special optical projectors (Race & Rosenbaum, 1966; Riggs et al., 1953). These experiments showed that “...with an essentially motionless retinal image prolonged fixation results in disappearance of objects from the field of view.” (Riggs et al., 1953). Complete fading of the image can occur within several seconds. The stabilized image is a particularly graphic example, but receptor adaptation is ubiquitous: In every neural system, at every level of the animal kingdom, whenever receptor temporal properties have been accurately measured, adaptation has been found.

Mechanisms of adaptation: Various biochemical and physical factors account for receptor adaptation. For example, in Pacinian corpuscles, as in certain interoceptors, mechanical high pass filtering by the surrounding tissue is an important component of the adaptation mechanism (Lowenstein & Mendelson, 1965); however, even with removal of the mechanical filtration of the viscous lamellae or capsule, the generator potential of a naked receptor has a duration of less than 100 msec. (Lowenstein & Skalak, 1966). The range of the time scale of adaptation is such that receptors considered notable for being *slow* to adapt, such as muscle spindle, bee hair-plate, or slow crustacean stretch receptors, actually sustain generator potentials for only seconds or minutes.

Whether or not adaptation holds for every membrane bound receptor, neural or not, is unknown, but in most systems with the presence of persistent ligand levels, there is “down regulation” or reduced receptor sensitivity of both a fast and slow kind. There are various neurochemical mechanisms of adaptation; however, recovery of sensitivity after long-term ligand exposure probably requires protein synthesis (Axelrod, 1984; Browning, Brostrom, & Groppi, 1976; Deguchi & Axelrod, 1973; Gavin et al., 1974; Mallorga et al., 1980; Strulovici et al., 1984; Terasaki et al., 1978).

Interoceptor adaptation: When exposed to a static stimulus all known interoceptors eventually cease to fire; thus, the sensory manifestation of adaptation for visceral receptors, parallels that of the stabilized image for the retina. The central nervous system representation of any completely constant stimulus gradually fades, and is eventually obliterated; moreover, the constant component of a variable stimulus also disappears. So, for example, although the pulse variation of the blood pressure continues to be indefinitely reflected in corresponding fluctuations in the firing rate of the baroreceptor nerves, the mean arterial pressure (MAP), the central value around which the pulse pressure varies, gradually disappears from the afferent signal. Table 21.1 is taken from Chernigovskiy’s (Chernigovskiy, 1967) extensive monograph.³ It lists the

³ For additional general references on interoceptor properties see (Mountcastle, 1980).

Table 21.1. This is abstracted from Chernigovskiy's (Chernigovskiy, 1967, pp. 228–29) extensive monograph. It lists the approximate time of adaptation for a number of carefully studied interoceptors. Note the actual time to adaptation given for the "very slow" adaptation receptors

Receptors	Adaptation speed	Adaptation class
Mechanoreceptors of the carotid sinus (cat)	25% of the initial impulse frequency within 6 sec of stimulation; the initial rapid phase of adaptation is practically absent.	Very slow
Mechanoreceptors of the aortic arch (rabbit)	Complete adaptation within 5–10 min.	Very slow
Mechanoreceptors of the atrium (cat)		Very slow
Mechanoreceptors of the urinary bladder (dog)	1. Complete adaptation within several fraction of a second (only 10–30 impulses). 2. Incomplete adaptation within 15–25 min.	Very slow
Mechanoreceptors of the urinary bladder (cat)	Complete adaptation within fractions of a second.	Very rapid
Various types of stretch receptors of the lungs (cat)	Not more than 5% of the initial impulse frequency within 10 sec. 1. Decrease in impulse frequency by 10–55% during the 2nd sec of stimulation. 2. Complete or almost complete adaptation by the end of the first sec of stimulation. These receptors are distinguished by a high threshold.	Slow Very rapid

approximate time of adaptation (to a constant stimulus) for a number of carefully studied interoceptors: again especially note, what are actually rather rapid adaptation times of those receptors that Chernigovskiy saw fit to classify as being "very slow" to adapt. Figure 21.1 shows the response of a typical "slowly adapting" cardiovascular receptor to a constant stimulus at its receptive surface (Mifflin & Kunze, 1982).

INTEROCEPTORS AND STEADY-STATE PHYSIOLOGICAL REGULATION

Interoceptor adaptation poses some intractable and perplexing problems for conventional theories of physiological regulation, and because of this, its ubiquity has not been accepted without controversy. Many authors either have ignored evidence of receptor adaptation, or attempted to dismiss it as a technical artifact of the isolation and measurement procedure.⁴ The analysis of the carotid baroreceptors by Landgren (Landgren, 1952) is typical. For carotid sinus pressures below 100 mmHg he found the usual rapid adaptation; however, above 100 mmHg, the time until "complete" adaptation was much longer. On the basis of this, he surmised that there was a term in the step response that represented a time invari-

ant pressure dependent firing rate, wrote the equation for the receptor as $Frequency = A(p) + Bt^{-0.65}$, and explicitly characterized the baroreceptor response to pressures above 100 mmHg as "steady discharge." By including $A(p)$,

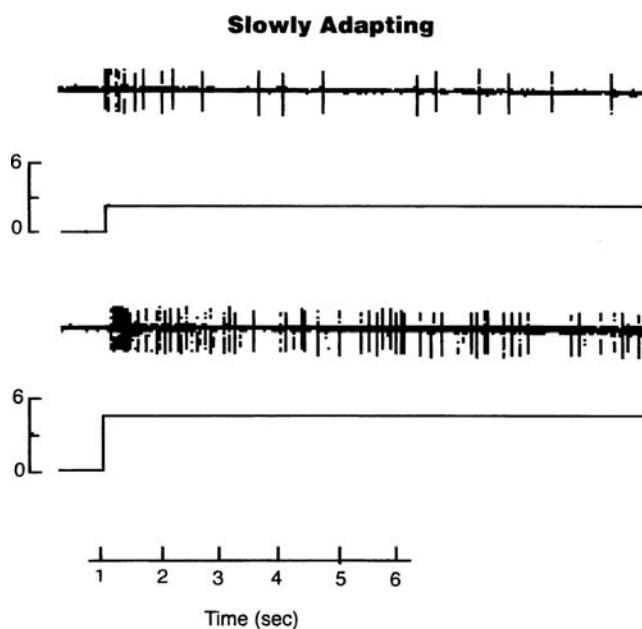

Figure 21.1. Slowly adapting low-pressure vagal receptor of the rat. The spike record shows the fall-off in firing rate following application and maintenance of a stimulus step. Adaptation occurs with both high-and low-strength stimuli, but complete adaptation is usually more rapid with weaker stimulation. The classification as "slowly adapting" is made relative to other kinds of interoceptors, studied under similar conditions (see text).

⁴ This idea has been prevalent in autonomic nervous system neurophysiology for many years. When, in 1969, as a student, I asked the influential autonomic nervous system neurophysiologist, Detlev Bronk, about the apparent ubiquity of receptor adaptation, and its implications for physiological regulation, he insisted that it was not a real phenomenon, but an artifact of damage inflicted by the dissection required to isolate the receptor.

a purely pressure dependent term, Langren implicitly asserted that at higher pressures the baroreceptors did not fully adapt, and thus that they indefinitely continued to transmit steady-state pressure information. This result challenged the assertion that adaptation was ubiquitous; however, Langren observed receptors at constant pressure for no more than 10 minutes.⁵ The firing rate, at that point in time, appeared stable and, because of this, he concluded, "The curve approaches a constant asymptotic value."

Given the putative role of the baroreceptors in blood pressure regulation, "steady discharge" to a constant pressure was an important finding. Langren's result was readily accepted as evidence that the baroreceptors indeed had sufficient long-term stability to regulate basal blood pressure. However, by the mid 1950s, baroreceptor "resetting" (McCubbin, Green, & Page, 1956) was experimentally demonstrated, and with it, serious doubts arose about whether the baroreceptors were involved in tonic blood pressure control.

The controversy about the baroreceptors points up a general problem in interpreting interoceptor adaptation data. In all cases, the temporal response establishes the regulatory limitations of the receptor; for example, if a receptor, which adapts to 50% of maximum firing rate in 20 seconds, is the afferent element of a phasic reflex that requires only a few seconds of firing to initiate, that receptor is "slowly adapting." For a baroreceptor, an orthostatic response to postural change fits that case well. On the other hand, if the same baroreceptor is assumed to sense mean blood pressure, it needs to maintain its firing rate for very much longer – in certain (quite conventional) conceptions of the regulatory process – possibly even for years. Thus, compared to the time scale of steady state blood pressure regulation (and this was the important physiological issue), observation of a receptors response for 10 minutes was too brief to make a useful inference.⁶

In sum, all interoceptors appear to adapt within seconds or minutes. Interoceptor adaptation has profound implica-

⁵ Because the empirically observed firing rates always include some random variability, appropriate statistics must be used to convincingly show that the firing rate actually approaches a final, non-zero, constant level. The assertion that a curve has reached "asymptotic level" means that the regression line fit to data on the terminus of the linear plot has a slope of zero to within an acceptable error. It is important to appreciate that Langren did not use an appropriate statistical criteria to evaluate the slope of the terminal firing rate, even within the specified 10-minute observation period.

⁶ Langren's was an early and pioneering study, but similar criteria also characterize more recent interoceptor studies. For example, Mifflin and Kunze (Mifflin & Kunze, 1982) studied slowly and rapidly adapting low pressure receptors in the left superior vena cava of the rat (see Figure 21.1). For the slow receptors they observed substantial (60%) increases in threshold following 15-min exposures to pressures of 5 mmHg, which agreed with other results (Kappagoda & Padsha, 1980), and these, they explicitly claimed, did show time invariant firing. However, when their published data was reanalyzed with standard regression techniques and conservative criteria (Dworkin, 1993, p. 139), the firing rate had actually continued to decline substantially during the last 10 minutes of observation.

tions for control system models of long-term or steady state regulation: If the key assumption of the conventional regulatory paradigm – that some receptors continue to faithfully transduce the absolute level of physiological variables for many months, and can provide the sensory substrate of long-term central regulation – is valid, there should be many studies convincingly documenting hours or more of stable transduction by various interoceptors; in fact, there appear to be none whatsoever.

ACCOMMODATION

Accommodation is when stimulus change is sufficiently gradual that, because of adaptation, it fails to fully activate a receptor. As such, accommodation is simply another facet of adaptation. It is, however, an especially interesting facet, because it illustrates the regulatory implications of adaptation.

If a receptor adapts, given an appropriate stimulus rate of change (driving) function, it can be made to fire at a constant frequency. If the driving function is sufficiently gradual, the constant firing frequency can remain close to zero (Gray & Malcolm, 1951; Gray & Matthews, 1951). In other words, because of accommodation, a stimulus can increase from zero to the physiological maximum without ever changing the receptor's firing rate. A more precise and quantitative way of defining accommodation is in terms of the receptor transfer function: If a time domain step function response has a Laplace transform, $F(s)$, its transfer function, $T(s)$, is $F(s)$ divided by $1/s$, the transform of a zero time aligned step. The transform of the output function that describes a particular constant firing frequency R , is R/s . And, it follows that,

$$H(s) \cdot T(s) = \frac{R}{s};$$

$$H(s) = \frac{R}{sT(s)}$$

where $H(s)$ is the Laplace transform of the stimulus or driving function that will cause the receptor to fire continuously at constant frequency R . This relationship can be applied to the step function data for an interoceptor, and used to derive a cumulative stimulus drift function that will produce a constant, arbitrarily low, firing rate. For example, for feline right atrial mechanoreceptors Chapman and Pankhurst (Chapman & Pankhurst, 1976) found no evidence of time invariant firing in the atrial volume receptors, that is, the receptors adapted to a zero firing rate. At above the threshold volume, the firing rate was characterized by $Frequency = \frac{12Hz}{ml} (\frac{t}{1sec})^{-.24}$; thus, the transfer function for this receptor is, $T(s) = \frac{12Hz}{ml \cdot sec^{-.24}} \Gamma(.76)s^{.24}$, and the inverse of $H(s)$ for $R = 1$, a firing rate of one impulse per second, is $h(t) = \frac{ml}{12\Gamma(.76)\Gamma(1.24)} (\frac{t}{1sec})^{.24}$, which describes a volume drift curve that will evoke a constant rate of firing over the linear range of the receptor (from threshold to saturation). Solving this shows that as much as 0.5 ml of additional atrial volume can accumulate, within an hour,

without perturbing the firing rate. Thus, under appropriate circumstances, even an “extremely slowly adapting” interoceptor can fully accommodate to a rate of volume change that would soon accrue to a substantial physiological error.

Is adaptation an experimental artifact?: A possible way to dismiss the physiological implications of interoceptor adaptation is to argue that adaptation is an artifact that results from damage inflicted in preparation for recording, on a receptor or its nerve. Because, direct quantitative measurement of interoceptor adaptation *in situ* is impractical (For one thing, accurately controlling the stimulation level in an intact animal is difficult), this assertion is extremely hard either to prove or refute.

The Russian visceral physiologists had an explicit theoretical commitment to brain mediated interoceptive regulation of the physiological state. They, thus, found the relentlessness of receptor adaptation particularly vexing, and were especially motivated to seek an alternative explanation that would mitigate the adaptation data. Their predicament had two aspects: first, if the primary interoceptor adapts, it is impossible for the brain to continuously acquire information from it, and, second, in addition to primary adaptation, observed *ex situ*, there was undeniable evidence for adaptation, resetting or habituation of many different *in situ* visceral reflexes.⁷ Given these facts, and especially if the second phenomenon is actually a manifestation of the first, they asked, How can the brain have an important role in long-term regulation? Their putative explanations were: (1) primary receptor adaptation, observed *ex situ*, is an experimental artifact; and (2) adaptation of intact reflexes is due to an active inhibitory process that occurs in the brain, not at the interoceptor. To test these hypotheses, the leading Soviet sensory physiologist N. Chernigovskiy did an experiment that attempted to directly challenge the notion that the universally observed adaptation of visceral reflexes is a direct consequence of interoceptor adaptation (Chernigovskiy, 1967, pp. 230–34).

The experiment used a loop of intestine and its mesenteric nerves. Distending the segment stimulated mechanoreceptors in the wall, which through afferent nerves to the brain, caused a reflexive increase of blood pressure and respiratory rate. The investigators found that, following its increase, the blood pressure gradually returned toward normal as the wall tension was maintained constant for several minutes. This was exactly as expected, and the conventional explanation of this result is that the interoceptors of the gut wall eventually adapt to the constant stretch. However, in Chernigovskiy’s experiment, once adaptation developed and the reflex magnitude diminished, the mesenteric nerve was subjected to transmission block by cooling it to 5°C. As would be expected,

the cold block, at that point in the protocol, was without effect on either the blood pressure or respiration. Again, the usual and obvious explanation is that there was no activity on the nerve to be blocked. But, a less readily explained result occurred when the temperature was returned to 37°C and afferent nerve conduction was reestablished: Blood pressure and respiration again rose, and the change was as large, or even larger, than to the original distension. Chernigovskiy argued that this proved that the receptor had continued to fire undiminished throughout the protocol; that the observed adaptation of the reflex was due only to a process somewhere central to the block, and, most important for the central regulatory theory, that information from the receptor had, in fact, continued to reach the brain. He said, “Thus, on the basis of these experiments it can be concluded that the apparent cessation of the reflex response takes place not in the least as a result of receptors’ adaptation but is due to changes in the excitability of the vasomotor center which develops in the course of the reflex response itself.”

These were interesting observations (c.f. Thomas E. Lohmeier, et al., 2004), but Chernigovskiy was almost certainly wrong in his conclusions. Besides the immediate effects of rewarming on the activity of the afferent nerve, which Chernigovskiy claimed (but did not explain how) he adequately controlled, his experiment had other probable pitfalls. In particular, along with stretch afferents, the mixed nerve of the pedicle contains motor, secretory, and vascular fibers, and cooling to 5°C would have blocked these efferent fibers and also probably lowered the temperature of the arterial blood supply and, thence, the tissue of the loop itself. Consequently, the vascular, and possibly thermal and motor, disturbance produced by the cold block would almost certainly have newly activated many different kinds of interoceptors, and the effects of this stimulation would not have become apparent until the afferent nerve was rewarmed.

Chernigovskiy’s experiment is, nonetheless, informative for two reasons, first it illustrates some of the possible ways that interoception experiments can become confounded by failure to isolate pure afferent effects; second and more generally, it underlines that a well recognized authority on the physiology of interoceptors saw a serious inconsistency between the established *ex situ* adaptation characteristics of visceral sensory receptors and the participation of the central nervous system in long-term regulation of the physiological state. Clearly, he was troubled sufficiently by this disparity that he attempted a difficult experiment to reconcile interoceptor function with the conventional feedback regulation concepts of the prevalent regulatory theory.

In sum, adaptation is an established feature of all interoceptors which have been adequately studied. The erroneous conclusion that an interoceptor can have time independent functional activity derives from prematurely curtailing observations, or inaccurately measuring the terminal changes in firing rates. In all published cases, observation for periods even remotely comparable to the

⁷ Chernogovskiy (1967) gives a many examples for intestinal reflexes, but the best documented example in the Western literature is the resetting blood pressure baroreflexes. See (Kezdi, 1962; Koushanpour & Kelso, 1972; Koushanpour & Kenfield, 1981; Kreiger, 1970; McCubbin et al., 1956).

time scale of steady-state physiological regulation have disclosed evidence of continued monotonically declining firing rates. The direct physiological implications are that, in all cases, information about the absolute stimulus magnitude is gradually distorted by an interoceptor, and after sufficient time, the visceral stimulus (similar to a stabilized visual image) probably fails to register altogether. Similarly, for accommodation, a sufficiently gradual rate of stimulus drift will not change the firing rate of the receptor, and the drift will elude detection and correction by regulatory mechanisms that depend at some link on sensory neural transduction.

EXPERIMENTAL METHODS IN INTEROCEPTOR RESEARCH

The experimental analysis of interoceptor function requires selective activation of the pathway(s) of interest. In general, researchers strive to confine and focus stimulation, so they know exactly what is being stimulated. There are a number of methods for accomplishing this; some of these can be used in humans, but others, because of their invasive and injurious nature can only be applied in animal studies. At present no interoceptive stimulation method for animals or humans that can be applied without the addition of specific control procedures to verify its effectiveness and/or specificity. The following describes some typical methods, their potential pitfalls, and usual controls.

Direct Nerve Stimulation: In principle, the most precise way to activate a particular fiber or circumscribed group of fibers is to surgically isolate and electrically stimulate them; however in practice, most sensory fibers are accessible to stimulation only after they have entered mixed nerves; thus, a satisfactory stimulation method depends on detailed knowledge of the relevant anatomy and physiology. For example, in humans the innervation of the tooth pulp is almost exclusively by nociceptive c-fibers, and it is possible to induce a relatively pure pain sensation by applying a dental probe electrode to the surface of a tooth (this is the principle of the "pulp tester" which has been used by dentists for many decades); however, with the conventional technique, current leakage to the gingiva reduces the accuracy of the stimulation, because the stray current activates mucosal receptors, producing additional non-pain sensations. Together, these factors degrade the accuracy and specificity of the tooth pain psychophysical function, which is obtained with this method (Zamir & Shuber, 1980). However, precise repeatable (within subject) stimulation of the pulp with a constant stimulation area (and current density) can be achieved with a tooth that has a vital pulp and a stable metal filling. The method involves imbedding the electrical contact in an individually molded, tightly fitted, rubber cap that completely insulates the electrode from the mucosa (Lee et al., 1985). It yields far better data than a simple hand held probe, but involves extensive preparations and is far more time consuming. Whether

the effort is worthwhile again depends upon the question being asked: for example, does the hypothesis make highly quantitative predictions about pain as distinct from other oral sensations?

In another approach, when diverse pathways are unavoidably activated by an electrical stimulus, selective lesions often can be used to verify those component paths that are needed to produce the observed effect. For example, the general sensory effects of stimulation of the baroafferent pathways has been of increasing interest in recent years (Ghione, 1996). The rat vagus includes baroafferent fibers, and to study antinociceptive effects, Randich (Randich, Ren, & Gebhart, 1990) has used electrical stimulation of the whole central vagus as a technically simple means of activating these fibers. He controlled non-baroreflex effects by making selective ibotenic acid lesions in appropriate areas of the brain stem, and found that lesions placed in regions known to be involved in blood pressure control substantially blunted the antinociceptive effects of vagus stimulation, whereas other located lesions had less or no effect. This method is subject to all of the usual caveats for lesion procedures, but, in knowledgeable hands, can effectively help to verify the locus of mixed nerve stimulation effects. Specific lesions or nerve sections also can be used to limit the extent of non-electrical stimulation methods discussed below.

An additional issue about direct electrical stimulation of an afferent pathway is that, in general, the quantitative equivalence between electrical nerve stimulation and natural stimulus parameters is indeterminate: Higher stimulus current cannot be tacitly assumed to mimic stronger natural stimulation (although, as described above for cutaneous receptors, at a constant supra-threshold current, for certain kinds of individual fibers, the impulse rate of stimulation can have a useful physiological relationship to the properties of a distal stimulus). The general problem with using current strength as a stimulation variable is that, in a whole nerve, increasing current strength is more likely to recruit additional, smaller, fibers, than to more strongly activate those that are already recruited. In particular, when a nerve is composed of a mixture of myelinated and non-myelinated fibers, the myelinated fibers will be recruited at considerably lower current than the non-myelinated ones. Thus, it is often possible to selectively activate myelinated fibers, but not vice versa; furthermore, because "current" is determined by the local voltage gradient across the active neural membrane, the geometrical relationship between the stimulating electrode and nerve can strongly affect which fibers are actually stimulated at a particular current. On the whole the problem of electrically stimulating a mixed nerve is sufficiently complicated that another approach should be employed when the exact identity of the fibers stimulated is crucial; for example, when, to separate specific sensation from pain, large sensory fibers, but not c-fibers, need to be stimulated.

In the few cases of anatomically distinct nerves that are known to be physiologically homogeneous, electrical

stimulation can be a clean and precise technique. Often the stringent requirements are met in only certain species. For example, the baroreceptors of the aortic arch reach the CNS through nerves that travel through the neck along the vagus and sympathetic trunk. These “aortic depressor nerves” (ADN) are very readily identified and isolated in the dog, rabbit, and rat; however, whereas the ADN of both the dog and rabbit also include many fibers from chemoreceptors in the arch, the rat ADN is composed entirely of pressure afferents. When the rat ADN is successfully isolated, it is a pure baroreceptor input.

The conclusion that a nerve is “pure” depends on several kinds of evidence. In some instances, it is possible to dissect the nerve over the entire course to the actual receptive field; then the effects of various stimuli at the receptors can be directly observed. This has been done for the rat ADN (Numao et al., 1985; Sapru, Gonzalez, & Krieger, 1981). Another important, and often more easily achieved criteria, is consistency of the response properties (or sensations) over a range of stimulus strength and rate parameters: Responses should monotonically relate to stimulation strength from threshold to saturation. This has also been done for the rat ADN (Dworkin & Dworkin, 1995; Dworkin, Dworkin, & Tang, 2000). Monotonicity is potentially a convincing criterion; however, for it to be so, the subject must be capable of expressing a wide range of responses, and all putative extraneous responses must be recorded. For example, the rat ADN enters the superior laryngeal nerve (SLN) near the carotid bifurcation, and the SLN is very much easier to identify and isolate than the much smaller ADN; it is thus technically easier to stimulate baroafferents within the SLN; however, the SLN contains numerous laryngeal afferents. Notwithstanding, for several typical baroreflex responses (including blood flow), Faber and Brody showed convincingly monotonic relationships between SLN stimulation parameters and depressor effects (Faber & Brody, 1983); however, because they used anesthetized rats, the effects of the laryngeal afferents were probably blunted or entirely eliminated. When the SLN is stimulated in conscious rats, the mixed effects of stimulation are depressor responses for low levels, often nothing at all for moderate levels, and clear pressor effects for stronger stimulation.

In sum, direct electrical stimulation of afferent nerve tracts can be a useful well controlled method for interoceptive stimulation,⁸ but when modal specificity is important, controls are needed to verify that extraneous pathways are not being inadvertently activated.

Surgically isolated receptive fields: The usual goal of surgical isolation of a receptive field is to create a sensory surface to which stimuli may be applied with greater accuracy, convenience, and specificity than is possible *in situ*.

⁸ Direct nerve stimulation can rarely be used in normal humans; however, there are occasional opportunities to study patients. For example, stimulation of the carotid sinus nerve is sometimes used to control severe hypertension; some such patients have implanted pacemakers that can be externally controlled.

There are many examples of this method. Two illustrative ones are the isolated carotid sinus, and the isolated intestinal segment. A further advantage to using a surgically isolated receptive field is that the stimulus environment can be explicitly controlled, and the local sensory apparatus is less likely affected by endogenous physiological processes. An isolated intestinal loop is not inadvertently stimulated by the uncontrolled passage of chyme, and the arterial cul de sac can be stimulated, at an arbitrary pressure, independently of the systemic pressure.

The original carotid sinus cul de sac technique is attributed to Moissejeff (Heymans & Neil, 1958). It involves ligature of the internal and external carotid arteries (the former being tied cephalic to the sinus, carefully avoiding the carotid sinus nerve) and, cannulation of the central stump of the common carotid. Using this method, it is possible, by generating specific pulsatile or static pressures in the cannula, to accurately stimulate the carotid sinus baroreceptors. With a similar preparation, by irrigating the isolated sinus at constant pressure, the carotid chemoreceptors also can be independently stimulated. Although, in larger animals, such as the dog, it is possible to create a chronic isolated sinus preparation by anastomosing the common and internal carotid arteries, usually for chronic stimulation, a balloon is inserted into the carotid sinus via an incision in the common carotid artery, with a competent Circle of Willis, net brain blood flow is minimally affected. Balloons have been used to study the effects of carotid stimuli in intact conscious dogs and rats (Adam, 1967; Dworkin et al., 2000; Koch, 1932), and provided some of the earliest evidence that the carotid pressure receptors had general sensory effects.

The gut is an especially surgically tractable and plastic structure, and many ingenious methods have been invented for experimentally modifying its architecture and isolating its various regions. Everyone is familiar with Pavlov’s innervated stomach pouches, which he used for collecting specimens of pure gastric juice in studies of the cephalic phase of digestion. Similar pouches and diverticuli can be constructed along the extent of the gastrointestinal tract, including completely isolated loops, which enter and exit at the external skin surface, preserve the nervous and vascular supply, and which if properly maintained, can be patent and functional for many years.⁹ Various stimuli are easily applied to these cul de sacs and/or loops, which are readily distended by balloons or obturators, or irrigated with solutions of experimental compounds, such as acids, fats, or neurotransmitters. The more involved intestinal surgeries are more easily accomplished in the

⁹ Typical are Thiry-Vella loops, which are completely isolated sections of intestine. They are removed with the circulation and nerve supply intact, the ends are brought through and sutured to outside of the abdominal wall to form two papillae, and the remainder of the intestine reconnected with an end to end anastomosis. The resultant loop is easily accessible in a unanesthetized animal, and with reasonable care, various pressure, and thermal and chemical stimuli can be applied surreptitiously.

dog or monkey, because of the strength of their tissues and size of the structures, but it is also possible to make sophisticated surgical rearrangements of the gut in smaller animals, such as rabbits, or even rats (Bàrdos, Nagy, & Àdàm, 1980; Schwartz & Moran, 1996).

Observations of intestinal perception in humans are usually carried out with cannulas introduced per os or per anus; but, also at times, researchers have recruited, as research subjects, patients who have had medically prescribed ileostomy or colostomy procedures. Using stimuli produced by balloon inflation, Àdàm has done an extensive series of carefully controlled perceptual experiments with such subjects. These are discussed in more detail on pages 503 however we note here that using a surgically isolated receptive field does not automatically obviate the need for control procedures to exclude the effects of inadvertent stimulation of adjacent sensory structures: for example, distention of a carotid cul de sac or an isolated intestinal loop can inadvertently stretch overlying skin.

Non-invasive or minimally invasive methods for humans: These are techniques which are considered to involve only minimal risk for participating human subjects; however, "invasive" has a range of definitions, depending on who the subjects are, whom the procedure is performed by, and the extent to which the principal of intention of the procedure is therapeutic (versus purely scientific study). To a cardiologist, placing a catheter into the brachial artery of a heart patient may be considered minimally invasive; whereas, in most psychological research, a venous catheter is thought invasive, and even oral administration of approved drugs may be classified as invasive. Intent is possibly also as important as the actual manipulation. Almost everyone considers mild electric shock that is intended to produce even slight pain to be highly invasive; yet, the same or stronger electric current applied through the same electrodes, with the intention of producing muscle contraction or sweat secretion, might well be considered innocuous or "minimally invasive." In practice, what is "invasive" is determined by local (community) standards, and the arbiter is the legally constituted institutional review board (IRB) to which the investigator is professionally responsible. All human research must be approved by an IRB, and investigators are strongly advised to consult with the executives of the IRB at the earliest possible stage of research planning in order to obtain an estimate of the probable acceptability of what they plan to do. Often this can save much frustration and wasted time.

Minimally invasive procedures avoid penetration of the skin, and since the locus of stimulation in interoception studies is beneath the skin, and the skin is richly endowed with sensory receptors, the design problem often devolves to stimulating a structure under the skin without stimulating the skin itself. The proximal parts of the gastrointestinal tract are exceptions; where per os or per anus, access to the lumen can be achieved with minimal discomfort or risk; however, here also, if the stimulus involves distention of the lumen, distortion of the overlying skin is a potential

source of extraneous sensation, for which appropriate controls must be devised and incorporated.

A novel stimulation technique can sometimes provide the key to an experiment that would otherwise appear to be impossible. Non-invasive stimulation of specific cardiovascular receptors presents an especially difficult problem: In addition to actual access, because the vascular system is both anatomically distributed and tightly coupled, the effects of locally applied stimuli propagate to, and influence, distant structures.

Pharmacological activation of the baroreceptors: Bolus injections of vasoactive drugs are technically the most straightforward methods for stimulating the baroreceptors. The injections are to an extent invasive in that they require venous access, and the drugs used are not without some inherent risk – a too rapid rise in blood pressure can be very dangerous; nonetheless, the procedures are considered a standard part of medical practice, and the drugs, which are readily available, have been extensively tested in humans.

Vasoactive drugs were first used to experimentally stimulate baroreceptors and study baroreflex gain in the late 1960s. The drug employed is phenylephrine, which has vasoconstrictor actions similar to the naturally occurring adrenergic neurotransmitter, norepinephrine, but is more stable than norepinephrine and, thus, more convenient to prepare and administer. The baroreflex gain measurement technique is known as the Oxford method (Smythe, Pascoe, & Storlien, 1989).¹⁰

Vasoconstrictors cause blood pressure to rise by increasing the peripheral resistance; the rise in blood pressure stimulates the high pressure baroreceptors, and the (cardiac inhibitory) baroreflex gain can be assessed by observing the fall in heart rate as a function of the rise in blood pressure or by changes in sympathetic nerve traffic. Phenylephrine, and similar drugs also have been used in behavioral studies of baroreceptor stimulation in humans (Rockstroh et al., 1988). Vasoactive drugs have the advantage that, if administered through an indwelling venous catheter, the actual administration is indistinguishable (to the subject) from that of a vehicle control. For behavioral studies, however, there are two substantial disadvantages to using vasoactive agents to stimulate the baroreceptors, first, most have direct excitatory effects on the CNS (Dworkin et al., 1979), and second, because vasoactive agents act by raising systemic blood pressure, the net blood pressure effects, which are key indices of barostimulation, are not directly observable.

Lower body negative pressure (LBNP): LBNP is a mechanically cumbersome, but physiologically straightforward technique for increasing the proportion of the circulating volume that is sequestered in the large veins,

¹⁰ Angiotensin II has also been used for baroreceptor stimulation; however, it has few advantages when compared to norepinephrine analogs, and has the disadvantage of affecting the R-R interval independently of baroreflex mechanisms (Ismay, Lumbers, & Stevens, 1979).

primarily those in the legs. The removal of a volume aliquot from the central circulation, decreases the net venous return to the heart, reduces cardiac filling, and unloads low pressure receptors in the thoracic vascular bed. The LBNP apparatus consists of a large rigid cylindrical tank with a pneumatic seal at the waist. The tank encloses the entire lower body, and in the tank pressure is reduced with a pump, such as a domestic vacuum cleaner, usually by 10–40 mmHg, but sometimes by as much as 70 mmHg. (Larger negative pressures almost always produce syncope, but even pressures as low as –10 mmHg can produce periods of asystole in healthy individuals). It is probable that low levels of LBNP (<20 mmHg) selectively activate volume receptors, and that higher levels also engage the high pressure arterial receptors.

LBNP has been used in both physiological research to analyze reflex interactions in humans (Eckberg & Sleight, 1992), and to an extent, in psychophysiological research to study baroreceptor effects on sensory perception. For perceptual studies the method has the obvious disadvantage that the suction also activates receptors of the skin and pelvic organs, and convincing controls for these extraneous stimuli are difficult to implement. It should also be noted that, although apparently “non-invasive”; there are several reports of extended periods of asystole being induced in healthy volunteers by LBNP (Eckberg & Sleight, 1992, pp. 196–197).

Neck Suction: Distention of a surgically isolated carotid sinus cul de sac is the most widely accepted experimental barostimulation method, and a related, but non-invasive, external pressure stimulation method has been used in humans: The method depends upon the fact that the baroreceptors are actually stretch receptors in the arterial wall, and that although pressure inside the artery normally *pushes* the wall outward, the wall also can be artificially *pulled* outward by extravascular suction applied through an pneumatically sealed collar that encircles the neck. In the usual arrangement a constant or *static negative* pressure in the “neck chamber,” sums with the natural pulsatile intracarotid *positive* pressure, and increases the average stretch of the sinus; thus, simulating an elevated mean arterial pressure (MAP). The neck chamber has been used extensively to study the peripheral physiology of the human baroreflex, but, as with LBNP, the “static pressure” neck chamber has a drawback for psychological studies: the neck suction activates receptors in the skin and deeper neck structures, and potentially has additional perceptual/behavioral effects that are unrelated to barostimulation. The static chamber is an effective, but non-specific, barostimulation method.

The usual “first line” strategy for dealing with stimulus non-specificity is to compare the experimental stimulus to an appropriate control stimulus, for example, suction applied to the skin a distance away from the target receptive field; however, for neck suction, a satisfactory way to do this has not been found. Some investigators have used positive neck pressure as the control procedure, but for

several reasons this is not very convincing (Elbert et al., 1988; Rockstroh et al., 1988). The solution to this problem provides an informative case study in designing a stimulation technique. In general, for any interoceptive stimulation method there are always several issues, which need to be considered; these are:

1. What is the effective natural stimulus for the target receptors?
2. Where are the target receptors located?
3. What non-target receptors could be affected?
4. What differences in modal sensitivity exist between the target and non-target receptors?

For the neck chamber, the first three were discussed above. As regards the fourth, an essential fact is that baroreceptors are at least as sensitive to changes in pulse pressure as to the mean pressure. Thus, instead of static or constant suction, it is possible to use sequences of brief cardiac cycle coordinated pressure changes to stimulate or inhibit baroreceptor activity. Eckberg had already shown that brief suction pulses applied randomly during various parts of the cardiac cycle differentially affected subsequent P-P intervals (Eckberg, 1976). However, because suction pulses were random, the barostimulation or inhibition effects that they produced were not controlled, and were transitory (lasting for only a single cycle). This was fully satisfactory for Eckberg’s purposes, but limited the utility of the method for psychophysiological studies. To stimulate or inhibit the carotid receptors continuously for as long as several minutes, Eckberg’s method was augmented by replacing the randomly produced suction pulses with computer generated cardiac-cycle-synchronized trains of repeatedly alternating pressure and suction pulses that were phase-locked to an R-wave trigger (Dworkin, 1988). Alternating suction during systole with positive pressure during diastole augmented the endogenous carotid sinus pulse pressure (CSPP), whereas reversing the phase relationship (via the valve operating computer program) created a control condition, in which the endogenous CSPP was actually decreased. This Phase Locked Neck Suction (PLNS) method produced heart rates 5–10% lower during stimulation compared to the control condition. Although the pulse pressure effects of the barostimulation condition (cardiac phase synchronized suction), and control condition (cardiac phase inverted suction) have very different cardiovascular effects, they are indistinguishable to the subject (Furedy, Rau, & Roberts, 1992).¹¹

Comparison of PLNS and the original static neck chamber technique points up both the advantages and some of the “hidden” costs of specificity: Each method stimulates the baroreceptors; the static technique is a far simpler and, in fact, somewhat more effective in producing baroreflex

¹¹ For better pressure symmetry between conditions, a variable length atmospheric pressure pulse can separate the suction and positive pressure pulses (Rau, Elbert, Geiger, & Lutzenberger, 1992) methods have never been shown to be functionally different.

activation; on the other hand, the PLNS method is considerably more specific: the stimulation and control conditions differ only in baroreceptor activation. In general, it is not unusual for specificity to be obtained at the price of some loss in efficacy. No procedure is completely specific, and a control procedure, if it is efficient, will to some degree stimulate the target receptors. A similar example is found in studies of intestinal pressure sensitivity discussed below.

THE REGULATORY FUNCTIONS OF INTEROCEPTORS

The best studied and most generally accepted role of interoceptors is as afferent components in control loops that regulate the viscera. In fact, interoceptors are the first element of the feedback path of all reflex mechanisms of physiological regulation. In closed loop control systems, usually within broad parametric limits, the characteristics of the feedback path dictate the dynamics, and final level of the regulated variable (Dworkin et al., 2000). Because they occupy a crucial position, interoceptors are directly implicated in many medical conditions, and their properties, as simple transducers, are pivotal to important areas of basic psychophysiological research.

For example, all of the following processes involve closed-loop control mechanisms that depend upon information derived from visceral sensory receptors: neural regulation of the circulation; the central control of food and fluid intake, energy balance, and electrolyte metabolism; the sensory substrate of behavioral reward, the afferent mechanisms of conditioned aversions, emotion and pain; the mechanisms of addiction and the treatment of substance abuse, non-compliance with medical regimens resulting from the aversiveness of treatment associated side effects, and the pathophysiology of certain psychosomatic conditions.

Specific interoceptors with well defined reflexogenic effects were not directly observed until the second half of the nineteenth century. In 1866, Cyon and Ludwig found that, in the rabbit, heart rate and blood pressure were reduced upon stimulation of the central end of a small nerve that runs along the common carotid artery, adjacent to but separate from the vago-sympathetic trunk.¹² They recognized that the “depressor nerve” conveyed sensation, and, further, proposed that its receptors were in the heart, and were part of a regulator of the heart rate and blood pressure. Eighty years later Bronk and Stella (Bronk & Stella, 1935) used the single fiber method of Adrian (Adrian, 1926) to systematically investigate the properties of the high pressure baroreceptors. Since then, the baroreceptors have been the most thoroughly studied interoceptors, and it is now well established that the “aortic depressor nerves,” convey barosensory impulses from receptors

in the aortic arch and distal portion the carotid artery, and that these receptors, along with those in the sinus of the carotid bifurcation (those studied by Stella and Bronk), are the afferent limb of the blood pressure regulating buffer reflexes. The structural and quantitative dynamic aspects of the baroreflexes, and their relationship to the physiological state have been among the most extensively studied interoceptor mechanisms (Dworkin & Dworkin, 2004; Dworkin et al., 2000; Dworkin, Dworkin, & Tang, 2000, 2000; Sagawa, 1983).

Adrian’s technique, which has been a key method in interoceptor research involves recording from a small bundle containing a few distinct fibers that have been carefully dissected from a whole nerve. Using this method, Bronk and Stella showed that for a given fiber over a moderate range of pressures there was an approximately linear relationship between intra-sinus pressure and firing rate, and, further, that specific fibers were above threshold and below saturation in only over a limited part of the physiological pressure range. Together, their observations established the important principle of parallel systems of within and between fiber (dynamic and channel) coding that appears to characterize all interoceptors.

As discussed above, most receptors require seconds or minutes to adapt, sufficient time for phasic reflexes, such as orthostasis or salivary secretion, to act. A key property of the negative feedback scheme is that the corrective efferent action of the reflex effectively removes the initiating stimulus from the receptor, and the receptor returns to its basal state, ready for subsequent reactivation. If the corrective action is not achieved within the time constraint of adaptation, of the reflex becomes ineffective and, other mechanisms, which are functionally different from conventional negative feedback, are recruited to restore the basal physiological state. These mechanisms are either non-neural and non-adapting, or neural and adapting. The former are well documented and exemplified by the pressure diuresis effects in the kidney, the latter, which probably involve homotopic conditioning, are presently not well understood, but are likely implicated in long-term regulation of key variables, such as, blood pressure (Dworkin, 1993, see Chapters 7 & 8).

Interoceptive conditioned reflexes: Although the concept of association among stimuli dates to before the British empiricists, the first systematic observations of conditioning in defined reflex systems were by Pavlov in 1897. Pavlovian or classically conditioned responses develop when a sensory conditioned stimulus (CS), which has a weak or no physiological effect, is repeatedly followed by a strong distinct physiological perturbation or unconditioned response (UCR). The UCR is itself produced by application of a second more potent unconditioned stimulus (UCS) that acts at the receptive field of a reflex. With each pairing or trial the physiological effect of the CS increases, and eventually the CS begins to elicit a conditioned response (CR) that mimics the unconditioned physiological reaction.

¹² Two years later in 1868, Hering and Breuer identified receptors in the lung which initiated respiratory reflexes. For a detailed history of the discovery of the baroreceptors see Heymans and Neil (Heymans & Neil, 1958, pp. 18–25).

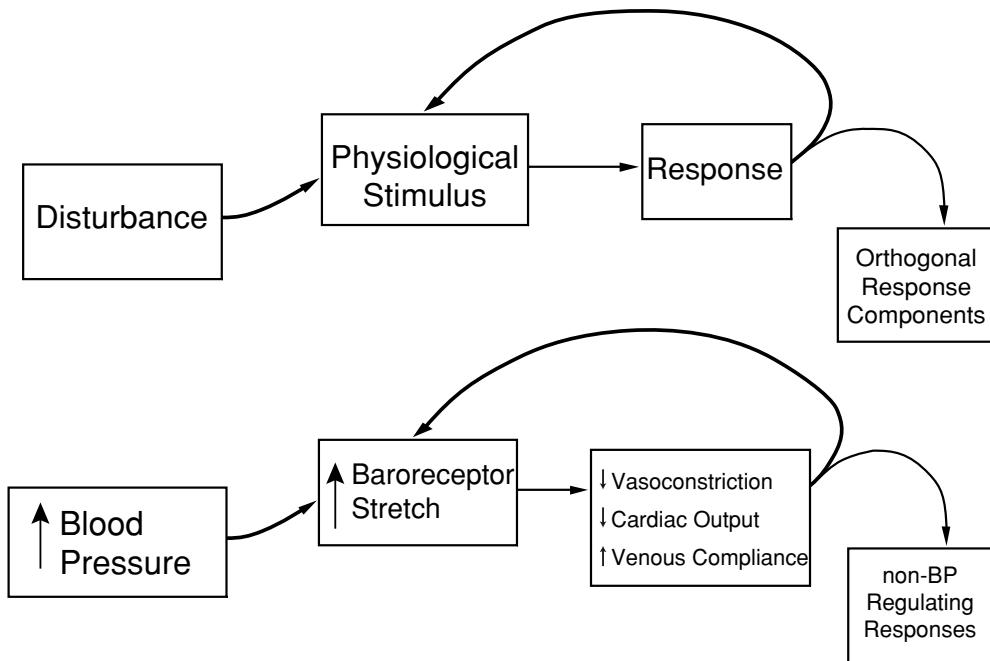

Figure 21.2. The general scheme of an unconditioned physiological reflex (top) and the specific example of the baroreflex (bottom). The leftmost box represents the initiating events of the DISTURBANCE. These events along with the non-orthogonal components of the RESPONSE determine the PHYSIOLOGICAL STIMULUS. The events of the DISTURBANCE form a sequence in time and, thus, the physiological component of the DISTURBANCE is, itself, a function of time. In the baroreflex example a rise in blood pressure distends the blood vessels, and thus stretches endings in the vessel walls. This causes depolarization and firing, which is propagated via afferent fibers in the aortic depressor nerve (ADN), the superior laryngeal nerve (SLN), the vagus and the glossopharyngeal nerve to synapses in nucleus of the solitary tract (NTS). Fibers from the NTS distribute to the cardioinhibitory and vascular depressor centers of the brain stem where efferent activity to the heart and blood vessels is modulated. With increased blood pressure, the modulation is achieved by (somatoinhibitory) reduction of arterial resistance, relaxation of the veins, reduction of the pressure and volume ejected in each cardiac cycle; and (parasympathetic excitatory) slowing of the heart. The net result of this action is a decrease in blood pressure toward the pre-rise baseline, which restores the stretch on the baroceptor endings to the original level, and thus terminates the reflex activity.

It has been thoroughly accepted for nearly 100 years that conditioning can directly modify visceral function. Pavlov's first conditioned reflexes, secretion of gastric juice and saliva, were both glandular responses, and since Pavlov, psychologists and physiologists have established a large literature on classical conditioning of autonomic reflexes, including salivary, sudomotor, cardiac, vascular, pupillary, and gastrointestinal.

Kinds of conditioned reflexes: The common CSs of the conditioning paradigm are sounds, lights, tastes and odors, but, pertinent to the topic of this chapter, various interoceptive stimuli, are also effective conditioned stimuli. In fact, on the basis of the sensory mode of the conditioned and unconditioned stimulus, there is a logical fourfold classification of conditioned reflexes:

- (1) Extero-exteroceptive conditioned reflexes associate a weak exteroceptive stimulus such as, a sound, light or vibration, with a stronger, reflex eliciting, somatosensory stimulus such as electric shock.

Elaboration of extero-exteroceptive conditioned reflexes is usually technically straightforward and reliable;

and, typically, they are both rapidly acquired and stable. Extero-exteroceptive conditioned reflexes are most commonly used in research where the focus is on such things as neurophysiological mechanisms of association; the effects of general variables such as stress, diet, or aging on the discrimination, acquisition, retention, or extinction; or in other studies where the need arises for a convenient generic fragment of learned behavior to be used as a dependent variable.

- (2) Extero-interoceptive conditioned reflexes associate a weak exteroceptive stimulus such as a sound, light, or vibration with a stronger, reflex eliciting, visceral stimulus such as food induced gastric secretion, irritant induced salivation, or electrical baroreceptor activation.

Extero-interoceptive conditioned reflexes are usually more circumscribed in effect, and both the creation of the unconditioned stimulus and the measurement of the response are, technically, more involved than for extero-exteroceptive reflexes. Pavlov studied extero-interoceptive reflexes as components of the “cephalic” phase of digestion; however, he also extensively used conditioned salivation, as a “generic” learned response,

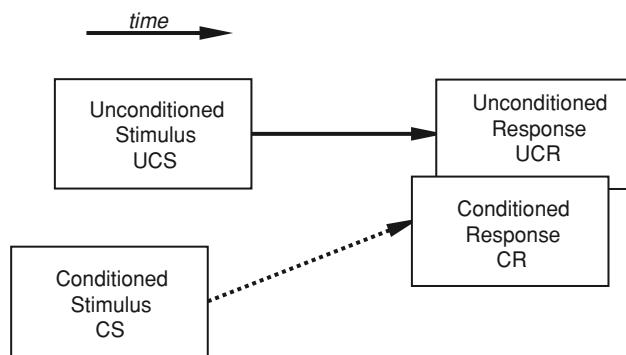

Figure 21.3. The traditional conception of the relationship among stimuli and responses in the classical conditioning paradigm

to study general aspects of association. In recent years, visceral conditioned reflexes have been only rarely used as general indices of behavior; however, there are many recent extero-interoceptive conditioning studies. These have concerned the role of context conditioned compensatory responses in the development of tolerance to drugs (Siegel, 1983; Siegel, Krank, & Hinson, 1987), and in adaptation to specific physiological stresses, such as induced shifts in blood pressure (Dworkin & Dworkin, 1995), blood glucose (Siegel, 1972) or temperature (Siegel, Krank, & Hinson, 1987).

(3) Intero-exteroceptive conditioned reflexes associate an interoceptive stimulus, such as distention of the small intestine, carotid sinus, or renal pelvis with an externally produced skeletal motor reflex, such as shock induced paw withdrawal. The usual goal is to estimate the detectability and discriminability of particular interoceptive stimuli. The conditioned response is a substitute for verbal behavior in infrahuman species, and, in certain special cases, with humans. Examples of this paradigm are discussed below with respect to visceral perception. In a variant of this paradigm the response is an operant, such as bar pressing, which is brought under control of an interoceptive stimulus, such as intra-intestinal pressure (Slucki, Adam, & Porter, 1965).

(4) Intero-interoceptive conditioned reflexes associate an interoceptive stimulus, such as distention of the small intestine, carotid sinus, or renal pelvis, or thermal stimulation of the stomach, or osmotic stimulation of the liver, with a visceral reflex, such as food induced gastric secretion or fluid load induced renal secretion, or the activation of baroreflex. More than 30 years ago Àdam wrote:

It seems likely that temporary connections initiated by visceral receptors and affecting both vegetative and somatic functions are being continuously established and extinguished, while never becoming conscious. On the basis of our experimental data we suppose that the unconscious interoceptive sphere, too, has a 'memory', i.e., an ability to retain experience, which helps adaptation to changes in the environment. (Adam, 1967, pp. 139-40)

Outside of Eastern Europe intero-interoceptive conditioned reflexes have been little studied; technically, they are comparatively quite demanding: Elaborating a clearly defined intero-interoceptive reflex typically involves performing several separate chronic surgical procedures to prepare access for application of the conditioned and the unconditioned stimuli, and for measurement of the response. Nonetheless, the intero-interoceptive reflex is probably of great importance in physiological regulation. In the quotation from Pavlov which began this chapter the phrase "a constant, correct, and precise correlation becomes established among the parts of an organism" almost certainly refers to intero-interoceptive conditioning.

In fact, normal anatomical juxtaposition of receptors creates many arrangements in which the temporal requirements of conditioning are automatically satisfied. For example, the essence of coordinated GI function is that partially processed chyme leaves one segment and enters the next. In principle, intero-interoceptive conditioning could coordinate action among different parts of the gut. For example, distention in a proximal gut segment could trigger conditioned reflex secretion or motility in a more distal segment. If an oral segment had the necessary receptors, entering chyme could activate these and produce a conditioned stimulus; then, as the chyme entered the next segment, it could produce an unconditioned secretory or motor stimulus that completed the paradigm; thus, with sufficient repetition (conditioning trials), the distension of the oral segment would trigger digestive activity in the aboral segment, which would effectively anticipate arrival of the chyme, and improve its digestion. This intero-interoceptive paradigm parallels the extero-interoceptive

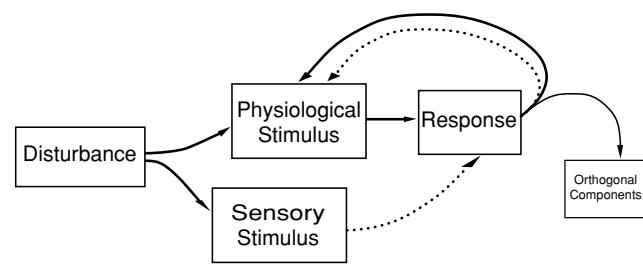

Figure 21.4. A modified conception of the classical conditioning paradigm for visceral reflexes that emphasizes the interaction between conditioned (dotted path) and unconditioned (solid path) reflexes. This revised scheme and terminology puts the conditioning process into a more biologically consistent framework: The Disturbance is an initiating event that changes the physiological and sensory state. It gives rise to a Sensory Stimulus and a Physiological Stimulus. The Sensory Stimulus is clearly the same as the conditioned stimulus, but there is ambiguity in the literature concerning the proper physiological identity of the unconditioned stimulus and unconditioned response. The unconditioned and conditioned responses are together equivalent to the Response; thus, the Response is the total regulatory reaction of the nervous system to the Disturbance (the “Orthogonal components” are other non-regulatory response components) (Dworkin, 1993, see Chapter 3).

paradigm, which Pavlov called the “cephalic phase” of digestion, wherein the sight or aroma of food is the conditioned stimulus that triggers anticipatory salivary or gastric secretion. The Russian physiologists took this general schema quite seriously. Their ideas remain provocative, but their experimental studies (see below) (Bykov, [1942] 1957, pp. 231–279; Bykov & Kurtsin, [1949] 1966, pp. 21–78) need to be replicated with better controls and appropriate statistical analyses.

When common drugs, such as morphine, or ethanol are repeatedly administered certain of their effects weaken, that is, the subject becomes tolerant to the drug. It is now accepted that conditioning of reflex compensatory responses elicited by the drug effects, is an important part of tolerance. The key studies establishing the role of conditioning in drug tolerance have effectively exploited the differential extero-interoceptive paradigm: specific environmental cues (tones, lights, odors, etc.) that could be manipulated were the CS, and the physiological effect of the drug was the UCS. Although the cumulative evidence from these studies showing that conditioning has a role in tolerance is convincing, there have been some contradictory reports. A plausible explanation of these exceptions is that “interoceptive” stimuli produced by the drug, during initial absorption, called “drug onset cues” (DOCs), can function as a potent CS, and “overshadow” explicitly manipulated, but less relevant, environmental stimuli. Because, these DOCs are inextricable from the drug administration, it is difficult to directly manipulate them; recently however, Siegel and his colleagues have described a series of trenchant experiments that convincingly distinguish the effects of the DOCs from the exteroceptive environmental cues (Kim, Siegel, & Patenall, 1999; Sokolowska, Siegel, & Kim, 2002). On the basis of their observations there appears to be little doubt that the DOCs have an important role in drug tolerance. However, whether the DOCs are, in fact, interoceptive stimuli, requires systematic exclusion of possible effects of the initial drug levels on the receptive fields of non-visceral receptors; for example, effects on visual or cutaneous receptors.

Heterotopic or homotopic conditioning: Within cases (1) and (4) above, it is possible to make the additional logical and biologically important distinction of whether the conditioned and unconditioned stimulus are applied in separate or the same sensory modes. For conventional or *heterotopic* conditioning, the CS and UCS are in *different sensory modes*; for example, the CS can be an auditory tone, followed by a UCS of an electric shock to a finger tip. After repeating this stimulus combination many times or “trials,” a withdrawal reaction develops to the sound, and the emergence of this new response is evidence of conditioning. For *homotopic* conditioning, both the CS and UCS are applied in the *same sensory mode*. In a roughly parallel example, the CS would be a mild electric current applied on a finger tip, followed by a UCS of a *stronger* current on the same finger tip: With repetition, the withdrawal reaction to the milder CS current will gradually strengthen

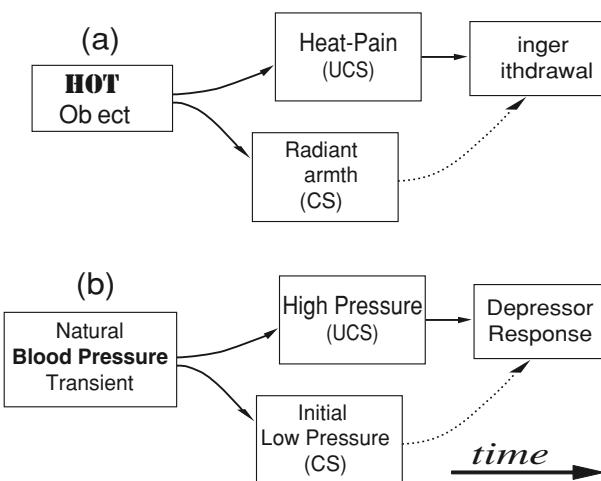

Figure 21.5. For the simple example of avoiding being burned by a sometimes hot object (a), homotopic conditioning effectively calibrates the sensory threshold of the defensive withdrawal reflex. By similarly calibrating visceral reflexes, such as the example of the baroreflex in (b), interoceptive homotopic conditioning could have an important role in autonomic regulation.

from what it was at the start. The *quantitative change* in the withdrawal response to the weaker current is the measure of conditioning.

There are many commonplace natural adaptations that fit the extero-exteroceptive *homotopic* paradigm. A simple case is the conditioned response that helps in avoiding burns from objects that are sometimes hot: the CS is the radiated warmth that is first sensed as the fingers approach the object, and the UCS is the heat-pain in the fingers on contact: The heat-pain activates a reflex withdrawal, and gradually with “experience,” that is, with the accumulation of conditioning trials, the sensation of warmth, that is the CS by itself, triggers the protective withdrawal (see Figure 21.5). If the sensory effects of drug onset cues are, in fact, visceral, then drug tolerance probably involves intero-interoceptive homotopic conditioning. In addition to the morphine tolerance studies cited above, conditioned hyperthermia has been produced using a low dose of ethanol as a CS, and a higher dose, which produces a clear hypothermia, as a UCS (Greely et al., 1984). In ethanol thermic conditioning, the UCS is hypothermia, which is due to vasodilatation and consequent heat loss to the environment; the hypothermia activates compensatory metabolic reflexes, which become conditioned to the CS (Dworkin, 1993, for an analysis of the mechanism see pp. 109–115).

In fact, in a neurophysiological sense, the general properties and cellular anatomy of homotopic conditioning probably closely parallel those of heterotopic conditioning. This is because for most sensory systems, over a wide stimulus range, coding of stimulus magnitude is not confined to increased firing rate, but also involves successive recruitment of higher threshold receptor populations. For example, there are two classes of heat sensing receptors in the fingers: “warmth” receptors, which respond with

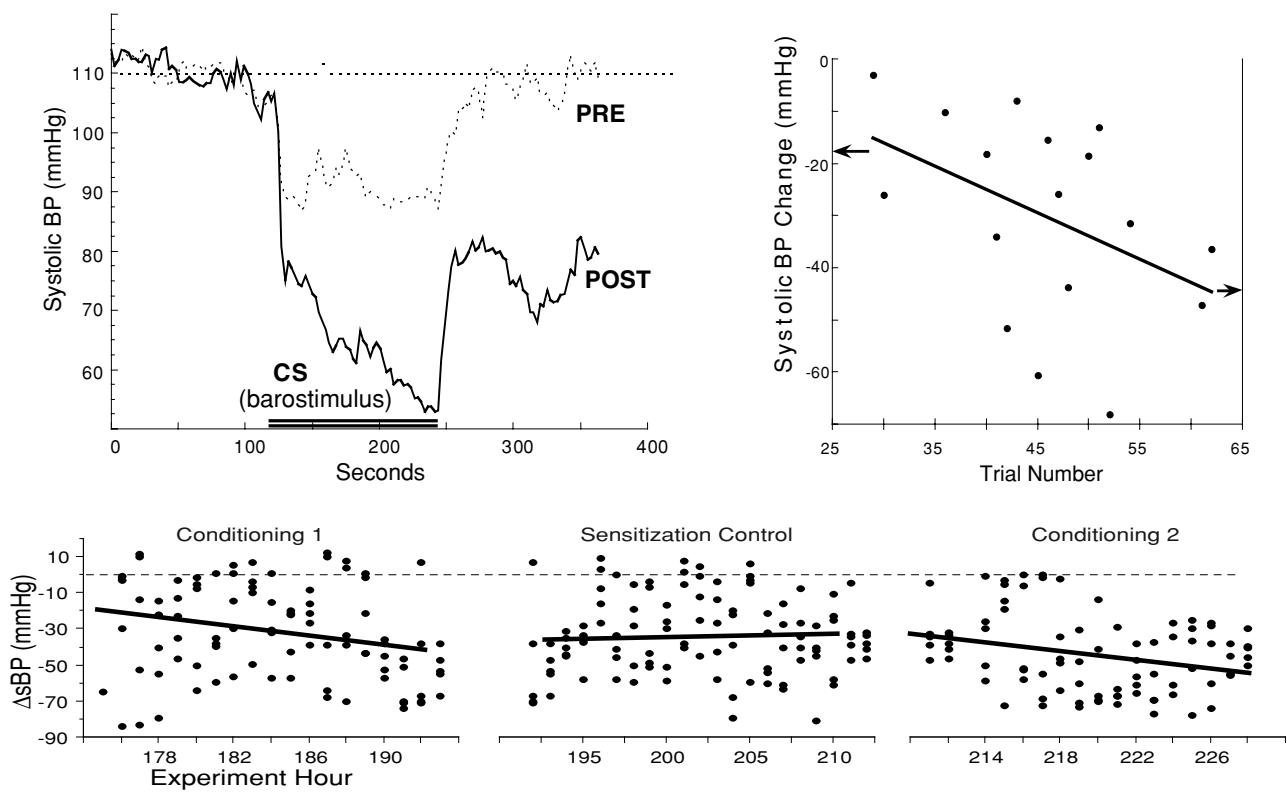

Figure 21.6. Homotopic conditioning of the baroreflex: A rat experiment in which the CS was A-fiber ($25 \mu\text{A}$, $100 \mu\text{s}$, 100 ips) and the US, A + C-fiber stimulation ($125 \mu\text{A}$, $200 \mu\text{s}$, 5 ips). Each sequence was 18 h (90 trials). The top left panel shows the response of a 5 Hz electrical stimulus (the CS) applied to the aortic depressor nerve of a rat, before (pre) and after (post) the CS had been paired with a 25 Hz UCS to the same nerve in a classical conditioning procedure. The top right panel shows the magnitude of the blood pressure response to the 5 Hz (CS) stimulus as a function of the number of conditioning trials (N.B. that the conditioned response is a blood pressure decrease). The effects are in the direction predicted for homotopic conditioning and statistically reliable. The bottom panel shows another homotopic conditioning experiment in which the CS was A-fiber ($25 \mu\text{A}$, $100 \mu\text{s}$, 100 ips) and the US, A + C-fiber stimulation ($125 \mu\text{A}$, $200 \mu\text{s}$, 5 ips). Each sequence was 18 h (90 trials). All of the effects are in the direction predicted for homotopic conditioning and statistically reliable.

increasing discharge rate to temperatures between 32 and 45°C , and heat-pain receptors that begin to fire at only $>45^\circ\text{C}$. As discussed above, the baroreceptors also have this kind of intensity-channel coding arrangement: In their study of the carotid receptors, Bronk and Stella observed that: "...wide variation in threshold for different receptors" (Bronk & Stella, 1932; Bronk & Stella, 1935). Thus, just as do the separate modalities of heterotopic conditioning, the neural representations of the *different strength* homotopic CS and UCS probably enter the CNS over separate axons and project to different synapses.

In the laboratory, homotopic conditioning has been studied much less than heterotopic, in fact, hardly at all; but, there is nothing in conditioning theory that prefers that the CS and UCS be from different sensory modalities; to the contrary, among learning theorists, the usual notion is that the more similar or related are the CS and UCS, the more easily conditioning can occur. In fact, the paucity of research on homotopic conditioning is more likely due to certain practical difficulties in doing the experiments. Although, the homotopic CS is a

relatively weak stimulus, when applied at the receptive field of the unconditioned reflex, before any conditioning has taken place, it measurably activates the reflex. Thus, studying homotopic conditioning requires, at least, the ability to make a reliable *quantitative measurement* of the change of the conditioned response strength from the beginning and to the end of conditioning. For the comparison to be meaningful, the state of the subject must be stable, the response measurements accurate, and the proximal stimuli constant (see Figure 21.6). Because conditioning takes time, these stringent criteria must be met throughout the many hours, or even several days, of an experiment, and the difficulty in accomplishing all of this is probably why intero-interoceptive homotopic conditioning has not been more extensively investigated by psychophysicists and regulatory physiologists.

Early work on interoceptive conditioning: Probably the first explicit description of an interoceptive conditioned reflex was in 1928 by Bykov and Ivanova (Bykov, [1942] 1957, pp. 246–7). They performed a urinary secretion conditioning experiment in which an unconditioned

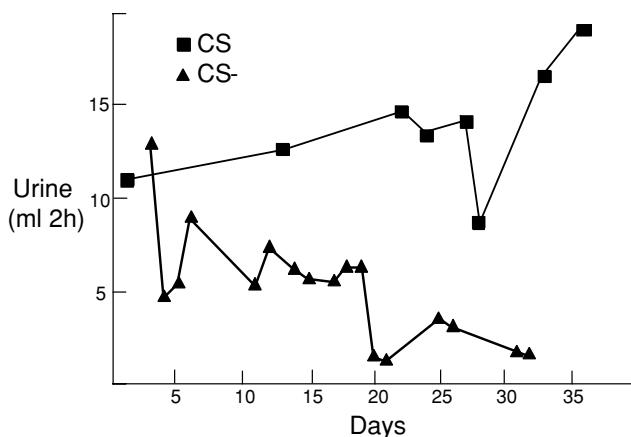

Figure 21.7. This Soviet era experiment used two distinctive stimuli. The “active” stimulus was the a distinctive room where the UCS was administered; the “differential” stimulus was a second dissimilar room, also equipped for measuring urine output. In the “active” room water was administered per rectum and urine collected; in the “differential” room, urine was collected, but no water was administered. The plot shows the daily urine output in the two rooms measured before any water was administered. Initially, the urine output in the differential room was nearly the same as it had been in the active room; this is a typical generalization effect in classical conditioning. As the trials progressed the rate of urine output in the differential room fell; at the same time the urine output in the reinforced room continued rising; thus, a discrimination formed. Bykov described several similar experiments with other dogs, one in which the water load was given by mouth, and another discrimination experiment that used two distinctive bell sounds as conditioned stimuli.

stimulus of 200 ml saline, was infused into a dog's stomach directly through a chronic trans-abdominal fistula. After giving approximately 25 infusions they began to observe that the dog secreted urine as soon as the gastric mucosa was wetted, before a physiologically significant amount of saline was introduced. Eventually they found that if saline was briefly introduced and removed, before it could be absorbed, urine flow developed that was of smaller magnitude, but of similar time course, to that caused by the full load. They designated this an intero-interoceptive conditioned reflex, because both the conditioned stimulus and unconditioned stimulus were interoceptive stimuli. Figure 21.7 describes a similar “discriminative” version of this experiment.

In other Russian experiments, designated “intero-exteroceptive,” the conditioned stimulus was interoceptive, but the unconditioned stimulus was exteroceptive. For example, the conditioned stimulus of wetting the gastric mucosa was repeatedly paired with an electric shock to the paw, resulting in conditioned paw withdrawal. Airapetyantz, (Bykov, [1942] 1957, pp. 249–51) another of Bykov's coworkers demonstrated the formation of a discrimination between 26°C and 36°C intragastric water. After 150 trials in which a salivary unconditioned stimulus followed a 36° but not (otherwise identical) 26° water infusions, only the 36° stimulus produced a reliable flow of saliva. Airapetyantz and his associates also did a number of similar experiments with other intestinal interoceptors

as conditioned stimuli, for example, they formed discriminated salivary responses to pH and temperature stimuli in isolated intestinal segments.

The general conclusions of the Eastern European scientists were that interoceptive conditioned reflexes, when compared to their exteroceptive counterparts, required a larger and more variable numbers of trials to become stable; however, that once formed, interoceptive reflexes had the essential characteristics typical of exteroceptive reflexes, including inhibition of delay and susceptibility to disruption by novel stimuli (external inhibition).

IS DRIVE NECESSARY FOR FORMATION AND CONSOLIDATION OF A CONDITIONED RESPONSE?

The standard conception of the classical conditioning paradigm is shown in Figure 21.3; Figure 21.4 extends the paradigm for visceral reflexes to include the feedback mechanisms of regulation, and emphasizes that, for visceral reflexes, the conditioned response also can have important regulatory consequences. Nonetheless, both figures presume a similar, relatively uncomplicated, and traditional neurophysiological conception of classical conditioning: Beginning with Pavlov, and for the 50 years following him, the central dogma was that the temporal contiguity of a neutral stimulus and a reflex formed an association; however, McGaugh's work in the 1960s suggested that learning, especially consolidation, in distinction to formation of an association, might be affected by pharmacological manipulation of relatively non-specific central adrenergic and cholinergic mechanisms (McGaugh, 1966); also, that certain kinds of natural stimuli also might influence consolidation (McGaugh, 1989). There is evidence that aversive stimuli, such as shock, can enhance the retention; that shock also activates central adrenergic mechanisms, and that the amygdala and its major pathway, the stria terminalis, are involved in both the pharmacological and shock effects. If these findings prove valid for interoceptive reflexes, such “motivational” influences on conditioning could have implications for the plasticity of regulatory mechanisms.

In the preface to the 1957 English edition of *The Cerebral Cortex and the Internal Organs*, Bykov wrote, “The higher regulating apparatus determines and preserves the unity and integrity of all the complex executive organs and tissues, receiving information through the extero- and interoceptors. The cortex is *at every moment* determining the fate of every reaction of the organism.” Reading Bykov's book leaves little doubt that he meant that there was a continuous formation and extinction of conditioned reflexes, with each successive association slightly changing the visceral regulatory network.

This view of an ongoing calculus, continuously reorganizing and adjusting the network to optimum (Dworkin, 1993, see Chapters 3 and 4) is possibly entirely correct; however, interoceptive conditioning also could be *saltatorial*: that is, new synaptic connections might form, or

connection strengths be modified only infrequently and under special circumstances, for example, when the extant central visceral network does not adequately constrain the physiological state within limits that are compatible with the adjustment capacity of non-neural peripheral mechanisms (Dworkin, 1993, see Ch. 6 pp. 118–122). Thus, for central connections to be modified, in addition to stimulus association, a net homeostatic imbalance also might need to be present. By activating visceral receptors, the imbalance would, in a manner similar to shock or direct neurochemical manipulations, activate central adrenergic mechanisms (Gold, 1984), possibly via the amygdala (McGaugh, Cahill, & Roozendaal, 1996), and enable consolidation.

Traditional conceptions of learning distinguish between the classical and operant conditioning paradigms, and the suggestion of a dependence of synaptic modification on “homeostatic imbalance,” inevitably brings to mind the operant model’s distinctive features of motivation or drive; and reinforcement or drive reduction (Dworkin, 1993, see Chapters 7 and 8). However, there is a substantial difference: in the operant model, the strengthening of a particular response requires, specifically, that the response bring about (or at least be well correlated with) a reduction of the homeostatic imbalance; whereas, in this “drive dependent” view of classical conditioning, the postulated neurochemical effects of the imbalance only must be present during and/or following the association of the CS and UCS.¹³

PERCEPTION OF THE VISCERA AND VISCERAL INFLUENCES ON BEHAVIOR

Historically “interoception” has had a number of different meanings. In addition to the well documented regulatory functions already discussed, interoceptors have been attributed more general perceptual functions that parallel those of the receptors of exteroception and proprioception. It is through exteroceptors that we develop a detailed functional model – a conscious perception – of the environment, and similarly through proprioceptors, that we apprehend the position and motion of the parts of our skeleton in space. The conscious perception of visceral states, and the control of autonomic and skeletal behaviors, including verbal reports of visceral stimuli are also potentially important. But unlike exteroception and proprioception, which are clearly phenomenologically valid,

¹³ The distinction between the classical, and operant or instrumental, paradigms is actually less definite: Although B. F. Skinner conceived of the operant response as a strictly random event (Skinner, 1981), in Neal Miller’s reformulation of instrumental learning (Miller, 1959) response probabilities (which determine the order of the “response hierarchy”) became a deterministic function of the motivational (drive) state, which, itself, is subject to classical conditioning. Especially for physiological regulatory responses, Miller’s idea of a response-determining drive (interoceptive stimulus) state fittingly brings together instrumental, and drive dependent classical, conditioning.

robust, and functionally important, there remains some reasonable doubt about whether conscious perception of the viscera is other than a comparatively fragile laboratory curiosity. There is no doubt that, for most visceral organs, sufficiently strong stimulation produces a conscious perception of pain; however, although there has been extensive and excellent work on visceral perception, it is not entirely established whether, under normal circumstances, except for some special cases, such as gastric “hunger”¹⁴ contractions, there is general awareness of sensations from sub-noxious stimuli in the *deep* internal organs. Furthermore, if substantial non-pain conscious awareness of the deep viscera does exist, its function, if any, is unknown.

Typical dictionary definitions distinguish “sensation” as the immediate result of a “sensory input” from “perception,” which involves a combination of sensations, as well as memory of past sensations. Psychologists often further distinguish perception from discrimination, which is the ability to distinguish stimulus levels and/or stimulus qualities. This distinction is important; however, it is necessary to also recognize that without there being direct perception or discrimination of the stimulus, a visceral stimulus can have substantial effects on perception and sensation.

For example, baroreceptor activation reduces the arousal level; and attenuates both spinal level reflexes, and the reported painfulness of noxious stimuli (Dworkin et al., 1994). But, most naive human subjects can not reliably distinguish baroreceptor activation conditions from control conditions (Furedy et al., 1992); thus, baroreceptor activation, itself, is probably not directly perceived or discriminated. This is an example of where, without being directly perceived, a visceral stimulus can measurably affect behavior and the perception of other stimuli. Parallel phenomena have been described for the abdominal organs: For example, Kukorelli and Juhász showed that EEG synchronization and sleep could be induced by levels of sub-noxious stimulation of the intestine and abdominal nerves (Kukorelli & Juhász, 1976, 1977), which probably would not be directly perceived.

The control of ingestion is the most extensively studied and analyzed example of interoception. The first modern observations of intestinal perception were made by Walter B. Cannon with his student Washburn. Using simultaneous kymographic recording of intragastric pressure and behavioral responses, they observed a temporal relationship between gastric contractions and “hunger pangs”(Cannon & Washburn, 1912). These observations (in which Washburn was the subject) are illustrated and described in Figure 21.8, and the accompanying legend. Largely on the basis of these and other “correlational” studies using kymographic or radiographic measures of intestinal movement, Cannon concluded that the experience of hunger derived from the perception of gastric

¹⁴ In fact, Cannon described hunger as, “a very disagreeable ache or pang or sense of gnawing or pressure which is referred to the epigastrium” (Cannon, 1939, p. 70); thus that hunger is a “non-noxious” interoception is at least arguable.

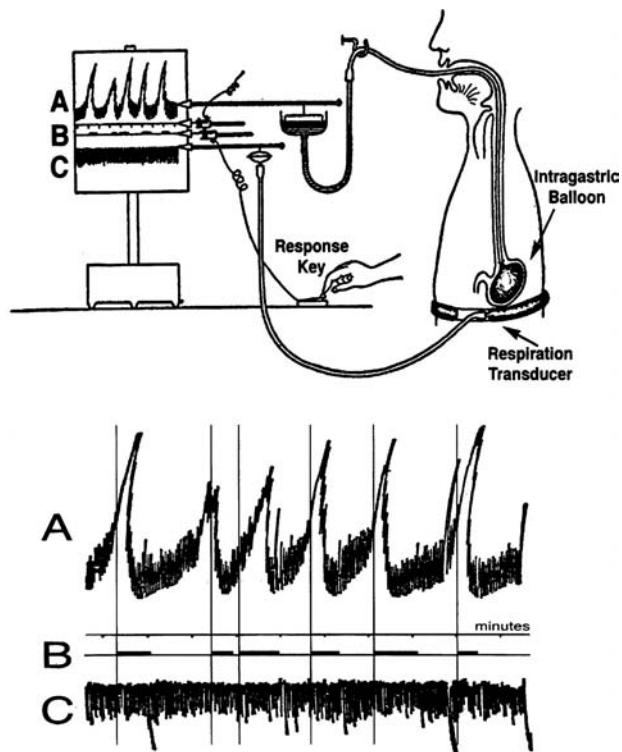

Figure 21.8. (top) Cannon's student, Washburn, learned to swallow a balloon, which registered the contractions of his stomach. Another transducer was placed around his abdomen to register the movement of his abdominal muscles. When Washburn perceived a "hunger pang" he pressed the response key. The entire set of events was recorded on a kymograph, a primitive polygraph device, as a function of time. (bottom) The record shows the relationship between the gastric contractions and the "pangs." Cannon concluded two things from this record: first, that the perception was related to stomach contractions, not to movements of the abdominal wall, and second, that the contractions preceded the perception in time. Cannon's original figure did not include the vertical cursors, which have been inserted in this version: he said that the "hunger pang" was not recorded until the contraction had nearly reached its peak"; yet the cursors show that the "pang" marker always begins quite early in the contraction, and that the relationship is, in fact, more variable than might be expected from a simple coupling.

contractions.¹⁵ However, by the mid-century a substantial body of data accumulated in conflict with Cannon's simple "gastric perception" model of hunger: For example, in humans, most of the stomach can be excised or the vagus nerve severed, without loss of either hunger motivation or the experience of hunger.

Nonetheless, in contrast to the clinical evidence that peripheral signals are not essential to the experience of hunger, sophisticated laboratory studies have clearly impli-

¹⁵ Cannon also had a similar conception of thirst. William James anteceded Cannon at Harvard, and in Cannon's time James's ideas about emotion were still influential. Although Cannon expressed doubt about the physiological basis of the peripheral emotion theory of James and Carl Lange, in fact, his conception of motivation unquestionably paralleled it.

cated gastrointestinal stimuli in the interoceptive control of *ingestion* (McHugh & Moran, 1985). Hunt showed that the osmotic pressure of the chyme influenced both gastric motility and the rate of gastric emptying; and that energy content and volume were also important control stimuli (Hunt, 1961; Hunt & Stubbs, 1975), and Mei found specific glucoreceptors in the small intestine (Mei, 1978). Additional studies of the control of motility, gastric emptying, and satiety, have focused on the role of gastric load, mechanical and chemical properties of intestinal contents, and various hormonal receptors, particularly those sensitive to, the octapeptide, cholecystokinin.

The work of McHugh, Moran, and Schwartz is especially notable in emphasizing the integration of various stimuli by individual interoceptors. For example, Schwartz and Moran (1996) have described the additive effect of cholecystokinin on the firing rate of intraluminal volume sensitive vagal afferents. Using a sophisticated rat preparation (see Figure 21.9, left), they showed that isolated single vagal afferents had polymodal sensitivity, "responding to both mechanical stimulation...and to exogenous administration of a peptide that is released by the duodenum presence of nutrients." Pre-treatment with cholecystokinin caused the vagal gastric mechano-sensitive afferents to fire at a higher rate for the same load. At concentrations of cholecystokinin, or at intragastric volumes, that individually were too low to activate the afferents, prior application of cholecystokinin produced rapid firing to the volume stimulus (see Figure 21.9, right); thus, operating within a classical regulatory mechanism, cholecystokinin and mechanoreceptor effects apparently summate and enhance the activity of the efferent limb of appropriate digestive reflexes. Because effects of the compound stimulus were effective at levels that individually were ineffective, at low stimulus levels, the effects have features of a multiplicative interaction. If the subthreshold levels used in the analysis are in the normal physiological range, then an interaction would have regulatory implications beyond simple summation; however, given the apparent linearity of the combined suprathreshold effects (see Figure 21.9) it is more probable that the afferents are polymodal and that the cholecystokinin and mechanical receptors, are distinct structures that independently produce additive effects. This means that either cholecystokinin or gastric load would have similar functional consequences in the CNS; in other words, that for reflex activation, neither depends upon the other.

In a conceptualization, somewhat reminiscent of the Russian School, Moran and Schwartz (Schwartz & Moran, 1996, p. 49) have emphasized the general perceptual nature of the complex stimulus patterns that arise in the gut: "Furthermore, we view the constellation of meal-related stimuli arising from several gastrointestinal compartments as comprising a context representative of the internal milieu during a meal.... Thus, it is critical to establish responses to individual properties

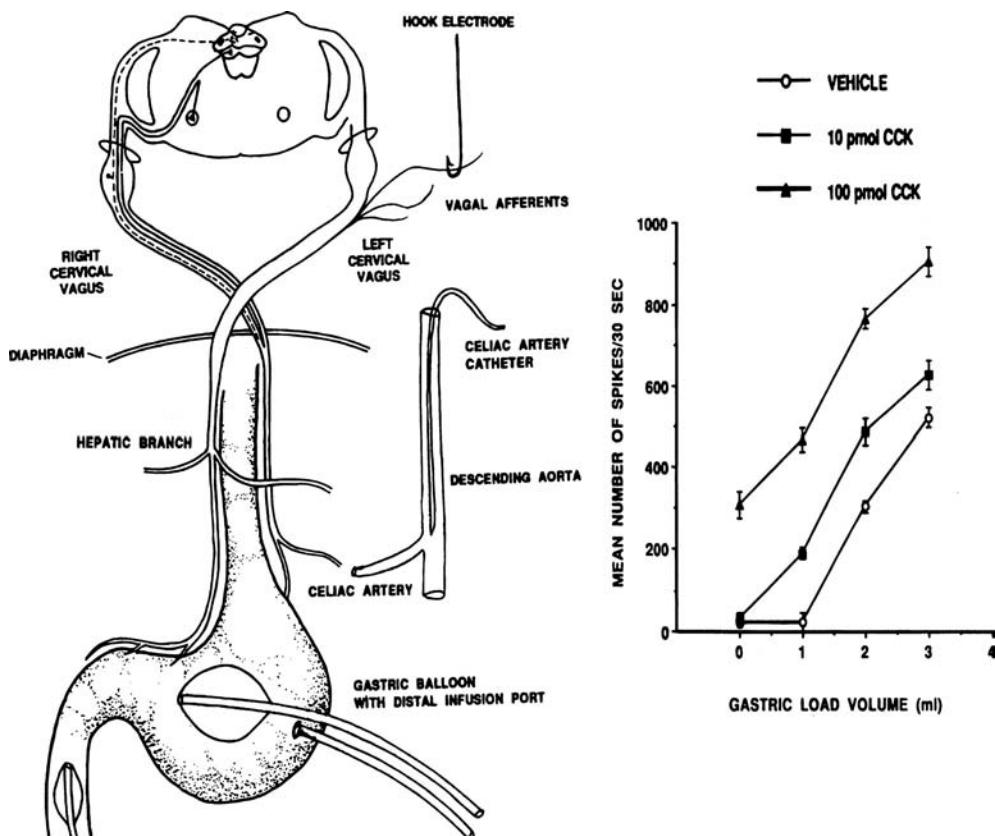

Figure 21.9. The preparation used by Schwartz and Moran for analysis of the interaction of the effects of cholecystokinin and mechanical (volume) distention on single vagal afferent fibers with receptors in the stomach. The left panel shows the experimental preparation, which enables simultaneous stimulation of gastric mechanoreceptors, infusion of CCK into the celiac artery and recording of afferent activity in single vagal fibers. The right panel shows the effect of various doses of CCK on the response of vagal afferents. Note that at higher doses the effect is additive.

and then elucidate the integrative capacities of sensory afferents responding to combinations of properties likely to occur in the context of a meal in the gastrointestinal tract.” It remains to be determined whether, in understanding complex integrative processes, this quasi-cognitive formulation has advantages over explicit algebraic control-theoretic, or statistically based “autonomic space” (Berntson, Cacioppo, & Quigley, 1991) formulations of the same effects.

Innate and learned conscious perception: In that stimulation that does not normally reach consciousness can have detectable behavioral effects, it is arguable that given the possibility of learning, a non-conscious stimulus could eventually become conscious. For example, if a non-conscious *conditioning* stimulus affects general arousal or modifies the conscious perception of other stimuli, with appropriate discrimination training, a subject should be able to acquire the capability to estimate and report, at least indirectly, the presence and/or intensity of the *conditioning* stimulus itself. Discrimination training is known to be helpful in reestablishing bowel continence in adults (Whitehead & Schuster, 1983); it is also likely an important factor in the normal development of the perception

of bladder and rectal distention, and is almost certainly involved in the primary establishment of fecal and urinary continence. Experimental results, discussed below, indicate that the perception threshold for bowel distention can, in fact, be lowered with training.

Whether normal consciousness of interoceptive stimuli, any more so than consciousness of exteroceptive or proprioceptive stimuli, requires discrimination practice is not known. A more biological way of putting this same question is to ask, Does the neuroanatomy of interoception provide access to the neurophysiological substrates of consciousness, equivalent to that of exteroception or proprioception? Without doubt, various forms of this question tacitly motivate much of interoception research; however, at present, our understanding of what consciousness is (and isn’t) neurophysiologically, and conceptually remains sufficiently immature that it is difficult to know where to start seeking an answer. Notwithstanding, it is clear that neither interoception or consciousness are homogeneous classes of phenomena, and that both interact with, are affected by, and effect changes in behavior; thus, without getting into the nature of consciousness, some useful distinctions can be drawn.

Visceral sensations have obvious and direct effects on behavior, but the selectivity and sensitivity of different tissues varies enormously. For conscious perception, and other effects on behavior, the strength of a stimulus and its anatomical site of application interact.

Strong visceral stimuli can function in two ways: First, because various unconditioned defensive reflexes confer a survival advantage, they were selected and well conserved during the evolutionary history of the species. Strong visceral stimuli can promptly activate these simple defensive reflexes that directly and efficiently ameliorate the visceral irritation. Second, in addition to specific reflexes, general mechanisms of behavioral reinforcement and learning were also established during evolution. Acting through these mechanisms, pain or discomfort of visceral origin mobilizes more complex and flexible sequences of behavior. In contrast to the specific reflexes, motivated sequences are not focused, and do not immediately ameliorate the initiating stimulus; however, because the reduction of pain or discomfort is a powerful behavioral reinforcer, *for a given individual*, those behavioral sequences, which reliably antecede pain reduction, have a high probability of being selected and strengthened by learning mechanisms.¹⁶

Distention of the urinary bladder is a straightforward example of both kinds of interoceptor effects: The muscle of the bladder wall, the detrusor, contains mechanoreceptors; extreme distention strongly activates these receptors and triggers an organized reflex that incites prompt “involuntary” enuresis; whereas, moderate bladder distention *motivates* a more elaborate and variable pattern of behavior that potentially leads to better controlled and more convenient micturition. This sequence is then reinforced by relief of the aversive sensations from the bladder. Another example of both mechanisms is mechanical or chemical stimulation of the nasal mucosa: Strong stimulation by an irritant produces greatly increased serous and mucous secretion, and sneezing, which together comprise a protective defensive reflex that can immediately clear the irritant from the upper respira-

tory tract; whereas, weaker stimulation *motivates* a more flexible and variable behavior pattern leading to more controlled expulsion of the irritant – for example, by blowing the nose into a handkerchief. Again, the successful sequence is reinforced by relief from the irritation.

In normal individuals both moderate and strong sensations from the mechanoreceptors of the detrusor are readily perceived, and the presence of a nasal irritant is also easily recognized. However, recognition of the irritant is not ipso facto required to activate simple reflexes, and awareness also may not be prerequisite for the irritant to have a motivational effect (Hefferline & Perera, 1963). Instead, the crucial factor is whether the neural activity, generated by the receptor, reaches the integrative centers where an appropriate effect is initiated.

It could be asserted that bladder distention and nasal irritation are special cases because, although the receptors involved are not actually on the body surface, they are just barely within it. In fact, this assertion has some merit, and in general, the distinction between exteroception and interoception is often not definite. A brief tour through the gastrointestinal tract illustrates this: From the top down, most everyone would agree that sensations of the lips are not interoception; most would also concur that sensations from the oral mucosa, and maybe even the pharynx should not be considered interoceptive. But, at the esophagus, the consensus would likely weaken. There are certainly reflexes, which are activated when things go wrong in the esophagus, there is pain (heartburn) and more moderate sensations as well. We perceive “burning” from too hot a beverage, and often even can sense the passage of a hot bolus down the tube; this is also true for very cold liquids or ice cream. We also are aware when something too large or dry has been swallowed and is having a difficult passage. On the whole, most sensations from the esophagus are unpleasant, but not necessarily “painful.” Esophageal sensations are not as well defined as those from more oral loci: spatial discrimination is less precise, and stimulus qualities are not as distinct. Aside from the special case of sensations associated with hunger, there little if any evidence of any entirely non-painful sensation from receptors in the stomach.

Beginning at the bottom and proceeding orally the sequence is similar: The anus has clear and detailed sensation; the rectum certainly has pain, distention, and probably some amount of temperature sensitivity. Activation of receptors in both regions can trigger both direct reflexes and motivate more complex behaviors: for example, toilet use. However, above the sigmoid flexure perception is again more equivocal. There are some laboratory data which show that, below the pain threshold, the colon has sensitivity to distention, and that stimuli in the descending colon, which are only several centimeters apart, can, after special training, be discriminated. But there is no evidence that different qualities, such as temperature and pressure can be discriminated.

¹⁶ Motivation might also be derived from positive sensations. Students of learning have long debated about the differences between the function of positive and negative sensations in eliciting reflexes and motivating behavior (Miller, 1959, 1966; Stellar & Stellar, 1985). For example, Pavlov used both weak acid and meat powder to elicit salivation (Pavlov, [1897] 1910). Acid is an obvious irritant, and the bicarbonate secretion of the salivary reflex neutralizes the acid, but is it reasonable to consider meat powder, in a parallel sense, also as an irritant? Probably not: The effects of the meat are more complicated, and this becomes evident when the acid or meat are used as behavioral reinforcers, to modify more general behavior, rather than as simple unconditioned stimuli. The reinforcing effects of the two on antecedent behavior are, in fact, opposite. Along related lines, the sensory effects of the intestinal hormone cholecystokinin have been the subject of vigorous debate. CCK produces satiety, i.e. simulating the sensory effects of a satisfactory meal (Smith & Gibbs, 1994), but at higher doses its effects more closely resemble nausea. Although nausea and satiety may have similar unconditioned effects on eating, the potential motivational consequences are likely quite different.

The small intestine has an extensive array of sensory receptors: Distention or surface irritation activates local peristaltic and other reflexes, which are mediated both by the intrinsic myenteric plexus, and extra-intestinal intersegmental pathways. For example, stimulating the duodenum or proximal jejunum by distention, acid or lipid, promptly inhibits gastric motility, and relaxes the stomach. Nonetheless, evidence of specific sub-pain level perception in either half of the small intestine is equivocal. Àdàm originally showed that sub-noxious balloon distension of the duodenal wall causes desynchronization of the EEG (Àdàm et al., 1965). He eventually extended this fundamental finding to a differential (two point) paradigm, which was mentioned above. The details of these studies were described in his monograph on interoception and behavior (Àdàm, 1967). More recently, to explore the sensibility of distal intestinal segments, Àdàm studied enterostomy patients. He found that some of these subjects could successfully discriminate moderate degrees of balloon distension of the small intestine; however, the subsequent inclusion of carefully designed control procedures in these studies showed that the apparent interoception was likely, at least in part, due to stretching of the overlying abdominal wall or the skin surrounding the papilla.

To do these enterostomy studies, Àdàm constructed a special intraintestinal catheter with an attached annular skin stimulation balloon. Using a similar but modified instrument, for colon stimulation in normal subjects, Hölzl extended Àdàm's findings, and developed a sophisticated signal detection analysis of the interaction of the skin and intraintestinal stimuli. In irritable bowel patients, Hölzl found that, depending on the temporal and spatial relationship among the stimuli, skin stimulation can either summate with, or mask, intestinal stimulation (Holzl et al., 1996). Hölzl has also analyzed these effects in terms of intra or intersegmental convergence of the sensory fields. His results in normal subjects and patients indicate that detection of stimuli is possible without the subjects awareness, but that "localization" requires stimuli sufficiently strong to produce "conscious subjective sensation" (Hölzl, Erasmus, & Möltner, 1996).

Concerning the conscious perception of visceral stimuli, in 1967 Görgy Àdàm said,

In summarizing, we tend to believe that in man the majority of interoceptive impulses influence behaviour without, however, causing any subjective sensation.... The question might now arise as to whether... visceral impulses entering consciousness actually occurs in conditions of normal life. It can be assumed that the interoceptive components of functions important for the individual (hunger, thirst) and socially (micturition, defecation) become conditioned in early childhood with exteroceptive stimuli, and the reinforcement of impulses other than these would constitute too great a stress for the higher nervous centers; in other words, to bring into consciousness such internal processes would be pathological.

– (Adam, 1967)

Although there remains little support for the notion that consciousness perception of the viscera can be "pathological," research in the intervening 35 years has not substantially contradicted Àdàm's basic conclusion.

SUMMARY

- (1) Almost all visceral structures have an extensive array of primary sensors, or interoceptors that are the sensory radix of the afferent limb of the dynamic visceral reflexes that stabilize the internal milieu. It is well accepted that many different unconditioned interoceptive reflexes have important physiological functions.
- (2) Interoceptive stimuli can function as conditioned stimuli for visceral and somatic conditioned reflexes, and these intero-exteroceptive, or intero-interoceptive reflexes may coordinate of various visceral-visceral and visceral-somatic relationships. Interoceptive conditioning is fruitful subject for further study with important implications for drug tolerance and autonomic regulation.
- (3) The special case of the homotopic conditioned reflex, particularly the intero-interoceptive form, could have a central role in drug tolerance and in calibration of the sensitivity and dynamic characteristics of visceral regulators, such as the baroreflex.
- (4) There is conscious perception of non-noxious stimuli from certain visceral organs; however as emphasized throughout this chapter, the validity of this conclusion depends on the definitions of "perception" and "visceral." For the most part, it can probably be said that normal perception of non-noxious stimuli is limited to special functions, such as hunger, or to special structures, such as the bladder or rectum. There is a strong possibility that conscious perception in special structures, especially those which communicate with the external environment, is not direct, and that perception exists, at least to a large degree, because of learned associations with more perspicuous proprioceptive and exteroceptive stimuli during ontogeny. Aside from certain well recognized special cases, it is not clear that conscious perception of visceral stimuli is important to normal physiological function.
- (5) Separate from conscious perception, there are well established effects of non-noxious interoceptive stimuli on higher CNS function and on behavior. Appropriate interoceptive stimulation can affect satiety, modify reflex activity or pain perception and produce EEG synchronization and sleep. In addition to their direct consequences, these "non-conscious" CNS effects may be substrates of associative processes involved in the development of conscious visceral perception.
- (6) All visceral sensory receptors adapt, and therefore do not provide the continuous negative feedback signals required steady state regulation through

conventional control mechanisms. If interoceptors do participate in long-term regulation, the mechanism, by which they do, remains to be demonstrated. This is also an important area for future investigations.

The Anatomy and Physiology of the Motor System in Humans

ANA SOLODKIN, PETR HLUSTIK, AND GIOVANNI BUCCINO

INTRODUCTION

Sensation and volition, so far as they are connected with corporeal motions, are functions of the brain alone... The will operating in the brain only, by a motion begun there and propagated along the nerves, produces the contraction of the muscles.

— William Cullen (1710–1790)

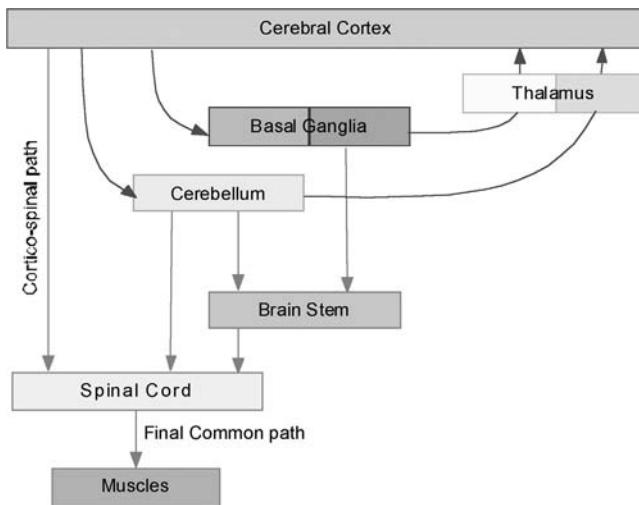

The behavioral *repertoire* of humans is broad, extending from simple behaviors such as sensory perception to more complex cognitive behaviors like language or creativity. Interestingly, no matter how simple or complex are these behaviors, they share without exception the common feature that their expression is a motor act. For the motor system to implement this large variety of cognitive behaviors, there must be an evolutionary bias toward a highly sophisticated and expanded organization of the system. Indeed, according to some (Freund, 1983), association cortical motor regions are among the cortical areas that have changed the most from non-human to human primates. They further manifest a parallel increase in complexity of their connectivity patterns (Zilles et al., 1995). This means that while subcortical motor regions (from spinal cord to cerebellum and basal ganglia) might not be that dissimilar among mammals, cortical motor regions have changed significantly, reflecting a link between motor output and cognitive processing.

This chapter on motor physiology intends to provide an overview on how the nervous system has implemented the ability to produce complex motor behaviors in the human. Although the following sections will place special emphasis on “skilled” movements, some comments on rhythmic movements will also be included.

Coordination of movements between the upper limbs is a function highly distributed across the animal kingdom, from tetrapod taxa to primates (Iwaniuk & Whishaw, 1999). Although this coordination can be considered to be homologous across species, and although the movements *per se* are not very different between animal species and humans, there are two aspects of this homology to highlight: First is that there are at least two types of limb

synchronization, one involving simpler, generally rhythmic, movements and another incorporating more complex movements. The simplest movements are generally associated with posture and locomotion and are, at least in part, controlled subcortically (Poppele & Bosco, 2003), generated in specialized circuits originally described as “motor pattern generators” (Grillner & Wallen, 1985; Pearson, 1995). By contrast, more complex movements, sometimes called “skilled” movements, have evolved to the highest levels in humans. In terms of evolutionary biology, motor skill refers to the “ability to solve a motor problem correctly, quickly, rationally and resourcefully” (Bernstein, 1996, cited in Wiesendanger, 1999). According to Wiesendanger (1999), the high degree of development of hand dexterity in hominids is reflected by the fact that they not only have the ability to use tools but are also able to fabricate them. In this context, the concept of hand dexterity implies goal-directed action that has been previously learned and practiced. Throughout evolution, the increase in hand skill, tool making and vertical locomotion (that freed the hands), has been accompanied by a parallel increase in the size of cortical motor association areas. Anatomically, this increase is specifically related to an increased volume of neuropil, reflecting an increase in the complexity of connectivity (Zilles et al., 1995).

Albeit somewhat artificial, an anatomical division of regions involved in the production of movement can be instructive in understanding the physiology of the human motor system (Figure 22.1). The brain stem and spinal cord can be viewed as the regions of the central nervous system that contain the interneuronal-motoneuronal networks responsible for the production of reflexive and rhythmic motor behaviors. These networks can be regulated by descending modulation from the cerebral cortex (to produce voluntary movements) or from sensory afferents from the peripheral nerves to produce reflexes. Sherrington (1906) called this the *final common pathway* to denote the fact that this is the final output from the whole system to the muscles. The Basal Ganglia and the Cerebellum are important regions of the Central Nervous System that play a crucial role in the coordination of

movement by exerting a modulatory influence on most of the cerebral cortex. These complex regions form two important re-entrant systems to the cerebral cortex (as seen in Figure 22.1), where they can produce widespread effects. Finally, the motor cortical regions are interesting to study particularly in the context of cognitive functions. Some of these cortical motor regions are among the regions that have suffered a large change through evolution, as commented previously (Freund, 1983), but others included in modern maps of motor anatomy (Rizzolatti, Luppino, & Matelli, 1998) are located mainly in the parietal lobule, and have not traditionally been considered integral areas for motor control. Because of the inherent importance of skilled movements in the evolution of species, including humans, this chapter will provide some specific examples (motor imagery, motor imitation, and motor learning) to illustrate potential interactions between movement production and higher cognitive functions.

METHODS FOR THE STUDY OF HUMAN MOTOR PHYSIOLOGY: HISTORICAL PERSPECTIVE

Neuroanatomical substrate of motor functions

To know the brain... is equivalent to ascertaining the material course of thought and will, to discovering the intimate history of life in its perpetual duel with external forces.

— Santiago Ramón y Cajal (1852–1934)

The concept and study of human motor function (along with all other brain functions) progressed greatly with advances in science and anatomy starting in the late 18th century, when sophisticated techniques of brain tissue fixation and sectioning provided a new window on the three-dimensional anatomy of the brain. Since Schwann proposed the cell theory in 1939, the field of histology and microscopic anatomy developed rapidly. In 1906, the Nobel Prize in Physiology or Medicine was awarded to Camillo Golgi and Santiago Ramón y Cajal in recognition

Figure 22.1. Diagram of the general organization of the Motor System in Humans. This figure depicts a simplified organization of the motor system in humans. Note the variety of descending pathways originating from the cerebral cortex that will finally convey into the final common pathway on its way to the effector muscles. The cerebellum (CRB) and the basal ganglia (BG) are important components of this system since they not only have descending inputs into the brain-stem, but also, they are part of closed loops from and to the cerebral cortex. Note that even when both loops pass through the thalamus towards the cerebral cortex, each one of them has a private line in different thalamic regions. Modified from: Heimer L (1994). *The human brain and spinal cord: functional neuroanatomy and dissection guide*. 2nd. Ed. Springer Verlag.

of their studies on the structure of the nervous system. In fact, their approach provided for the first time the notion of the neuron as the basic unit of the nervous system.

Regionally specific features of the central brain region were described by Betz (1874), making one of the first steps toward the microstructural, cytoarchitectonic parcellation of the entire human cerebral cortex, a task later pioneered by Campbell (1905), Elliot Smith (1907), and, most prominently, Brodmann (1909) (Figure 22.2). Cortical fields associated with motor function were further differentiated by the Vogts (Vogt & Vogt, 1919), who, among other advances, divided the premotor regions (BA 6) into two subregions, a division later justified by physiological differences in human and non-human primates.

Contemporary anatomical methods of the motor system are based on the visualization of specific groups of brain cells (both neurons and glia) using immunological methods. These cells are detected using specific antibodies against proteins present in cell organelles or in chemical elements contained in them (e.g., neurotransmitters). This method has uncovered specific groups of cells (e.g., pyramidal cells or glial and endothelial cells) as well as cells that contain specific neurotransmitters (e.g., GABA, glutamate, amines, NO) or specific proteins, some of which are present only in certain states (e.g., apoptosis, the process of programmed cell death). Since these techniques are performed *post-mortem*, they have facilitated construction of chemo-architectonic maps of the brain in humans as well as animals, thus permitting direct comparison among species. As an example of these neurochemical techniques, Figure 22.3 shows the giant Betz cells located in the primary motor cortex (M1) in humans detected with an antibody against a non-phosphorylated neurofilament protein called SMI-32. Note the great detail that can be achieved with this type of method. For an interesting example of these techniques, we refer the reader to the chemoarchitectonic maps based on the distribution of transmitter and neuromodulator receptors in the human brain (Zilles et al., 2002).

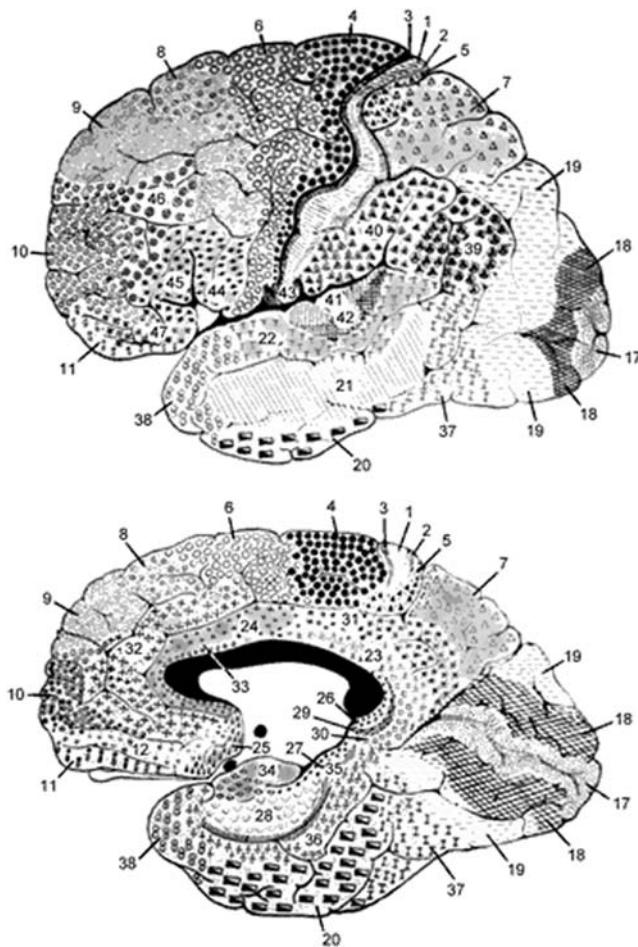

Figure 22.2. Brodmann's cytoarchitectonic map of the human cerebral cortex. These numbers are still commonly used to refer to different brain regions. The reason for its universal use is perhaps the fact that by describing anatomical differences among cortical areas, implicitly he provided a map for functional differences as well.

Relating brain lesions to motor deficits

Effects of brain lesions on human behavior have been observed for centuries. The Edwin Smith papyrus provided the first written record about a case of hemiplegia after (closed) head injury, as well as cases of motor and sensory deficits after spinal cord injury. In 1760, Arne-Charles Lorry demonstrated that damage to the cerebellum affects motor coordination (Finger, 1994).

Nineteenth-century physicians studied patients with lesions to understand the cortical localization of function, including language (Broca, 1861) and motor function. Hughlings Jackson and Charcot (Charcot, 1877; Jackson, 1863; Jackson, 1873), studied both irritative (seizure-generating) lesions and stroke, and summarized their observations of motor abnormalities. They proposed, along with other motor features, an orderly gross somatotopic arrangement of motor control. In the precentral gyrus (i.e., M1), the head subdivision was localized most ventrally and laterally near the lateral sulcus, hand and

arm dorsal to the head, and trunk and leg most superiorly and extending onto the medial surface of the hemisphere.

Subsequent lesion studies (Foerster, 1909; Freund, 1987) generally replicated earlier findings, rather than providing novel information on finer aspects of motor control. The reason for this is that cortical lesions are typically large (Bogousslavsky & Caplan, 1995) and affect several motor cortical areas and/or a substantial portion of each. On the other hand, deficits resulting from a cortical lesion and limited to certain fingers or certain arm movements were reported early in the twentieth century (Foerster, 1909; Foerster, 1936a). With the availability of non-invasive brain imaging (X-ray computed tomography, CT, or magnetic resonance imaging, MRI), small brain lesions can now be detected *in vivo*, allowing clinical-pathological correlations in patients with small and/or transient motor deficits. Taking advantage of these methodological advances, several recent clinical studies described either focal finger pareses or pareses with radial/ulnar predominance with small lacunes of the precentral gyrus revealed on MRI (e.g., Lee, Han, & Heo,

Figure 22.3. Microphotograph of human Betz cells in the human. These motor neurons were stained with an antibody against a non-phosphorylated neurofilament protein found only in pyramidal cells. The microphotograph from neurons located in layer V of the human primary motor cortex, give rise to some (not all) of the descending fibers of the corticospinal pathway that will terminate in the spinal cord.

1998). Although such cases have been known to clinicians, they were dismissed as uninformative exceptions in previous discussions of human motor cortical organization.

Nineteen-century pioneers of the lesion method, Broca and Wernicke, also made an important distinction between lesions located in the gray and the white matter, thus differentiating cortical syndromes from “conduction” syndromes. The concept of white matter or “conduction” syndromes was further developed by Dejerine and Liepmann and reached maximal expression with Norman Geschwind (1965), who described specific syndromes in both animals and men in terms of disconnections among cortical brain regions.

Geschwind's approach to understanding neurological deficits was important not only because he highlighted the connections among brain regions as being the recipients of function, but also because he included in his analysis the actual connectivity patterns of the brain. In fact, among his speculations was the suggestion that the increase in association cortical areas in man would provide new connectivity patterns (not present in animals) to explain the presence of novel interrelationships among areas producing new functions (like language). The limitation of this early perspective, however, is that neurological syndromes were still described as specific lesions in specific white matter pathways, perpetuating in some sense, the localizationist approach to behavior.

The connectionist approach however, has been constantly evolving, and as we will see in the last part of this section, new methodological approaches for the study of the physiology of the CNS in humans, like brain imaging, are making feasible a more comprehensive study of the relationship between brain and behavior.

Electrical stimulation and ablation studies

Proceeding from these observations on the effect of natural lesions, pioneering physiologists conducted animal vivisection experiments and electrical stimulation and ablation studies on animals, including monkeys and apes.

Flourens (1824) conducted ablation and stimulation experiments examining motor functions of the cerebellum (where his conclusions regarding its role in coordination of voluntary movements remain valid) and cerebral hemispheres (where his method was inappropriate and therefore his conclusions, incorrect). German physiologists Fritsch and Hitzig (1870) carried out electrical stimulation studies in a canine model. Their findings overthrew three theories that had stood since Flourens: they established cortical excitability, a role for the primary motor cortex in the mechanism of movements, and cerebral localization.

Building on the efforts of Jackson and of Fritsch and Hitzig, Ferrier published detailed studies (1873; 1875) of cortical localization in non-human primates. He thus established stimulation mapping as a reliable experimental method. Ferrier also proposed that motor centers,

besides leading the “accomplishment of acts of volition”, form the organic centers for the memory of “accomplished acts”, that is, allow storage of learned movements. These early studies culminated in the work of Charles Scott Sherrington (1906), whose work “The Integrative Action of the Nervous System” formed the basic framework for the rest of the twentieth century. Similar information was also collected in the human, almost exclusively in patients planned for brain surgery (most often for epilepsy), rather than in healthy brains (but see: Bartholow, 1874).

Electrical stimulation of exposed cortical surface in patients scheduled for brain surgery (e.g., Cushing, 1909) confirmed the presence of somatotopic representations along the precentral and postcentral gyri (M1 and S1 respectively). Furthermore, an orderly arrangement was also found within the hand, where thumb was found most laterally and little finger most medially (Foerster, 1936b; Foerster & Penfield, 1930; Penfield & Boldrey, 1937). Most of these pioneering authors also commented on the complexity of the observed arrangement and the early researchers also reported on many complex features of primary motor cortex organization, such as overlapping functional codes of different movements and dynamic changes of function performed by a particular cortical location. For example, Jackson (1873) noted that although a single part of the body is represented “preponderating” (sic) in one area of the human precentral gyrus, it is also represented in other parts of the gyrus, though to a different degree and in different combinations with other body parts. Like Sherrington (on the instability of cortical point), Foerster observed that from a single precentral locus, repeated surface stimulation evokes a series of different movements of individual fingers, from which he concluded that each stimulation point on the motor cortex contains neurons representing different body parts (Foerster, 1936a). Finally, Penfield and Boldrey (1937) showed overlap of the motor cortical sites at which stimulation evoked movements of different fingers. They expressly warned against an oversimplified interpretation of their famous homunculus cartoon (See Figure 22.4).

Single-neuron recording in the cerebral cortex of awake, behaving primates (and, rarely, humans). Until the late 1970s, most human mental processes, including complex motor control, were not amenable to direct experimental analysis. Since that time, however, several different approaches have been developed to characterize the neural substrates of information processing.

Ed Evarts, studying the neural correlates of movement and, subsequently, Vernon Mountcastle and his colleagues, focusing on somatic sensation, helped establish the study of internal representations of specified behaviors by studying the activity of single neurons in the cerebral cortex in intact, awake, behaving primates that are trained to do particular motor or perceptual tasks. Human studies with cortical single-neuron recordings are rare. Goldring and Ratcheson (1972), for example, confirmed active and

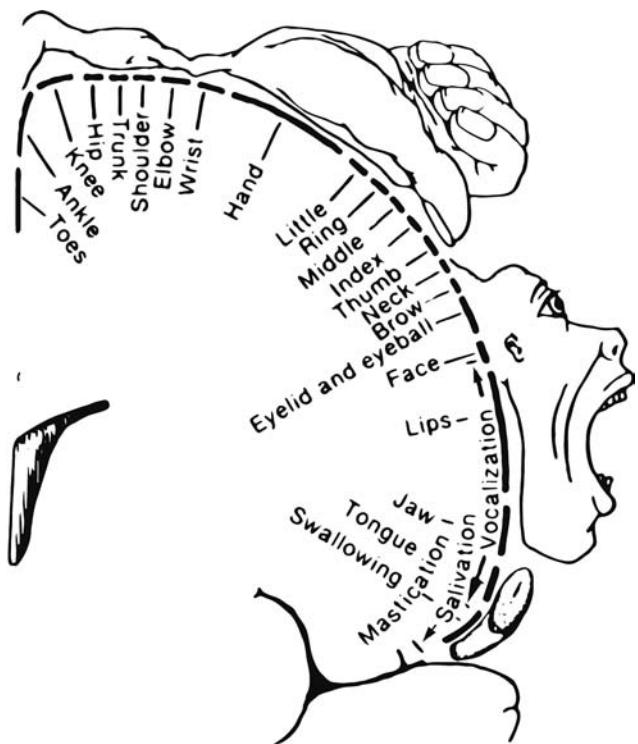

Figure 22.4. Somatotopic Organization of the primary motor cortex in Humans. Schematic representation of the location of different body parts within the primary motor cortex. Note that the areas that have the larger representations are the fingers, face and mouth. Even though when Penfield suggested a careful interpretation of the diagram since the divisions for each body part are overlapped, this diagram has been used extensively and sometimes over interpreted.

passive movement-related neuronal activity in human M1, while auditory and tactile stimuli produced no effect. For further examples see Engel et al. (2005).

These important studies (seldom done in humans) highlight the importance of the intrinsic features of the individual neuron with respect to function. However, they neglected the effects of ensembles of neurons in the generation of such behaviors. Additional methodological approaches, discussed in the following sections, provide a systems approach by determining the effects of activation at the population level on the production of motor behavior.

Electrophysiology methods

Electroencephalogram (EEG) – motor-related potentials. A noninvasive window on dynamic nervous system functioning was opened by the development of techniques to study nerve conduction and electroencephalography (EEG) by Sir Richard Caton in animals and Hans Berger in humans (1929). This methodological approach refers to the scalp recording of electrical field potentials generated on the surface of the cortical mantle. The analysis of this continuous EEG recording is based on the frequency of the signals and on the morphology of the waves.

In contrast, “evoked potentials” or “event-related potentials” (ERP) refer to changes in the patterns of activation produced by specific stimuli. The earliest experimental evoked potentials were described by Waldo in 1933, and the first EEG related to a human motor act was reported by Bates (1951), who described a negative potential after movement onset, originally interpreted as a reafferent sensory evoked potential. Different instrumental settings were required to detect the very slow changes or DC shifts reflecting preparatory movement-related components of the EEG signal: contingent negative variation (CNV) (Walter et al., 1964) and the *Bereitschaftspotential* or readiness potential (BP/RP), (Kornhuber & Deecke, 1965), which are markers of motor preparation for externally cued or internally initiated movements, respectively. The RP initially localizes to the midline but its amplitude becomes greater over the hemisphere contralateral to the responding hand (for a review, see: Coles, 1989). Another motor-associated phenomenon is EEG (event-related) desynchronization (ERD), observed contralaterally to the moving hand. All of these electrophysiological phenomena – RP, CNV, and ERD – have been related to different aspects of motor programming and have also been investigated and found pathological in patients with motor dysfunction, such as dystonia (Kaòovský, 2002).

Magnetoencephalography (MEG). One of the great limitations of the classical electrophysiological techniques (EEG and ERP) is their inability to record and/or localize electrical field potentials from brain regions that do not originate on the brain surface or close to the scalp. This limitation does not apply to the relatively new technique of magnetoencephalography (MEG) that detects the magnetic field generated by the neuronal electrical activity (Hari & Kaukoranta, 1985). MEG technology has grown from a single-channel to multi-channel techniques, and currently achieves spatial localization of dipole sources down to a few millimeters. MEG has been used to map movement-related magnetic fields, (e.g., Antervo et al., 1983), and has contributed to study of motor control timing (because of its excellent temporal resolution) and complex motor control, such as the study of motor correlates of long-term skilled motor practice (Elbert et al., 1995).

Transcranial electrical and magnetic stimulation (TMS)

Although direct electrical stimulation of the human brain has been possible only with the use of invasive techniques during neurosurgical procedures (see, for instance, Penfield & Rasmussen, 1950), the knowledge gained with this method in animal experiments is impressive. Thus, it is not difficult to understand the tremendous value in developing a technique to stimulate motor regions in a non-invasive manner in neurologically intact humans. Such a technique should not have direct contact with the motor regions (i.e., performed outside of the skull), and at the

same time, it should be painless. Electrical activation from the scalp (Levy, York, McCaffrey, & Tanzer, 1984) fulfills the first requirement but not the second. Hence, the alternative has been to induce electrical currents within the brain with time-varying magnetic fields (Faraday's law).

The history of magnetic stimulation is relatively recent (for review see Kobayashi & Pascual-Leone, 2003). The first report of a time-variable magnetic field producing physiological changes in the brain was written by d'Arsonval in 1896. In his study, a volunteer reported phosphene and vertigo when his head was stimulated by a coil at 42 Hz (not surprising he got those effects since that is a high frequency by today's standards).

Several subsequent studies were performed, many by stimulation of peripheral nerves rather than cortex, but these studies led to methodological refinements regarding the quality of the magnetic pulse needed to produce a response with minimal risk to the subjects. In the study of Barker et al. (1985), brief transcranial magnetic stimulation pulses over the motor cortex excited the corticospinal pathway (from M1 to spinal cord) and generated electromyographic signals (motor evoked potentials, MEPs), with or without brief contractions in the peripheral muscles. TMS has been widely used since that time to study the motor system in humans, both healthy and diseased. TMS helps to assess the excitability of the primary motor cortex and the corticospinal pathway, which can be enhanced during spontaneous mild voluntary contraction (Mills, Murray, & Hess, 1987), motor preparation (Barker, Jalinous, & Freeston, 1985) or motor imagery (Rossini et al., 1999), as well as after successful motor recovery from hemiparetic stroke (Liepert et al., 1998). For this, it has become a clinical tool as well. More sophisticated physiological studies have shown that the facilitation of responses in hand muscles produced by voluntary contraction is also present when contralateral muscles are used, but not when a leg muscle is contracted. These results demonstrate a close functional influence of one cortical hemisphere on the other, probably involving neural activity at both spinal and cortical levels.

Motor evoked potentials can also be obtained by stimulation of the spinal cord (Figure 22.5) or the cerebellum. Not surprisingly in these cases, the latency of the MEPs is shorter and the conduction velocity is faster when compared to the stimulation in the primary motor cortex. These latter examples highlight further the value of TMS in assessing motor physiology.

Brain imaging

Following the development of quantitative methods for measuring whole brain blood flow and metabolism in animals by Kety and his colleagues (Landau et al., 1955), David Ingvar, Neils Lassen, and their Scandinavian colleagues introduced methods applicable to humans that permitted regional blood flow measurements by using scintillation detectors arrayed like a helmet over the head

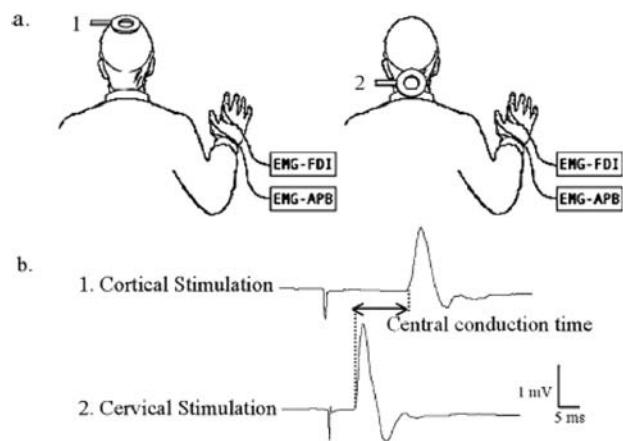

Figure 22.5. Principle of transcranial magnetic stimulation. **a.** Representation of the placement of the stimulating coil (on the scalp overlying the primary motor cortex and over the cervical spinal cord targeting the dorsal roots). These cartoons show also the recording sites on hand muscles (either the first dorsal *interosseus* (FDI) or the abductor *pollicis brevis* (APB)) where the motor evoked potentials are recorded. **b.** Panels showing the actual muscle response (MEPs) as a result of the stimulation at the level of the cortex (1) and in the spinal cord (2). Note the difference in latency for each response. The central conduction time is calculated by the difference between them. *From: Maeda and Pascual-Leone (2003). Transcranial magnetic stimulation: studying motor neurophysiology of psychiatric disorders. Psychopharmacol.* 168:359–376. With permission of Dr. Pascual-Leone.

(Lassen et al., 1963). They subsequently demonstrated that blood flow changed regionally during changes in brain functional activity in humans (Ingvar & Risberg, 1965). This approach was not initially embraced by many neuroscientists or psychologists, an interesting indifference that was to disappear almost completely in the 1980s.

Applying image reconstruction techniques introduced in X-ray computed tomography, researchers envisioned another type of tomography, positron emission tomography (PET), which created *in vivo* autoradiograms of blood flow and glucose metabolism reflecting brain function (Ter-Pogossian et al., 1975). As expressed by Marcus Raichle (Raichle et al., 1983), “a new era of functional brain mapping began.”

One of the advantages of PET is the possibility to simultaneously investigate different physiological processes. For example, studying regional cerebral blood flow (CBF) and cerebral metabolic rate of oxygen (CMRO₂) (Fox, Mintun, & Raichle, 1986) uncovered their uncoupling during cortical activation, which has provided a physiological mechanism to explain the functioning of subsequently developed functional MRI (see below).

Functional brain imaging with PET targeted many issues in the organization of the human motor system, (see, for example Passingham, 1998).

Magnetic resonance imaging (MRI) and spectroscopy (MRS). MRI has pushed non-invasive brain imaging yet another step further towards our understanding of the

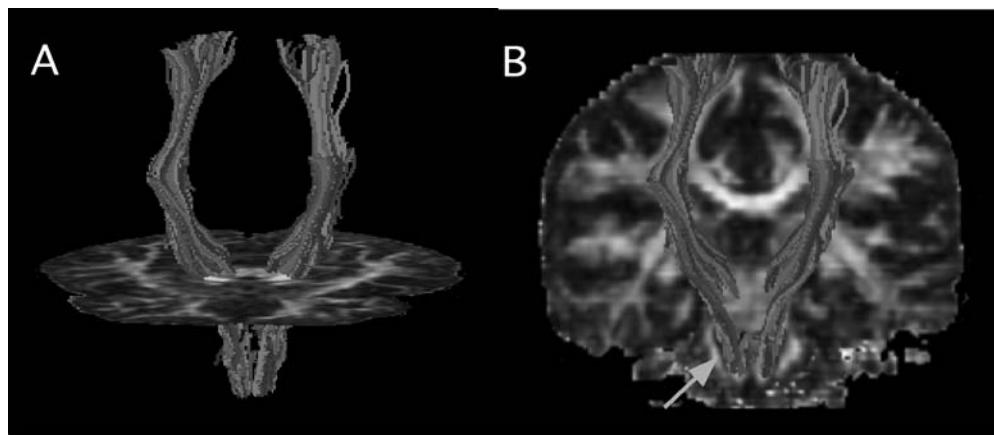

Figure 22.6. Image of the cortico-spinal path of humans using DTI. These figures show in blue, corticospinal fibers going from cortical motor and sensory areas, in their way to brain-stem and spinal cord. **a.** Descending fibers shown in three dimensions, crossing through an axial structural MRI. **b.** Same fibers superimposed to a coronal MRI slice. mind-brain relationship. MRI provides significantly higher sensitivity than other structural imaging techniques like CT in the detection of abnormal or malconfigured brain tissue, as well as providing higher resolution in the anatomical features of normal brains. The benefit of morphological MRI in detecting small brain lesions and thus allowing fine-grained lesion studies has been already mentioned. However, the main new feature of this methodology is that the MR scanner may be “tuned” to detect other properties of brain tissue (beyond anatomy), providing information on brain metabolism, function or connectivity. Magnetic resonance spectroscopy, functional MRI (fMRI) and diffusion tensor imaging (DTI) represent three such applications, and the acquired data from each MR modality can be easily integrated within the same studied brain.

Functional MRI takes advantage of similar tissue processes as other previous functional imaging methods, e.g., single photon emission computed tomography (SPECT) and PET, namely the rise in local metabolism and local cerebral blood flow with increased synaptic activity. The most frequently used blood oxygenation level-dependent (BOLD) fMRI technique (Ogawa et al., 1990) exploits the uncoupling of oxygen consumption and blood flow: changes in blood flow are accompanied by much smaller changes in oxygen consumption. Thus, the venous blood leaving active cerebral tissue contains relatively more oxygenated hemoglobin. Since hemoglobin oxygenation changes its magnetic properties, this change in blood oxygen content at the site of brain activation can be detected with MRI.

Free from the radiation load of emission-computed tomographic methods and faster in acquiring functional brain mapping data, fMRI has allowed an explosion of functional brain experiments to investigate brain responses to myriad tasks and stimuli, not in the least from

the motor domain. High spatial resolution has enabled the study of cortical organization on a millimeter scale for example, to study somatotopy within the hand area of the motor cortex (Hlustik et al., 2001). The reader is referred to review articles (e.g., Jezzard, Matthews, & Smith, 2001; Picard & Strick, 2001, and fMRI textbooks) and fMRI textbooks (Jezzard, Matthews, & Smith, 2001; Moonen & Bandettini, 1999) for examples of applications to the study of the motor system. It should be mentioned that fMRI (as well as other functional brain mapping techniques) is most useful when combined with (or preceded by) well-conceived behavioral experiments, as in the work of cognitive scientists (for review, see Posner & Raichle, 1994).

DTI can probe, *in vivo*, the intrinsic diffusion properties of water in deep tissues (Basser, Mattiello, & LeBihan, 1994). One of the most interesting aspects of DTI is that it describes not only the magnitude of the diffusion of water but also, the degree of “anisotropic diffusion” (diffusion in a preferential direction) and its primary direction. When DTI is applied to the central nervous system, it has revealed that the diffusion of water in the white matter is “anisotropic.” The suggested reason for this anisotropy is the ordered structure of axons and myelin sheaths, which imposes a heavy constraint on the diffusion of water in directions perpendicular to the axons but not parallel to them. In this way, information about diffusion acquired with DTI can be translated into the detection and assessment of pathways in the brain as well as to changes in the pathways related to pathology. Diffusion tensor imaging is a promising technique that potentially can allow us to trace and measure, for the first time, pathways in the human brain *in vivo*. Figure 22.6 shows the path tracing of the corticospinal pathway in a human without neurological disease. The traced path has been superimposed on an anatomical MRI section in the axial and the coronal

$$Z = \beta_{zx}X + \psi_z$$

$$Y = \beta_{yx}X + \beta_{yz}Z + \psi_y$$

Figure 22.7. Theoretical Principle for the determination of the Structural equation models. This diagram shows a simple algorithm describing the effects of regions X, Y and Z onto each other (effective connectivity: element “ β ” plus an error variable Ψ representing unknown influences). An important aspect of the model, differentiating it from some other multivariate methods is that it explicitly represents directionality of effects since it assumes a causal relationship of one area over others with which it is anatomically connected. Modified from: McIntosh and Gonzalez-Lima (1994). *Structural Equation Modelling and its Application to Network Analysis in Functional Brain Imaging*. Human Brain Mapping, 2: 2-22.

planes. Note the origin of this pathway (in the cerebral cortex) descending through the brain stem to cross over at the level of the medulla. Refer to a recent review (Mesulam, 2005) for additional information.

Computer modeling

Computer science also has made a distinctive contribution to systems neuroscience. Learning and memory have been modeled by associative neural networks of Hopfield and others, and the back-propagation learning algorithm of Rumelhart and Hinton. They have shown that complex behaviors could arise from the intrinsic properties of neural nets. Computer models simulate some aspects of the activity of large populations of neurons, thus providing an environment for testing possible neural implementations of particular behaviors in the brain. Neuronal network properties go well beyond the properties of individual neurons and provide for the emergent properties that are commonly referred to as higher brain functions. Computational approaches along these lines, and especially when combined with psychophysics, as in the work of Terry Sejnowski, Steven Lisberger, Richard Andersen, Emilio Bizzi, and Tony Movshon, have been informative in suggesting explanations for functional properties and capabilities of specific neural systems. In the motor domain, for example, modeling suggested a possible mechanism of aligning cortical motor and somatosensory maps (Chen & Reggia, 1996).

An additional approach to computer modeling has been the construction of networks of activation based on PET

and fMRI imaging data. Several tactics have been proposed for using network analysis based on brain imaging data. Notable examples are principal and independent components analysis, and structural equation modeling (SEM). The description of brain imaging data using structural equation modeling as depicted in Figure 22.7 (Buchel & Friston, 1997; Gonzalez-Lima & McIntosh, 1994; Horwitz, Friston, & Taylor, 2000) has produced a conceptual change in the way we interpret such data. In particular, by characterizing networks of activation, SEM describes the functional influence of a specific anatomical brain region on other areas with which it is anatomically connected. The emphasis thereby changes from the individual brain regions active in each condition to the relationships among them. This functional influence of one region over others is called “effective connectivity.” In the past, McIntosh and his collaborators (1999, 2000) have referred to the modulation of effective connectivity over time or over different conditions as “neural context” to denote the fact that a single anatomical region can play different roles depending on its interactions with regions with whom it is related. This means that behavior will be generated depending on the dynamics of the temporo-spatial relationships among brain regions. An example of SEM applied to the study of motor physiology can be found in this chapter in the section dedicated to motor imagery.

Combined methodology

Added power can be gained by combining different complementary research techniques within the same subject

and study. For example, combination of fMRI and EEG/MEG yields data with both high structural resolution (benefit of fMRI) and high temporal resolution (EEG/EMG). In a different way, DTI allows more advanced network analysis of fMRI data by providing direct within-subject estimates of brain connections among the active regions.

Another approach combines functional mapping of active brain areas during specific behavioral conditions with subsequent studies of single neuronal activity in the corresponding areas in the brains of conscious monkeys carrying out essentially the same behavioral task. This combined approach in monkeys and humans promises to be a powerful tool for analyzing those complex higher-brain functions that have correlates in non-human primates.

THE ANATOMICAL ORGANIZATION OF THE MOTOR SYSTEM: A MODERN VIEW

In the previous section of this chapter, we highlighted the methods used for the study of motor physiology and anatomy in humans. However, even when not explicitly stated, the section also suggested the importance of neural networks for understanding motor control mechanisms. This section on anatomy of the motor system will emphasize pathways of the brain associated with motor control.

Concretely, we can consider the motor pathways as belonging to one of three distinct categories: Descending pathways that produce the actual movement; re-entrant circuits that modulate the ongoing activation of other motor circuits; and cortico-cortical pathways determining interactions among motor cortical regions. Because of the prominent role of the cortex in the generation of motor cognitive functions, our emphasis will be biased towards the latter connections.

Descending pathways

The role of the descending pathways includes not only the regulation of skeletal muscles (i.e., from reflexes to skilled voluntary movements), but also the regulation of smooth muscle for autonomic control. Descending pathways (e.g., cortico-spinal path) that originate in the cerebral cortex terminate in the brain stem for the control of head and face movements and in the spinal cord for the control of the rest of the body. These however, are not the only descending pathways. Additional paths originate in brain stem nuclei (red nucleus, vestibular nuclei, superior colliculus), also terminating in the spinal cord. Because of its prominent role in the control of voluntary movements in humans, we will limit our description to the descending pathways originating in the cortical regions, i.e., the corticospinal path. A depiction of this pathway in a human *in vivo* as seen with diffusion tensor imaging can be appreciated in Figure 22.6.

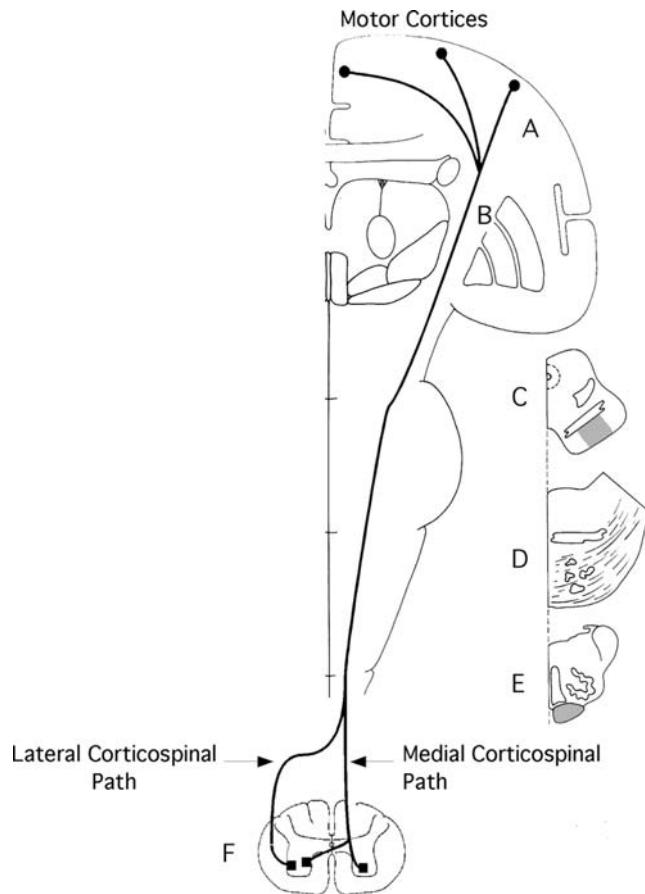

Figure 22.8. Trajectory of the medial and lateral corticospinal path. **a:** Corona radiata; **b:** Internal capsule; **c:** Midbrain; **d:** Pons; **e:** Medulla; **f:** Spinal cord. Note the somatotopic termination in the spinal cord, of the medial and lateral components of the pathway carrying information for proximal and distal movements respectively. Modified from: Haines D. E. (1987) *Neuroanatomy. An Atlas of Structures, Sections and Systems*. Second Ed. Urban & Schwarzenberg, Germany.

Corticospinal pathway. The neurons of origin of this pathway are located in several cortical regions (all displaying somatotopic organization). Among them, the primary motor (Brodmann's area 4; M1) and sensory (especially BA3; S1) cortices, the premotor regions (BA 6 medial and lateral or supplementary motor area: SMA and lateral pre-motor cortices: LPMC respectively), and the anterior cingulate motor area: CMA (BA 24). This descending pathway has two different components: one is a pathway that descends laterally in the spinal cord and controls the movements of the distal muscles (hands); the other is a medially descending pathway that controls the movements of the proximal muscles (trunk). Whereas the entire lateral corticospinal path crosses over to the contralateral side at the level of the medulla (resulting in a contralateral motor control of hands), the medial path does not cross. As a consequence, injury to the right primary motor cortex produces a deficit in the left hand and vice versa.

Figure 22.8 shows the trajectory of both components of the corticospinal path through the different levels of the brain (from cerebral cortex to spinal cord).

The corticospinal path originates in deep layers of several motor and sensory regions in the cerebral cortex. The axons of these neurons descend through the *corona radiata* and form a tight bundle descending in the internal capsule. The pathway continues on its way down forming the middle portion of the cerebral peduncles in the midbrain. After that, the compact bundle passes through the pons on its way to the medulla, where in its lower levels, all the fibers forming the lateral cortico-spinal path cross but the fibers forming the medial path do not. The final destination of the bundle is in the spinal cord, where these long axons synapse either in the motoneuronal pool, in the interneurons located in the middle portion of the central grey, or in the sensory neurons located in the posterior horn. As seen in Figure 22.8 the spinal cord also has a somatotopic organization: whereas the lateral corticospinal path terminates in the motoneuronal pool located in the lateral regions of the anterior horn, the medial path terminates bilaterally in the medial motoneuronal pool. In turn, the axons of the spinal motoneurons travel in the peripheral nerves to reach and synapse in the appropriate muscles.

The organization of the motor path that controls muscles in face and head have a very similar organization, except that the termination of the cortical neurons is not at the level of the spinal cord but at the level of the brain-stem (cortico-bulbar path), where they synapse with the cranial nerve nuclei in *lieu* of the spinal cord.

Re-entrant circuits

There are two important subcortical motor regions intimately related to the cortex: the basal ganglia and the cerebellum. These structures are sometimes referred to as forming an “extrapyramidal” system to distinguish them from the “pyramidal” corticospinal system. These structures modulate motor activation through two re-entrant circuits to the cortex via the thalamus.

Cerebellum. The cerebellum plays an important role in the coordination of fine movements and in the control of posture. This structure consists of a number of central nuclei surrounded by hemispheres whose intrinsic anatomy resembles the layered organization of the cerebral cortex. The cerebellum receives a variety of afferent inputs from subcortical regions in spinal cord and brain-stem (reticular formation, inferior olive, vestibular system, raphe nuclei), conveying information for the control of reflexes involved in posture and eye position during head movements (Heimer, 1983). In addition, the cerebellum receives inputs from motor and sensory cortical regions, instantiating its role in the modulation of voluntary movements. Output from cerebellum terminates mostly in the red nucleus in the midbrain and the ventral lateral nucleus (VL) of the thalamus. This thalamic nucleus projects to several cortical motor regions, closing a loop between cerebellum and cortex. For a review of the cortical regions receiv-

ing indirect inputs from cerebellum see the work by Peter Strick (Middleton & Strick, 1997).

Basal ganglia. A primary function of the basal ganglia is motor control. The basal ganglia consist of two large structures, the caudate and lentiform *nuclei*. The lentiform *nucleus* is composed of the putamen and the *globus pallidus*. Due to similarities between the putamen and the caudate, some authors group them together under the term *striatum*.

Figure 22.9 shows the main inputs and outputs from the basal ganglia involved in motor control. By far, the cerebral cortex provides the main input to the basal ganglia through the putamen, with all cortical areas sending afferents to it. In addition, the putamen receives well-known dopaminergic input from the *sustantia nigra pars compacta*. Two paths loop back from the putamen to the cortex, one direct and the other indirect. The direct path goes to the internal *globus pallidus*, which in turn projects to thalamus, specifically the ventro-anterior and ventral lateral *nuclei*, (independent of the cerebellar input to these nuclei). The final part of the pathway originates in thalamus and projects to cortical motor regions. The indirect path goes from putamen to external *globus pallidus*, and from there, to the subthalamic nuclei. The path then projects to the internal *globus pallidus* and the *sustantia nigra pars reticulata* regions that project to VL thalamus and then to motor cortices. An interesting aspect of these two pathways is the large number of inhibitory connections (represented in Figure 22.9 with grey arrows producing double inhibitory effects). A number of researchers have attempted, with limited success, to apply this network to understanding the motor deficits of Parkinson's disease. What is clear is that the basal ganglia are not only involved in the modulation of

motor functions, but also play a role in cognitive functions (Middleton & Strick, 1994).

Cortico-cortical connections

Neurophysiological, cytoarchitectonic, and histochemical studies have radically altered our view on the cortical motor system over the last two decades. Until then, the prevailing notion was that the cortical motor system consisted of three main sectors: the primary motor cortex (M1), lying in the precentral gyrus, the premotor cortex (LPMC) located in the precentral gyrus in front of the primary motor cortex, and the supplementary motor area (SMA) on the mesial surface of the hemisphere. The primary motor cortex was thought to be involved in the actual execution of movements, while the premotor and the supplementary motor areas were thought to be more involved in motor planning. Numerous cytoarchitectonic and histochemical studies have challenged this view. Figure 22.10 shows a modern subdivision of the cortical motor areas originally proposed by Massimo Matelli and coworkers (1985). Figure 22.10 clearly illustrates that the organization of the motor system is more complex than previously thought. In fact, this system consists of numerous areas, each indicated in the monkey with the letter F (frontal) followed by a number. F1 corresponds to the classically defined primary motor cortex (area 4 of Brodmann); the premotor cortex (BA 6l) is further divided into a ventral premotor cortex (LPM Cv) and a dorsal premotor cortex (LPM Cd). The ventral premotor cortex consists of two distinct areas: area F5 (BA 44 in humans), rostrally located, and area F4 (LPM Cv in humans), caudally located. The dorsal premotor cortex is also composed of two areas: area F2, rostrally located (rostral LPM Cd in humans) and area F7 (caudal LPM Cd in humans), caudally located. On the mesial surface of the hemisphere, the premotor cortex includes a caudal area (area F3, which corresponds to the classically defined SMA in humans) and a rostral area (area F6, also called pre-SMA in humans). An additional area shown in both species is the cingulate motor region (CMA or BA 24c and 23c).

Each of these cortical areas is not only anatomically distinct, but also functionally distinct, since they display specific motor representations of actions somotopically represented (e.g., hand or mouth). At the same time, motor acts involving a specific body part may be represented in several areas. This multiple motor representation of actions is due to the fact that each area codes for a different aspect of the action. For example, among other features, grasping an apple implies knowing *where* the apple is and *how* big it is. In order to grasp an object properly, one needs to localize it in space, code its pragmatic features, and determine the position of the body in relation to the object. Different areas of the motor system play a specific role in this coding.

All areas in the motor system are connected to additional regions of the cerebral cortex. Some of them (F1-

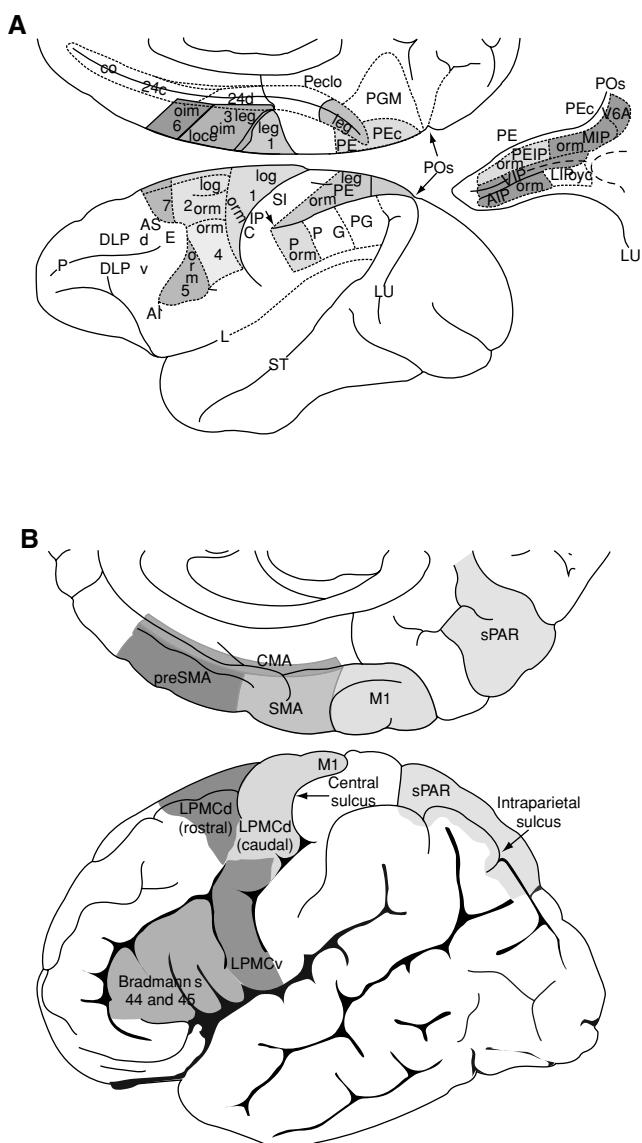

Figure 22.10. Cortical maps of the motor regions in macaque and humans. **A:** Cortical regions in the parietal and frontal lobes in the macaque. **B:** Cortical motor regions in humans. Similar colors between species suggest homology. Modified from Rizzolatti, Luppino and Matelli (1998). *The organization of the cortical motor system: New concepts.* *Electr. Clin. Neurophysiol.* 106: 283–296.

F5, i.e., M1, posterior LPM Cd, SMA, LPM Cv, and Broca's area) are connected to specific areas located in the posterior parietal lobe, whereas some others (area F6 and area F7, i.e., preSMA and rostral LPM Cd) are connected to the prefrontal cortex. Interestingly, while motor areas heavily connected to parietal regions project to spinal cord, motor areas heavily connected pre-frontal regions do not. Furthermore, areas functionally connected to the parietal lobule form a fronto-parietal circuit, devoted to a sensory-motor transformation necessary to act properly on an object and to perform actions accurately. In addition, whereas the prefrontal regions are more devoted to motor planning, cingulate motor regions are involved in motor control related to emotional expression.

It is beyond the scope of the present chapter to describe in detail all of the motor cortical circuits and their functional roles. We will consider three such circuits as examples of the organization of skilled movements. Although most data come from anatomical and physiological studies carried out in the monkey, there is increasing evidence that the same organization is also present in the human brain. When available, data will be reported to show a parallel functional organization in both species.

AIP-F5 circuit for grasping. Area F5 (BA 44 in humans) lies in the rostral part of F4 (LPM Cv). Electrophysiological studies have shown that this area contains motor representations for both mouth and hand object-directed actions. Neurons found in this region discharge when one executes specific goal-directed actions like grasping a piece of food with the hand or the mouth, holding it, tearing and manipulating it. There are even neurons that discharge with specific types of grasping. Notable examples of this include precision grip (a prehension obtained opposing the index finger and the thumb, e.g. grasping a piece of food); finger prehension (obtained by opposing the thumb and the other fingers, e.g., grasping a pen); whole hand prehension (obtained by closing the whole hand around an object, e.g., grasping a little ball). Since their discovery, it has been proposed that these neurons build up a “vocabulary” of hand/mouth actions that, like words in a language, can be used in different contexts, whenever appropriate.

Besides motor properties, neurons in area F5 also encode visual features. Based on their visual properties, F5 neurons are divided into a) mirror neurons and b) canonical neurons. Mirror neurons (that will be described in a latter section in this chapter) are neurons that discharge not only when the monkey performs a specific object-directed action with the hand or the mouth, but also when it observes another individual (monkey or human) doing the same or a similar action. They are called “mirror” because the observed action seems to be reflected like in a mirror in the motor representation coded by the neuron. Canonical neurons are not different from mirror neurons as far as their motor properties are concerned, but their visual response is triggered by the observation of an object congruent to the type of action coded by the neuron. For example, if a canonical neuron codes precision grip, it may respond to the observation of a piece of food (which is an object normally grasped with a precision grip). It has been proposed that canonical neurons are able to “describe” the observed object in motor terms and therefore “translate” the pragmatic features integrating them into the appropriate action. Area F5 is intimately connected with the intraparietal area (AIP), an area located inside the intraparietal sulcus. Electrophysiological studies in neurons of area AIP show that they share common features with those of area F5. Most of these neurons discharge during the execution of hand and finger actions (like grasping), activation that in some of them can be modified by visual stimuli. During the act of grasping, for example, area AIP can extract relevant

physical features of the object, whereas area F5 selects the most appropriate type of prehension among those present in the motor “vocabulary” of the area.

Although data coming from monkey studies are not easily comparable to those obtained in humans, there is increasing evidence from brain imaging studies that a fronto-parietal circuit like monkey AIP-F5 is also present. During an fMRI experiment in which participants were required to grasp and manipulate different objects, the main active areas were the LPM Cv (including Broca’s region) and an area inside the intraparietal sulcus in the parietal lobe, which could be considered the human homologue of area AIP (Binkofski et al., 1999). Furthermore, patients with lesions within the intraparietal sulcus, are not able to grasp and manipulate objects reinforcing the role of this area similar to that in non-human primates.

VIP-F4 circuit for space coding. Area F4 lies in the caudal part of the ventral premotor cortex in the monkey. In humans, it is the most ventral portion of the pre-central gyrus (LPM Cv). Electrophysiological studies have shown that this area contains a motor representation of proximal arm and mouth actions, the data showing that neurons discharge during the execution of reaching movements directed towards or away from the body. F4 neurons also respond to visual and tactile stimuli. Hence, depending on their responses to sensory stimuli (visual and somatosensory), they can be uni- or bimodal. For instance, bimodal neurons respond not only to tactile, but also to visual stimuli presented in the space adjacent to the tactile receptive fields (personal space), thus forming a single responsive region that includes the skin and the space adjacent to it. Most interesting is the fact that the coordinate system in which visual receptive fields are coded is in somato-centered coordinates (i.e., their location is independent of eye position). Area F4 is connected with the ventral intraparietal area (VIP). Again, neurons of area VIP share common features with those of area F4 since they can be uni- or bimodal. What is the role of the VIP-F4 circuit? It has been proposed that this circuit plays a role in coding personal space by transforming the location of objects in space in order to execute appropriate movements to reach them.

Area F2-V6A-MIP circuit for online up-dating of grasping actions. Area F2 lies in the caudal part of the dorsal premotor cortex in the monkey and in the dorsal portion of the pre-central gyrus in humans (LPM Cd). Electrophysiological studies have shown that this area has a rough somatotopic organization, with hindlimb movements located medial to the superior precentral dimple and forelimb movements located in the cortex lateral to it. A recent study (Fogassi et al., 2001) showed that this region displays (a) purely motor neurons, which discharge during grasping conditions; (b) visually modulated neurons, that are active during grasping accompanied with visual perception of an object; and (c) visuomotor neurons, that discharge during the perception of objects in the absence of

any overt movement. Taken together, these data indicate that area F2, like area F5, plays an important role in the control of goal-directed hand actions. Area F2 receives its major visual inputs from area MIP, in the superior parietal lobule, and from area V6A in the occipital lobule. Although visual properties of area MIP are not very well-known, recent findings suggest that this area responds to the presentation of 3-dimensional objects. As for area V6A, it has been reported that neurons in this area are sensitive to the hand-target interactions, thus supporting its role in the visual monitoring of hand position in space. One can conclude that during grasping, the circuit F2–MIP/V6A could be updating on-line the configuration and the orientation of the hand when it reaches for objects.

MOTOR PHYSIOLOGY

Subcortical motor control: Reflexes and central pattern generators

The spinal cord and brain stem play an important role in the generation of movement because a large number of specialized motor circuits are located there. As an example, consider the generation of voluntary movements. Once voluntary movements are initiated, their production requires the activation of specialized circuits located in the spinal cord that in turn activates the corresponding muscles. Furthermore, since different segments of the spinal cord control different body parts, it is easy to understand that the production of complex movements requires the sequential activation of various levels of the spinal cord. In this section we will review two examples of such circuits: reflexes and central pattern generators.

Reflexes

Reflexes are stereotyped movements triggered by somatosensory stimulation. Spinal reflexes can be initiated by stimulation of receptors in the joints, muscles and the skin, with the resulting motor response controlled entirely within circuits located in the spinal cord and brain stem.

Is there a role for reflexive activity? Reflexes are ecologically important because they produce adaptive movements when integrated with centrally generated motor commands. Thus reflexes are an essential part of complex movements. For instance, multiple sensory stimulation is produced during coordinated movements (information coming from joints, muscles, and skin), providing feedback to the system to help with production of coordinated and smooth movements. When perturbations in the environment occur, sensory feedback information produces a reflexive response, making possible small adjustments in the ongoing movement. These adjustments are especially important in the control of tone in proximal musculature related to the maintenance of posture.

In early studies, reflexes were considered stereotyped unchangeable movements. Most recent observations, how-

ever, have shown that reflexes have a degree of flexibility and can adjust to changes in the external or internal environment. In other words, reflexes show plasticity. This feature makes them more interesting, since it implies a possible role in motor learning or recovery of motor function after neurological damage.

The stretch reflex. The stretch reflex is one of the better known reflexes since it is used in clinical practice, but it is also one of the simplest spinal reflexes, employing a neural circuit of few elements. This reflex is illustrated in Figure 22.11.

The stimulus that produces the quadriceps stretch reflex is typically a tap on the patellar tendon in the knee, although any action that stretches this muscle has the equivalent effect. When the muscle is stretched, sensory receptors (muscle spindles) located in the muscle fire in response. This produces electrical firing of the spindle afferents (called Ia afferents) that make direct synaptic contact with spinal motoneurons innervating the *quadriceps*. In other words, this network forms a loop, since it returns to the same muscle where the stimulated spindles are located. In addition, this type of circuit is called “monosynaptic” because it has a single synapse (between the Ia afferents and the motoneurons) in the spinal cord.

Since the synaptic contact between the Ia afferents and the motoneurons that innervate the *quadriceps* are excitatory, their activation triggers the motoneuron to fire, and in turn produces a contraction of this muscle.

While this is occurring, a concomitant pathway is involved in the reflex. The Ia afferent fiber activated by the stretch of the quadriceps muscle also makes a synaptic contact with inhibitory interneurons located in the spinal cord.

These interneurons inhibit the motoneurons innervating a knee flexor muscle (in this case the *semitendinosus*), an antagonist of the *quadriceps* (i.e., when it contracts, it produces the opposite movement), producing flexion of the knee in contrast to the extension produced by the *quadriceps*. The inhibition of the antagonist allows the *quadriceps* to contract easier since the *semitendinosus* relaxes. The end result of this balance is the well-known movement of leg (lift) when the patellar tendon is stimulated.

Because the inhibitory circuit includes more than one synapse (one between the Ia afferent and the interneurons and a second one between the interneurons and the motoneurons), the pathway is considered to be “polysynaptic.”

The balance of excitation and inhibition between agonist and antagonist muscles is called “reciprocal inhibition” and the spinal circuit associated with it is called “reciprocal innervation.” This important concept was described by one of the greatest physiologists ever to live who was already mentioned in the history section, Sherrington (1906), and refers to the fact that when a group of muscles is excited, the antagonist muscles to that first group of muscles are inhibited. The balance between excitation and inhibition

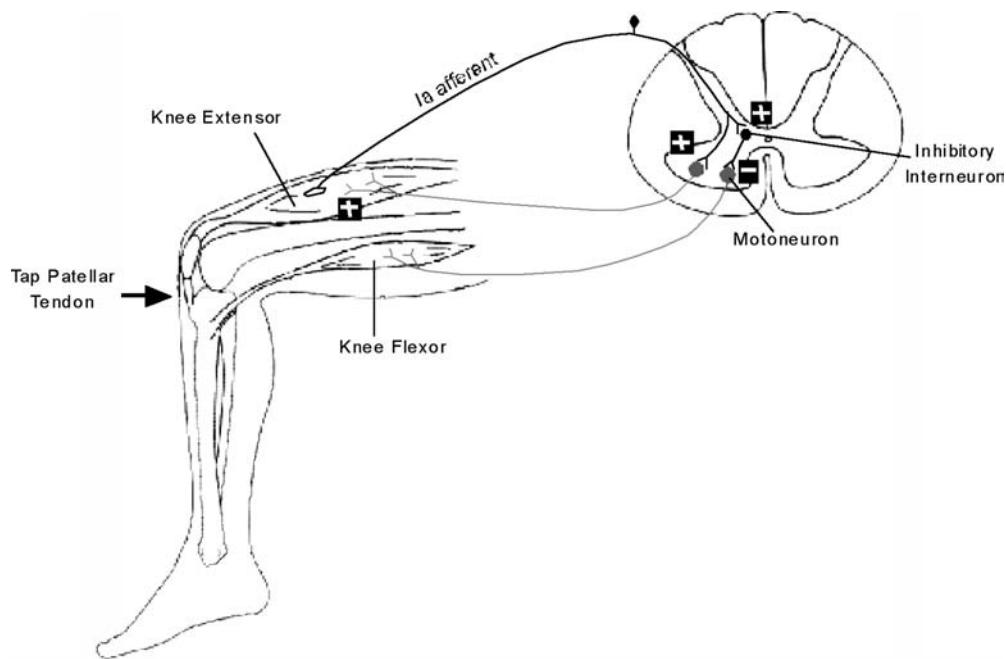

Figure 22.11. Circuit associated with the production of the flexor reflex in humans. Schematic representation of the two circuits associated with the generation of the knee jerk reflex. The monosynaptic circuit (marked with positive signs) is excited producing the contraction of the *quadriceps* muscle. At the same time, a polysynaptic circuit is involved with the difference that it involves inhibitory interneurons in the spinal cord (marked by the minus sign), that will produce a relaxation of the antagonist muscle. Modified from Boron WF and Boulpaep EL. (2003) *Medical Physiology*. Saunders. Elsevier Science (USA).

of reciprocal musculature is critical to the coordinated movement of the joints.

These examples of spinal reflexes illustrate a limited portion of what occurs constantly throughout the body to maintain posture. Sensory information is constantly delivered from the body. Control of posture (static or changing) requires incoming sensory information not only from muscles, tendons and skin but also from vestibular and visual receptors. These inputs originate in brain-stem, cerebellum and different levels of the spinal cord, and are integrated rapidly in the spinal cord through the activation of proprio-spinal paths whose function is the interconnection of different levels of the spinal cord and brain stem. The point of this example is to illustrate not only the apparent complexity of keeping posture (through activation of reflex activity) and the importance of reflexes in this control, but also, to illustrate the fact that all these adjustments are done automatically, without conscious control. This points out another feature of the motor system: Although we are aware of the initiation of some (voluntary) movements, not all movements are in the conscious realm. This fact becomes critical in situations where recovery of motor function is desired (after injury for instance) or for motor learning.

Central pattern generators (CPGs)

For years, the importance of network activation in the generation of motor behaviors by the CNS has been widely recognized. In this context, the motor system has often

been described as having a “hierarchical organization” (Wiesendanger & Wise, 1992) to define a situation where this complex system is composed of a number of relatively automatic subsystems capable of performing a specific task but also influenced by “general commands” initiated in higher levels or through sensory feedback (Arshavsky, 2003). This means that higher centers do not control individual elements within the lower circuits but rather, provide commands by which these latter networks can perform their tasks. The result of this organization is a highly efficient system.

Remarkable examples of these “autonomous centers” are what have been called: “Central Pattern Generators or CPGs.” The CPGs have been associated with the control of automatic, basic motor patterns such as locomotion, respiration, swallowing, chewing, swimming, scratching, and defensive behaviors, among others.

Formally the CPGs are defined as the neuronal networks that produce a basic motor output in the absence of sensory feedback. More precisely, Marsden has defined the CPG as: “a set of muscle commands (or motor program) which are structured before movement begins and which can be sent to the muscle with the correct timing so that the entire sequence is carried out in the absence of peripheral feedback.” What this means is that the direct electrical stimulation of specific circuits will produce rhythmic activation associated with complex motor acts as stepping or galloping, swimming, swallowing or breathing. Since stimulation in these studies is not “natural,” the resulting

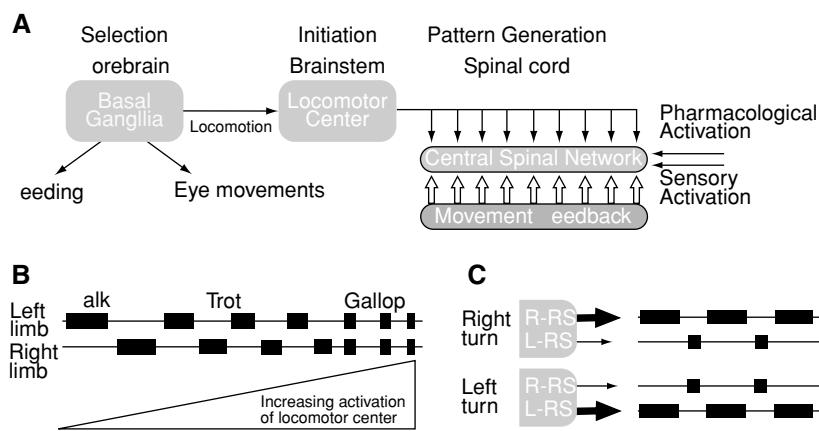

Figure 22.12. General organization of CPGs in vertebrates. Schematic representation of locomotion in vertebrates, that shows also the general organization of the CPGs. **a:** Forebrain structures initialize the spinal CPG activation. The resulting rhythmic activation is then modulated by sensory and pharmacological inputs. **b:** Representation of the interlimb coordination in quadrupeds. Note the alternation of the rhythm between both sides of the cord. **c:** Reticular activation leads to an asymmetric pattern that will result in the animal turning to one side. *From: Grillner et al. (2000). The intrinsic function of a motor system-from ion channels to networks and behavior. Brain Res. 886: 224–236. With permission of S. Grillner.*

motor behavior is called “fictive behavior” (for instance “fictive locomotion” etc.) to denote their distance from the ecological movements. Such fictive movements tend to be more stereotyped than true ecological movements.

Although it has been suggested that the structure of CPGs are genetically determined and their physiology does not depend on experience, they in fact can be modulated by sensory feedback and descending inputs. Because this influence from descending inputs and sensory feedback changes their functioning, the preferred approach to studying CPGs has been by isolating them from these influences. The easiest way to do this has been to use invertebrates (Arshavsky, 2003; Grillner et al., 2000; Marder, 2000; Marder & Bucher, 2001). This approach has provided a large amount of information on the physiology and anatomy of CPGs. In vertebrates, the methods of choice have been the use of isolation methods such as spinalization (Jankowska et al., 1967; McCrea, 1998) where the spinal cord is isolated anatomically from higher regions of the central nervous system or by the administration of pharmacological agents such as *curare* that eliminates the proprioceptive sensory input to the cord (Kiehn & Kjaerulff, 1998).

In general, these studies have focused on CPGs that generate rhythmic activity present extensively throughout the phylogenetic scale, from invertebrates (like mollusks and crustacea) to vertebrates (including mammals). In the latter, CPGs are typically located at the level of the spinal cord (for locomotion and scratching) and at the level of the brainstem for other motor behaviors such as respiration, swallowing and chewing.

The general organization of CPGs in mammals is depicted in Figure 22.12 (Grillner et al., 2000) where the influence of descending systems and sensory information is shown to highlight the fact that these circuits are highly regulated. In order to understand better the physiology

of these circuits, it is important to mention that all CPGs share several features:

- (a) The intrinsic properties of the neurons within the CPGs are important in the generation of the rhythmic motor behaviors. For instance, some neurons of the circuit are driven by pacemaker neurons. So the rhythmic activity is generated by the synaptic contact between the pacemakers (or core oscillators) and other neurons that do not have a rhythmic activity on themselves.
- (b) Even though it was previously thought that the generation of motor rhythmic behavior was solely through a chain of reflexes, the current view is that a central circuit generates the rhythmic patterns of activity including some reflexive activation (Marder & Bucher, 2001) and some other elements not part of the reflexive circuits.
- (c) CPGs are regulated by neuromodulators. Depending on the function of the CPG, they receive inputs from descending, sensory or hormonal origins. The function of these inputs is to initiate the movement (descending control), whereas in other cases (hormonal, sensory), these inputs either terminate or regulate the rhythmic activity.
- (d) Some complex motor behaviors might be produced by the coordination of one or more CPGs. A classic example is swimming (studied extensively in lampreys and frogs). Swimming behavior implies the simultaneous coordination of several body segments (up and down or right and left) and in consequence the coordination of several spinal segments is essential. In these animals, each spinal segment produces motor patterns that organize the local swimming movements (Marder & Bucher, 2001). It has been suggested that coordinated movements of the whole body result from the coupling of the individual CPGs along the cord. This coupling implies

the simultaneous coordination of several CPGs and the regulation of independent movements by each one in the same fashion as the control of posture was described in a previous section.

(e) Rhythmic movements associated with CPGs tend to be stereotyped (especially fictive movements) and some studies suggest, might be genetically determined (Marder & Bucher, 2001).

Locomotion. Traditionally, the spinal cord has been associated with the generation of non-flexible, automatic, simple motor behaviors. However, the types of motor behaviors that can be generated through spinal circuits can be much more complex than previously thought. This section will discuss one such circuit that generates locomotion.

The generation of locomotion within the spinal cord is particularly interesting because it is present in humans and is quite complex in that it involves long motor sequences and can be modified. Unfortunately, locomotion in humans with reference to the presence of CPGs has been difficult to assess due to obvious experimental limitations. Nonetheless, lesions to the spinal cord provide some data on this topic, and this will be presented at the end of this section.

Locomotion in mammals. The study of CPGs and locomotion in mammals has employed several experimental approaches: (a) spinalization of the animals where the spinal cord is isolated from higher centers; (b) administration of pharmacological agents such as *curare* that prevents sensory proprioceptive information from reaching the spinal cord; and (c) isolation of spinal neurons forming the CPGs (as in invertebrates) in neonatal rats (but not mature animals).

The study of locomotion in mammals has a long history, beginning with the pioneering work of Sherrington (1910), who determined that the spinal cord of cats has enough reflexive-related circuitry to produce by itself the rhythmic flexor-extensor pattern during locomotion. Almost simultaneously, Brown (1911) performed more descriptive studies in spinalized plus deafferented (i.e., no sensory inputs) cats where he confirmed the ability of these animals to perform stepping behavior in the absence of afferent input. He suggested that the spinal cord contains intrinsic circuits able to produce locomotion. Today, several studies in deafferented and spinalized animals have shown that the spinal cord can produce what has been called “fictive locomotion”, i.e., rhythmic patterns of activity in circuits that would drive rhythmic muscle movement (Marder, 2001). Furthermore, the most current theories (Jankowska et al., 1967) describing the CPGs for locomotion in mammals are a combination of reflex activation plus additional elements forming a complex circuit.

The existence of CPGs for locomotion have been demonstrated in several species with the interesting fact that the general organization seems quite similar in all species studied, even though the locomotion patterns seem at some level very different (from swimming to walking to trotting or running).

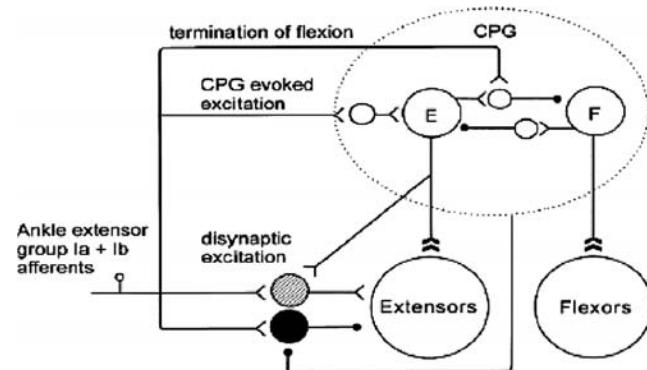

Figure 22.13. Theoretical network associated with the production of fictive locomotion in mammals. Schematic representation of the actual spinal generator. Inhibitory connections are represented by filled circles and excitatory connections by open forks. This model highlights the importance of reflexive activity between flexors and extensors. *From: McCrea (1998). Neuronal basis of afferent-evoked enhancement of locomotor activity. Ann. NY Acad. Sci. 860: 216–225. With permission of D.A. McCrea.*

Figure 22.13 depicts the hypothetical anatomical arrangement of a spinal CPG of the cat's spinal cord (McCrea, 1998). According to McCrea (2001) there are several relevant features of CPGs for locomotion in four paw mammals:

1. Since the rhythmic motor behavior during locomotion is stereotyped, the role of segmental reflexes circuits is to compensate for changes in the environment.
2. Fictive locomotion in decerebrate animals can be triggered by electrical stimulation of the midbrain or by the administration of adrenergic agents.
3. Afferent inputs can modulate the rhythmicity of locomotion. Even when it is clear that the rhythmic activation of neurons within the spinal cord during fictive locomotion is quite close to the activation during real movement, it is nevertheless not identical. More and more studies have shown the great relevance of sensory input as a determinant aspect of CPGs physiology especially for its role in adapting the CPGs activation to constant changes in the environment. The roles associated with sensory input are: Reinforcement of CPG activity related to load-bearing muscles; regulation of timing depending on the actual task performed and the facilitation of phase transitions (MacKay-Lyons, 2002).
4. Rhythmic activity is generated by the reciprocal inhibition of two sets of interneurons located on each side of the spinal cord – an extensor circuit and a flexor circuit – each exciting their corresponding motoneurons.
5. Supraspinal centers can regulate the activation of spinal CPGs for locomotion. Even though it is clear that CPGs can be activated in the absence of supraspinal centers, these regions play an important role in several aspects of locomotion, since they are crucial to the initiation of CPG activity and in controlling the intensity of their activity, maintaining equilibrium during locomotion, adapting limb movement to changes in

external conditions and coordinating locomotion with other motor acts. Among the supraspinal regions that have been associated with this control are the primary motor and sensory cortical regions, the cerebellum, and the basal ganglia.

Locomotion in humans. Based on the large number of studies on locomotion in animal species, an obvious question is to what extent human walking can be understood using similar principles.

Intuitively, human walking has obvious differences with other types of mammalian locomotion. First, humans walk erect on two legs; at the moment of the contact with the ground, the leg is almost completely extended and the body part that touches the ground first is the heel. One of the consequences of this is that simultaneous activation of flexors and extensors is present at heel contact (rather than in phase like other animals) (Capaday, 2002). Furthermore, when people suffer complete transactions of the spinal cord, that is, the spinal cord is completely isolated from the rest of the supra-spinal regions, one would expect recovery of locomotion with direct electrical stimulation of the spinal cord. Unfortunately, as we know, this is not the case.

In contrast to these differences with other mammals, locomotion in humans shares some features with both mammals and with other classes. Among these parallels:

1. Some spinal control of locomotion in humans is performed through the regulation of reflexes, especially the stretch reflex, which is thought to make a high contribution to walking in humans.
2. Sensory input is critical to the control and modulation of walking in humans. One suggestion has been that the stance-to-swing transition is promoted when the hip is extended, and the load in ankle extensors is decreased (these changes captured by sensory receptors) (Capaday, 2002).
3. The corticospinal pathway is involved in the initiation of walking (Capaday et al., 1999).
4. Lastly is the question of the existence (or not) of locomotion CPGs proper in the human spinal cord. The presence of CPGs for human walking would have tremendous implications for recovery of spinal cord lesions, with the option of activating them (as in other species) through sensory inputs, neuromodulators (like dopamine or adrenaline), or with direct electrical stimulation. As mentioned, the answer is not clear and at first glance, seems implausible. However, favoring the notion that human walking is performed with the participation of CPGs, it is possible to elicit rhythmic activity within the spinal cord of humans with intact sensory inputs, suggesting the existence of specialized circuits. Human spinal CPGs are undoubtedly weaker than those of other mammals, because after complete spinal cord injury, pharmacological interventions do not produce walking in humans as they do in rats and cats. More promising results, however, have been seen after partial transection

of the spinal cord, where a combination of pharmacological activation plus treadmill training has produced some improvement in locomotion of these patients.

MOTOR BEHAVIOR AND COGNITION

In the following sections, we will describe three examples of motor behavior closely related to complex cognitive functions. The idea is to provide a sense of the complexity of motor physiology in the context of cognitive processes. It is important, however, to understand that each of these examples (motor imagery, motor imitation, and motor learning) is intimately interrelated, even when presented as independent phenomena.

Motor imagery

Some cognitive psychologists (Annett, 1996) have suggested a distinction between two types of knowledge: explicit and implicit (or “knowing what” and “knowing how”). One of the features is that whereas explicit knowledge can easily be described verbally, implicit or procedural knowledge cannot. Motor acts tend to fall into the category of implicit knowledge, and as such, motor imagery can be considered the internal representation of the motor act.

Motor acts are triggered either by external sensory stimuli or by internal commands, implying that the central nervous system needs constantly to merge or transform sensory (or internal) codes into motor commands. As suggested by Passingham, Toni, and Rushworth (2000), this could be achieved through the use of what he calls “high-level representations” (or “cross-domain mappings”) Wise, di Pellegrino, & Boussaoud, 1996 where stimuli and actions must be represented (see also the cortico-cortical connections section in this chapter). In other words, motor imagery could be considered the internal representation of previously learned movements.

In the most general sense, motor imagery refers to the “mental rehearsal of simple or complex motor acts that is not accompanied by overt body movements” (Jeannerod, 1995; Porro et al., 1996).

Although the definition appears simple, people asked to perform motor imagery do not make an unambiguous interpretation unless instructed more specifically. In particular, people generally perform this mental rehearsal of movements according to one of two strategies: (1) they produce a visual representation of their moving limb; or (2) they mentally simulate the movements associated with a kinesthetic feeling of the movement. In the first case, the person is a spectator of the movements (external imagery). We will refer to this behavior as visual imagery (VI). In the second case, the person is a performer (internal imagery). We will refer to this behavior as kinetic imagery (KI).

In fact, each of these strategies of motor imagery has different properties: For example, while KI is difficult to verbalize, VI is not. Whereas KI follows Fitt's law (i.e., the imagined movement associated with KI shows the

same limitations as movements during execution), VI does not. This means that during KI, a person cannot perform movements at a higher rate than during overt execution, and this still holds after brain injury, when both execution and KI are diminished correspondingly. In contrast, during VI, a person can imagine movements that far exceed the physiological limitations of the execution (for review see Jeannerod, 1995). Moreover, certain physiological changes associated with KI mimic those occurring during execution, whereas during VI, they do not. For example, whereas electromyographic (EMG) activity during KI shows an increase in voltage in the muscles corresponding to movement execution, there are no such changes during VI (Fadiga et al., 1999). Furthermore, the excitability of the cortico-spinal pathway measured with transcranial magnetic stimulation is increased during KI but not VI (Abbruzzese et al., 1999; Fadiga et al., 1999; Rossini et al., 1999). In addition, if these imagery tasks involve strenuous movements, KI (but not VI) will show concomitant changes in autonomic function similar to those present during execution, including increases in heart and respiratory rates as well as in end-tidal PCO_2 (Decety et al., 1991; Oishi, Kasai, & Maeshima, 2000).

Since KI shares more physiological characteristics with the movement execution than does VI, it has been associated more closely with motor functions *per se* such as motor preparation, imitation and anticipation, restraining and the refining of motor abilities (Deiber et al., 1998; Jeannerod, 1995; Lotze et al., 1999; Stephan & Frackowiak, 1996). However, even when this correlation between motor execution and KI has been made, it is still not clear if KI and VI are sensory representations associated with the motor act or if they are in fact, true storage motor representations. This outstanding issue has been elucidated using a number of different techniques although the most revealing results have been obtained with functional brain imaging techniques. In the next section, we describe some conclusions that we have reached regarding motor imagery using modern techniques.

The physiology of motor imagery

With respect to imaging studies, several accounts of areas activated during KI or VI have been reported using PET or fMRI. Even though some of the studies do not differentiate between KI and VI, there are several features common to most of them (Jeannerod, 2001; Kim et al., 1995; Roland et al., 1980; Sanes, 1994; Stephan & Frackowiak, 1996). In general, studies have shown that several areas are activated during motor imagery tasks. Included in these active regions are the following: SMA, superior and inferior parietal lobule, LPMCd and LPMcv, pre-frontal areas, inferior frontal gyrus (BA44), superior temporal gyrus, M1, S1, secondary sensory area, insular cortex, anterior cingulate cortex, superior temporal gyrus, basal ganglia, and cerebellum. This extensive activation pattern suggests a complex distributed circuit. In studies that compared execution to motor imagery, it was found that even though the active

areas tend to be similar between the two conditions, in general, volumes of activation are larger during execution than during motor imagery (Gerardin et al., 2000; Jeannerod, 2001; Stephan & Frackowiak, 1996). A controversial point in some of these studies is the role of M1 during imagery, since its activation is not seen consistently in all studies and if seen, it is always less active than during execution (Beisteiner et al., 1995; Fadiga et al., 1999; Hashimoto & Rothwell, 1999). The lack of M1 involvement during motor imagery has been explained as the way the system avoids overt movements during imagery.

In summary, these studies suggest that the volume of brain activation differs between execution and motor imagery and that with few exceptions the distribution of activation tends to be similar in the two conditions.

So we have here an interesting riddle: on the one hand it seems that executing a movement and having KI of the same movement produce similar patterns of activation in the brain. However, moving is not the same as imagining that one is moving. What is the difference? In the following section, we demonstrate how brain imaging data provided a novel perspective on human motor neurophysiology.

There is no doubt that studies in systems neuroscience have benefited tremendously from the development of techniques such as functional Magnetic Resonance Imaging (fMRI). However, image analysis in fMRI has generally focused on enumerating areas of activation under different behavioral conditions, rather than characterizing the networks involved in the generation of those behaviors. Thus, with respect to localizational assumptions, these studies are analogous to lesion analysis studies, and incorporate some of the same advantages and limitations.

An alternative approach has been the efforts by some to assess networks of activation through the evaluation of effective connectivity among areas activated during different behavioral conditions (Buchel & Friston, 1997; Gonzalez-Lima & McIntosh, 1994; Horwitz et al., 2000). These models provide an interesting new perspective on experimental design and data analysis since they give an analytical approach to understanding integrated systems.

Network analysis in motor imagery

What does it mean to understand networks of activity? One of the most interesting features of the physiology of the CNS is the influence of regions on each other by means of established anatomical connections. Interestingly, not only have these connectivity patterns increased through the evolution of the cerebral cortex (Zilles et al., 1995) but in addition, the patterns of connections are not random: not all regions connect with all regions but rather, form specific patterns of connections. In terms of physiology, it means that changes in one region produce concomitant changes in regions anatomically connected to it. Although brain imaging has provided maps of regional activation, thereby giving an initial understanding to the neural basis of cognition, so far, we have not been able to establish the effect that one particular region is exerting upon the

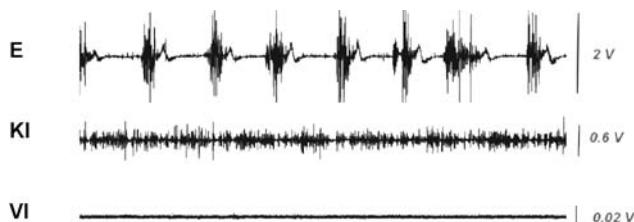

Figure 22.14. Electromyographic recordings during E, KI and VI. The upper trace shows EMG activation in the FDI during finger opposition movements. The second trace during KI and the third trace during VI. Muscle tone increased during KI but not during VI that did not differ from rest.

regions connected to it. Connectivity modeling is allowing us for the first time to quantify the effect of one region (node) over others. The directional effect of one region upon another as mentioned in the historical section, is called “effective connectivity.”

Following this idea of connectivity analysis, the present section will describe effective connectivity in networks associated with three different conditions: execution of hand movements (E), and kinetic and visual imagery of these same movements (KI and VI). These networks can help to inform about a possible role of “motor imagery” in the improvement of motor skill in normal subjects and in recovery after neurological damage. In normal subjects, for instance, motor imagery is used by athletes and professional musicians, where it is called “mental rehearsal,” to improve performance. By the same token, motor imagery is used therapeutically after stroke to stimulate recovery of motor abilities (Yaguez et al., 1999).

In a recent study, we aimed to understand the networks underlying hand motor imagery as compared to actual execution. This study was performed using fMRI (Solodkin et al., 2004). The first step in the study was to assess the subjects’ ability to perform kinetic imagery: One of the issues during motor imagery is the difficulty detecting if people are actually performing the task correctly. In general, most people will tend to perform visual imagery rather than kinetic imagery. For this, and before the subjects were

scanned for the fMRI session, outside the scanner, they were asked to perform either a finger opposition movement and both kinetic and visual imagery of the same movement. During the task practice, EMG was recorded in the first dorsal *interosseus*, one of the muscles controlling the opposition of the thumb and the index fingers. The results of this part of the study are illustrated in Figure 22.14. During execution, the EMG showed the typical muscle spindles associated with the contraction of muscles. As expected, these spindles were not present during either type of imagery, since during these tasks, there was no overt movement of the fingers. However, the EMG recordings during kinetic and visual imagery were not identical; kinetic imagery produced an increase in muscle tone (seen by the amplitude of the recorded band) whereas the muscle tone during visual imagery was identical to rest. This observation not only demonstrated that the participants were performing kinetic imagery correctly, but also illustrates the fact that kinetic imagery is associated with motor preparation that involves a change in the voltage of the involved muscles, shifting them closer to the contraction threshold (they are facilitated).

Second, an fMRI study was performed: The task during the fMRI session was as follow: The fingers of the dominant hand were numbered from 1 to 4 (1 = index, 2 = middle, 3 = ring, 4 = pinky). Numbers from 1 to 4 appeared randomly on a screen, and for each one, subjects performed the corresponding finger-thumb opposition. The task was externally paced at a rate of 2 Hz. The motor task paradigm included the execution of those movements alternated with either one of the two imagery conditions (KI or VI).

Figure 22.15 shows the fMRI activation patterns for each condition (the arrows are pointing to the central sulcus for guidance).

Note that the volumes of activation in the primary motor cortex during execution are larger than that seen during kinetic imagery (Jeannerod, 1995; Kim et al., 1995), general trend for all areas during the imagery tasks.

Third, we determined the networks of activation: By determining networks of activation, Structural equation

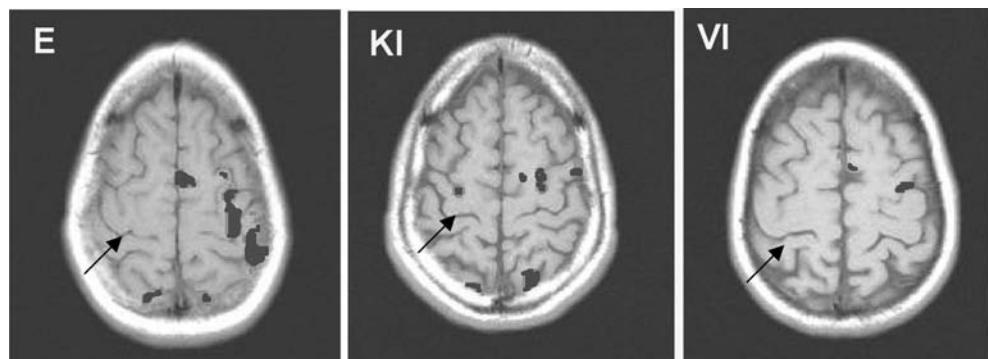

Figure 22.15. Single subject fMRI during E, KI and VI. Brain activation was seen in several sensory and motor areas during execution (E), kinetic imagery (KI) and visual imagery (VI). These axial slices depict regions at the level of the hand motor area of M1. For orientation purposes, the arrows are pointing to the central sulcus. Note that volumes of activation were much larger during E than during KI or VI. Since these are radiological images, the left side of the figure represents the right hemisphere.

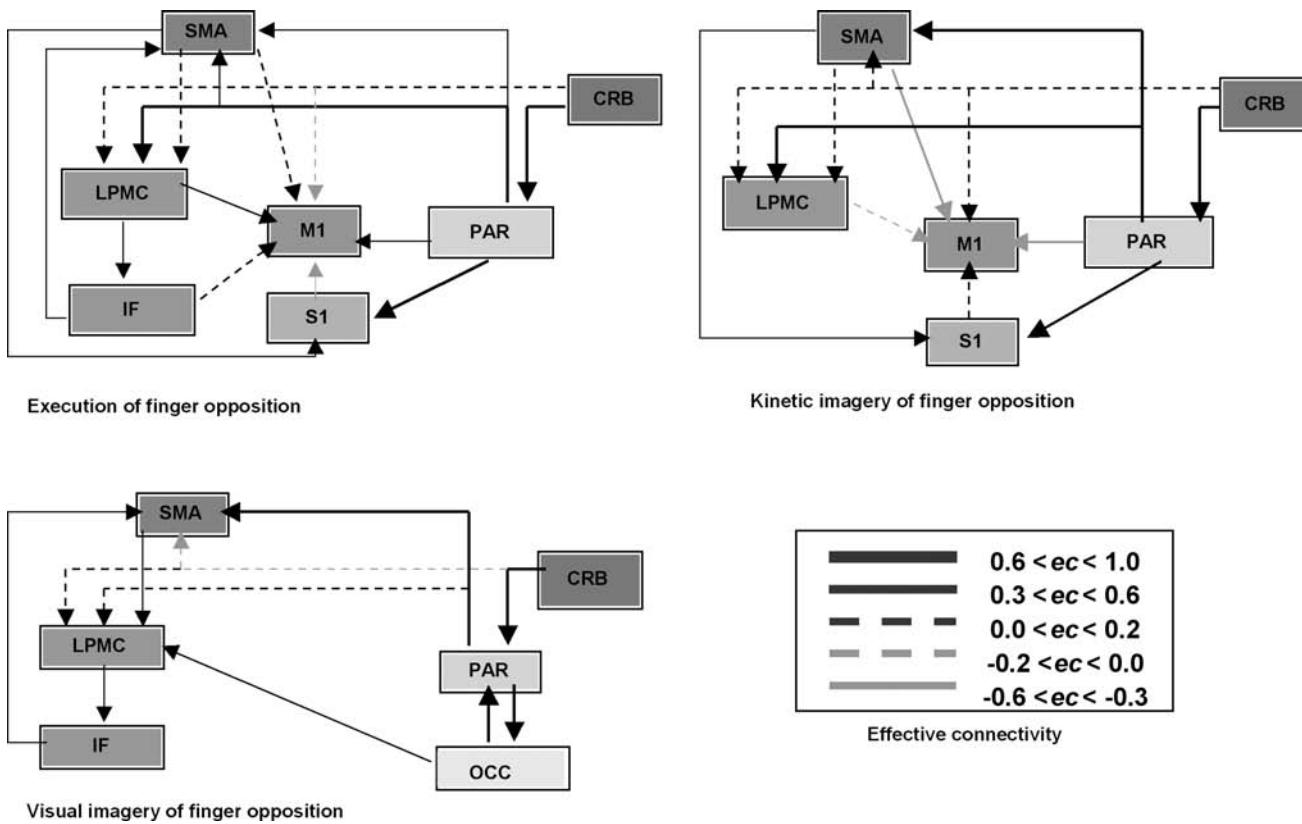

Figure 22.16. Final networks for E, KI, and VI. This figure depicts the values of effective connections during the three experimental conditions. Note the close parallels between E and KI except in the connections between association motor areas and superior parietal lobe with M1. In contrast, the patterns of connectivity in the VI conditions were biased towards visual areas.

modeling (SEM) describes the functional influences among anatomical brain regions. The emphasis thereby changes from the individual brain regions active in each condition to the relationships among them. The results of the present study demonstrated that independent of the volumes of activation *per se*, there are clear differences (and similarities) in the networks for E, KI, and VI. The following figure shows the networks associated with each condition.

As shown in Figure 22.16, E and KI are closely related tasks, since they share several, identical parts of the network. The VI condition differs the most. These results show that resulting networks can differentiate among conditions that activate the same regions by means of effective connectivity values, but also they denote if they are facilitatory (positive) or not (negative). These parallels suggest that influences among areas involved in sensory-motor integration are kept constant during E and KI. Thus during KI and E, not only are similar areas active, but the relative influence of these areas on each other also remains constant. This notion reinforces further the idea of KI as a true motor behavior, a postulate also supported by behavioral data, since KI has been associated with motor preparation, imitation and anticipation, motor restraint, motor execution, and motor learning (Deiber et al., 1998; Jeannerod, 1995).

In contrast, there are some differences between E and KI. The most notable differences were found in the inputs

to M1. During KI, many of the inputs from association areas (PAR and SMA) to M1 are strong and negative compared to their effect during execution. These negative values could be interpreted as a suppression effect (McIntosh & Gonzalez-Lima, 1998) of SMA and PAR on M1, since during KI there are no overt movements. The fact that these connectivity values change from weak and positive to strong and negative during a task with no overt movements (KI) provides a new perspective on how the motor system might be encoding information. In other words, we have two closely related tasks (E and KI), involving activation in similar areas, and with several similar interrelationships. Yet even when the volumes of activation in M1 during KI are not that different, the influence exerted by SMA and PAR is opposite their influence during E. This exemplifies how network analysis can provide a new perspective on the neurophysiology of the motor system by describing how changes in the interrelationships among areas can generate different motor behaviors.

Understanding actions done by others: the mirror neuron system

The mirror neuron system in monkeys

Many of the original studies done in the mirror system used non-human primates as experimental subjects. Because of this, we will refer first to this data followed by studies in

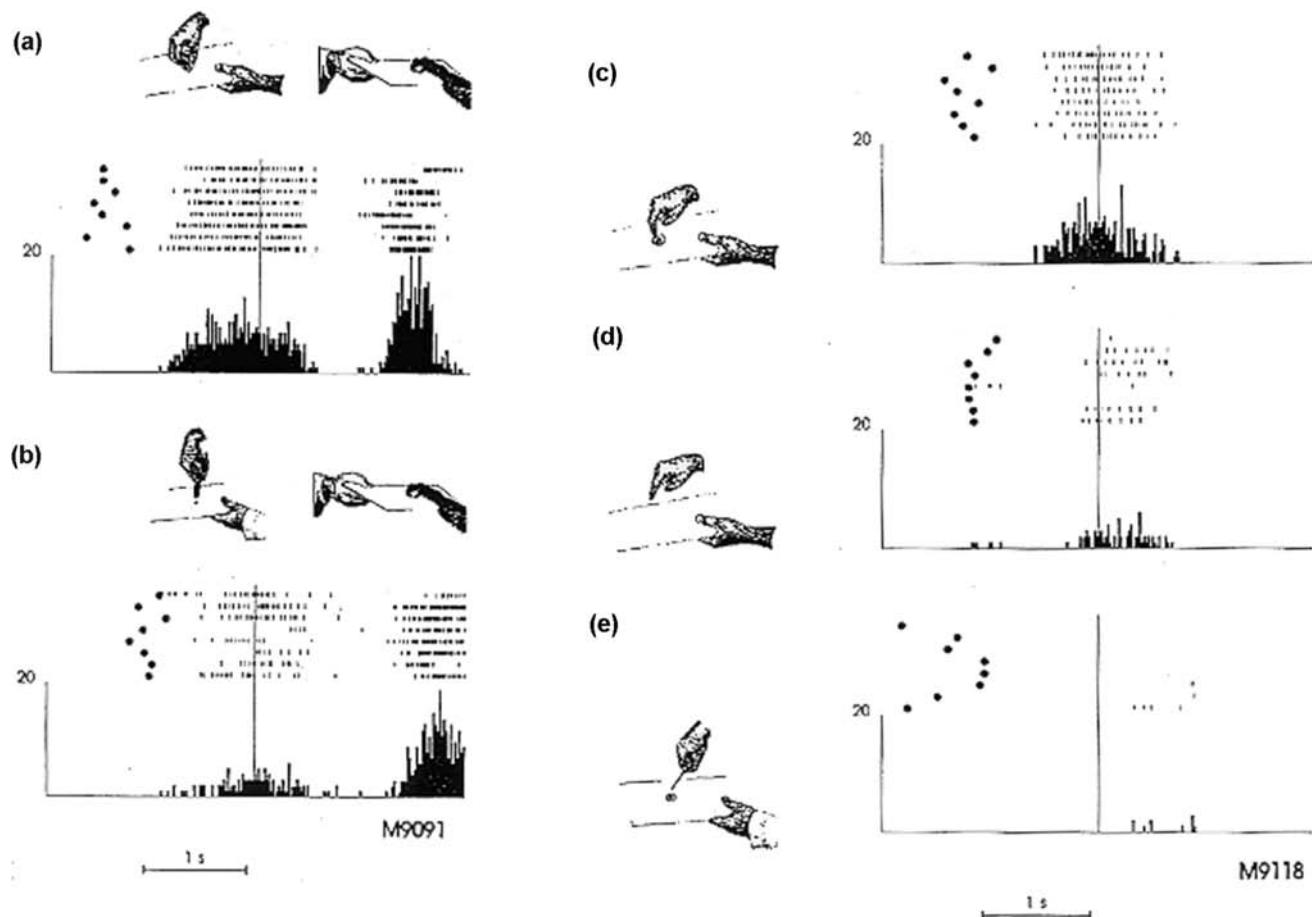

Figure 22.17. Mirror system in macaques. Firing patterns of neurons located in F5 from the observation and the execution of grasping movements. The discharge patterns of mirror neurons during action observation, are similar to execution ((a) left panel) or (c) but not during action observation when a tool is involved ((b) left panel) and (e) nor when the object is missing (d). Modified from: Rizzolatti et al. (1996). *Premotor cortex and the recognition of motor actions*. *Cogn. Brain Res.* 3: 131–141.

humans. As previously stated, electrophysiological studies have shown that area F5 contains a motor representation of mouth and hand goal-directed actions (Rizzolatti et al., 1988). Some of the neurons in this area (mirror neurons) discharge during the execution of both hand and mouth goal-directed actions, and also respond when the monkey observes another monkey or a human performing the same or a similar action (Gallese et al., 1996; Rizzolatti et al., 1996). The visual properties of mirror neurons resemble those of neurons found in the superior temporal sulcus (STS) region. These neurons, like mirror neurons, respond to the visual presentation of goal-directed hand actions, of walking, turning the head, moving the hand and bending the torso (for a review see Carey, 1996). However, differently from mirror neurons described in area F5, neurons described in the STS region do not discharge during the execution of any of the actions that may trigger them visually. The congruence between the action motorly coded by the neuron and that triggering the same neuron visually may be very strict: in this case only the observation of an action which is identical to that coded by the neuron can activate it. More often, this congruence is broader; in this case, the observed and the executed action coded

by the neuron match the goal of the action rather than the movements necessary to execute it. Some important features of mirror neurons should be highlighted: during action observation they discharge only when a biological effector (a hand, for example) interacts with an object; if the action is performed with a tool the neuron does not discharge. Mirror neurons are not active either when the observed action is simply mimicked, that is, executed in the absence of the object. Finally, mirror neurons do not discharge during the mere visual presentation of an object (Figure 22.17). Up to now only mirror neurons related to hand actions were described. More recently it has been demonstrated that in area F5 there are also mirror neurons which discharge during the execution and observation of mouth actions. Not surprisingly, most of the mouth mirror neurons become active during the execution and observation of mouth feeding behaviors such as grasping, sucking or breaking food. However, some of these neurons respond during the execution and observation of oral communicative actions such as lip-smacking (Ferrari et al., 2003).

Since their discovery, the preferred hypothesis has been that mirror neurons might play an important role both in action recognition and action understanding (Jeannerod

et al., 1995). If mirror neurons are responsible for action recognition, then these neurons should discharge also when the monkey cannot see the whole sequence of an action, provided that the goal of the observed action can be clearly inferred. A recent electrophysiological study (Umiltà et al., 2001) supports the claim that mirror neurons may infer the goal of an action. In this experiment, two conditions were presented: in the first one (vision condition) the animal could see the whole sequence of a hand goal-directed action, in the second one (hidden condition) the final part of the action was hidden from the sight of the monkey by means of a screen. In this last condition, however, the animal was shown that an object, for example a piece of food, was placed behind the screen preventing the observation of the final part of the performed action. The results showed that mirror neurons discharge not only during the observation of action, but also when the final part of it is hidden. As a control, a mimicked action was presented in the same conditions. As expected, in this case, the neuron did not discharge either in the full vision condition or in the hidden condition.

Actions may be recognized also from their typical sound, when presented acoustically. For example, we can recognize that an individual is manipulating some keys simply from the typical sound this action produces, even when we cannot see the individual performing it. Besides visual properties, a recent monkey experiment has demonstrated that about 15% of mirror neurons also respond to the presentation of the sound typical for a specific action. These neurons are called audio-visual mirror neurons (Kohler et al., 2002). Audio-visual mirror neurons could be used to recognize actions done by other individuals, when presented acoustically. It has been argued that these neurons code the action content, which may be triggered either visually or acoustically, thus representing a possible step for the acquisition of language. It is worth noting that for anatomical and physiological reasons area F5 is considered the monkey homologue of human Broca's region (Binkofski & Buccino, 2004; Petrides & Pandya, 1984; Rizzolatti & Arbib, 1998).

The mirror neuron system in humans

There is increasing evidence that a mirror neuron system also exists in humans. Converging data supporting this notion come from experiments carried out with neurophysiological, behavioral, and brain imaging techniques.

Neurophysiological studies. The first evidence of the existence of a mirror neuron system in humans was provided by Fadiga et al. (1995). During this experiment, a single pulse with transcranial magnetic stimulation (TMS) was delivered while subjects were observing an experimenter performing various hand actions in front of them. As control condition, single pulse TMS was delivered during object observation, dimming detection and observation of arm movements. Motor evoked potentials (MEPs) were recorded from extrinsic and intrinsic hand muscles.

Results showed that during hand action observation, but not in the other conditions, there was an increase in the amplitude of the motor evoked potentials recorded from the hand muscles, normally recruited when the observed action is actually performed by the observer. These results were recently confirmed by Strafella and Paus (2000). Furthermore, using the same technique, Gangitano et al. (2001) found that during the observation of hand actions not only there is an increase of MEPs amplitude in the muscles involved in the actual execution of the observed action, but MEPs are modulated in a fashion strictly resembling the time-course of the observed action. Taken together, the TMS data support the notion of a mirror neuron system coupling action execution and action observation in terms of both the muscles involved and the temporal sequence of the action.

Similar to these results are those obtained by Cochin et al. (1999) using quantified electroencephalography (qEEG). In this study "mu" activity was blocked during both the observation and execution of various hand actions, when compared to rest. It is worth recalling that similar results were observed by Gastaut and Bert (1954), who noted the suppression of "mu" activity in humans during the movie presentation of various actions, results also obtained by Hari and co-workers using magnetoencephalography (MEG) (Makela et al., 1993). In this study it was found a suppression of 15–25 Hz activity originated in the precentral motor cortex, during the execution and, to a less extent, during the observation of object manipulation. All of these studies provide further evidence that observation and execution of action share common neural substrates.

Behavioral studies. Evidence in favor of the existence of a mirror neuron system also derives from neuropsychological studies using behavioral paradigms. Brass (2000) investigated how movement observation could affect movement execution in a stimulus-response compatibility paradigm. Using a reaction time paradigm, they contrasted the role of symbolic cues during the observation of finger movements and during the execution of the same finger movements. Subjects were faster to respond when the finger movement was the relevant stimulus. Moreover the degree of similarity between the observed and executed movement led to a further advantage in the execution of the observed movement. These results provide a strong evidence for an influence of the observed movement on the execution of that movement. Similar results were obtained by Craighero et al. (2002) in a study where subjects were required to prepare to grasp as fast as possible a bar oriented either clockwise or counter-clockwise, after presentation of a picture showing the right hand. Two experiments were carried out: in the first experiment the picture represented the final required position of the hand to grasp the bar, as seen through a mirror. In a second experiment, in addition to stimuli used in experiment one, other two pictures were presented, obtained rotating of 90° the hand shown

in the pictures used in Experiment 1. In both experiments, responses of the subjects were faster when the hand orientation of the picture corresponded to that achieved by the hand at the end of action, when actually executed. Moreover the responses were globally faster when the stimuli were not rotated.

Brain imaging studies. All the cited studies provide little, if any, insight on the localization of the mirror neuron system in humans. This issue has been addressed by a number of brain imaging studies.

In an early positron emission tomography (PET) experiment aimed at identifying the brain areas active during action observation, Rizzolatti et al. (1996), comparing hand action observation with the observation of an object, found activation of Broca's region, the middle temporal gyrus and the superior temporal sulcus region. Broca's region is classically considered an area devoted to speech production. Recently, however, it has been demonstrated that in this area, a motor representation of hand actions is also present (Binkofski & Buccino, 2004; Binkofski et al., 1999; Ehrsson et al., 2000). Given the homology between Broca's area and area F5 in the monkey, (where mirror neurons were originally discovered), this study provided the first evidence on the anatomical localization of the mirror neuron system for hand actions in humans.

A recent fMRI study showed that in humans, the mirror neuron system is complex and related to different body actions performed not only with the hand, but also with the foot and the mouth. Buccino et al. (2001) asked subjects to observe video-sequences presenting different actions performed with the mouth, the hand and the foot, respectively. The actions shown were either transitive (the mouth/hand/foot acted on an object) or intransitive (the mouth/hand/foot action was performed without an object). The following actions were presented: biting an apple, grasping a cup, grasping a ball, kicking a ball, and pushing a brake. As a control, subjects were asked to observe a static image of each action.

The observation of both transitive and intransitive actions, compared to the observation of a static image of the same action, led to the activation of different regions in the premotor cortex and Broca's area, depending on the body part involved in the observed action. The different regions largely overlapped those where classical studies (Penfield & Rasmussen, 1950) had shown a somatotopically organized motor representation of the different effectors (Figure 22.18). Moreover, during the observation of transitive actions, distinct sectors in the inferior parietal lobule were active, including areas inside and around the intraparietal sulcus, with localization depending on the body part involved in the observed action. All activations found in this study are shown in Figure 22.18.

On the whole, this study strongly supports the claim that, as in the actual execution of actions, during action observation different, somatotopically organized fronto-parietal circuits are recruited (Jeannerod et al., 1995; Rizzolatti &

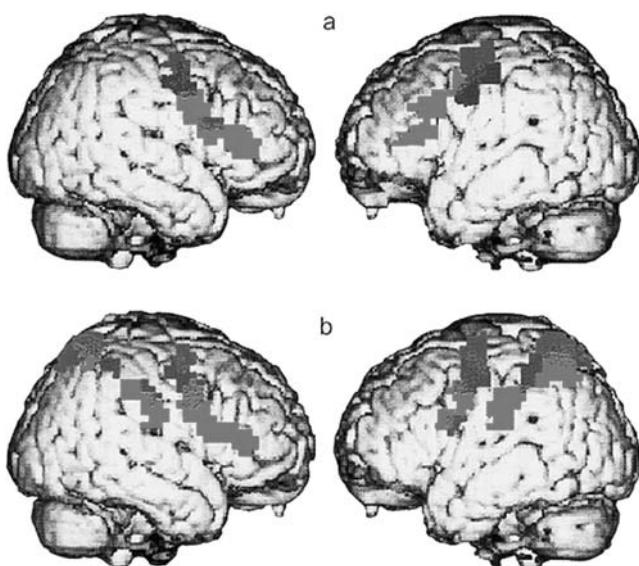

Figure 22.18. Mirror system in humans. Somatotopic fMRI activation in parietal and premotor regions during observation of intransitive (a) and transitive (b) actions in humans. Light: mouth related movements; Dark: hand related movements; Medium: foot related movements.

Fadiga, 1998). In this context, it is worth noting that mirror neurons, similar to those described in area F5, have recently been reported by Gallese et al. (2002) in the inferior parietal lobule of the monkey (area PF).

Contrast between the mirror system in humans and monkeys

As previously stated, in the monkey the mirror neuron system can be activated when the animal observes an experimenter, a member belonging to other species (non-conspecific), while performing a similar action motorly-coded by the neuron. A recent fMRI study (Buccino et al., 2004) addressed whether we recognize action performed by non-conspecifics using the same neural structures involved in the recognition of action performed by con-species (same species). In this study, normal subjects were asked to carefully observe different mouth actions performed by a man, a monkey, and a dog, respectively. Two kinds of mouth actions were visually presented: biting a piece of food and oral communicative actions (human silent speech, monkey lip-smacking, and silent dog barking). The results showed that during the observation of biting, there is a clear activation of the *pars opercularis* of the inferior frontal gyrus and of the inferior parietal lobule, regardless of the species performing the action. Interestingly, during the observation of oral communicative mouth actions, a different pattern of activation was observed, this time depending on the species performing them. During the observation of silent speech (human), there was a clear activation of Broca's area in both hemispheres, with a leftward asymmetry; during the observation of lip smacking (monkey) there was only a small bilateral activation in the *pars opercularis* of Broca's area, with no clear asymmetry.

between the two hemispheres. Finally during the observation of silent dog barking no activation was found in Broca's area, but activation was present only in the right superior temporal sulcus region. The results of the experiment strongly suggest that action performed by other individuals, including non-conspecifics, may be recognized in two different ways: for actions like biting or silent speech reading, there is a motor resonance of the cortical circuits involved in the actual execution of the observed actions. In other words their recognition relies on the mirror neuron system. For actions like barking, this resonance is missing. In the first case there is a "personal" knowledge of the action observed, in the sense that it is mapped on the observer's motor repertoire and therefore the observer has a direct, personal experience of its execution (e.g., I recognize it because I am able to do the same action I am looking at). In the second case, although the viewed actions are still recognized as biological motion (as suggested by the activation of the STS region), personal knowledge about these actions is lacking because the observer has no direct experience of the observed action in motor terms (e.g., I can approximately imitate a dog barking, but, as a matter of fact, I am not able to do it).

Finally, it is well known that we can recognize actions even when we look at point lights attached to the joints of an actor in motion. Early brain imaging studies on this issue demonstrated that observation of point-light biological motion leads to activation of superior temporal cortical areas. These early studies failed to show any activation in the motor system. The results of a very recent fMRI study, however, showed that areas responding selectively to point-light biological motion are found not only in the lateral and inferior temporal cortex but also in the pre-motor cortex. This result suggests that, although there is no direct matching between the observed action and the motor repertoire of the observer, in the case of point light biological motion the motor system is involved in filling in the simplified motor pattern obtained with point-lights and in "humanizing" the observed action.

MOTOR LEARNING AND MOTOR CORTICAL PLASTICITY

The areas of procedural learning, motor memory, and motor skill acquisition have been traditionally studied independently by different scientific disciplines. Psychology has a long tradition of studying human procedural memory and behavioral changes during skill acquisition without the possibility of observing the underlying cerebral processes. For the past 20+ years, neuroscience has emphasized the study of adult brain plasticity, including motor cortical plasticity, resulting from biological as well as environmental and behavioral changes. Finally, neurology and rehabilitation have studied deficits of motor behavior after stroke and re-gaining of motor skill during recovery and rehabilitation. Recently, noninvasive human imaging methods have provided a unique opportunity to

combine the research methods across disciplines to allow a more complete picture of the issues involved. Understanding the mechanisms and the subsequent optimization of the motor learning process are desirable for different fields of human activity: developing and improving manual skills for a job, training in sports, and neurological rehabilitation.

Motor learning and motor memory

Motor learning has been studied within several disciplines, although the acquired knowledge has not been fully integrated across disciplines. Psychology has studied both acquisition of complex motor behavior (skill) (i.e., motor learning) and the storage and representation of this acquired knowledge (i.e., motor memory). It is generally accepted that knowledge of skills or procedural ("how") memory is distinct from knowledge of facts or declarative ("what") memory (Cohen & Squire, 1980; Squire, 1987b). Procedural memory is acquired incrementally, is modality-specific, does not allow for storage of individual events, and is usually associated with motor skill learning (Squire, 1987a). Most commonly, psychological theories view learning and memory in abstract terms, without any consideration of possible neuronal correlates of their proposed components. This is in contrast to similar endeavors from the neuroscience community (Fuster, 1995). Recently, the integrative field of cognitive neuroscience has been trying to focus simultaneous attention on both behavioral issues and neurobiological substrates and constraints imposed by the nervous system (e.g., Clegg, DiGirolamo, & Keele, 1998).

The term "motor learning" may be used in a broad sense in the psychological and neuroscience literature to encompass many processes, including the following (Strangman, 1998):

Adaptation: This is the simplest process during which existing behavior is modified or rescaled in response to environment. Examples of adaptation are habituation, sensitization, and vestibulo-ocular reflex (Raymond, Lisberger, & Mauk, 1996; Squire, 1987b).

Conditional motor association: This involves learning to associate an available motor response with a given stimulus (Halsband & Freund, 1990; Petrides, 1985, 1997). Most monkey learning studies belong into this category.

Finally, motor learning in the narrow sense is a process that leads to the acquisition of a novel response pattern that involves little or no functional trade-off for other movements. While adaptation and conditional motor association modify an existing behavior or connect it with a particular stimulus, motor learning enriches the individual's motor repertoire.

Motor learning may vary according to the type of motor control necessary for successful task performance

(Strangman, 1998). Tasks that do not rely on somatosensory feedback are called open-loop (e.g., dart throwing, penalty kick in soccer). The movements are usually so rapid (under 500 ms) that there is not enough time to process proprioceptive feedback. The second class of tasks is closed-loop, and such actions are mediated and error-corrected in real time by somatosensory feedback (e.g., gymnastics, figure skating). This dichotomy is somewhat artificial, as the amount of somatosensory feedback and subsequent self-correction can vary continuously. Still, considering the importance of proprioceptive input for cortical motor processing, it is likely that the amount of this internal feedback modulates the learning process in a significant way.

One of the issues addressed by research in motor learning is the transfer of training, that is, transfer of behavioral improvement on one task to a different task, a movement effector (e.g., from one hand to the other), or the environment (Adams, 1987). Performance benefit from practice on specific motor skills often does not correlate with, or transfer to, similar but non-identical tasks. Performance on these “transfer tasks” is usually substantially poorer for subjects that practiced the original but not the transfer task (Adams, 1987).

Practicing under highly structured conditions (different skills practiced in blocks) leads to faster learning but poorer transfer of skills than training by randomly mixing different skills. There seems to be a trade-off between practice variability and learning time on one hand, and between practice variability and behavior generalization on the other (Strangman, 1998).

There is not a clear understanding in the behavioral literature on the kind of practice that is the most beneficial. It is understood, though, that (a) subjects should distribute practice over time rather than participate in one massed practice session, (b) subjects should get feedback on how they are performing, and (c) the task should be easy enough to make at least occasional success possible (Strangman, 1998).

Neuroscience: Motor learning and memory in the brain

Neuroscience arrived at the topic of motor learning and memory from a different direction than the behavioral sciences. The speculative connection between the structure of the nervous system and acquisition of skilled behavior was made at least a hundred years ago. Ramón y Cajal mentions in his autobiography (1923) at a conference presentation in 1893 when he suggested the encoding of skill through modulation of neuronal connections. In this presentation, he offered an

explanation of the adaptation and professional skills (physical education, language operations, writing, playing the piano, mastering fencing, etc.) by the progressive strengthening of nervous pathways... excited by the pass of a wave, as well as by the creation of new cellular appendages (den-

dritic growth and elongation or branching of nervous collaterals, non-congenital), capable of improving the adjustment and extension of the contacts, and of organizing completely new relationships between neurons that were originally not connected.

– Translation Dr. Ana Solodkin

More recently, the discovery of plastic changes in the adult mammalian brain have provided new evidence to explain mechanisms of motor learning and memory. Most of the research has focused on primary motor and sensory cortices, since the anatomical and functional organization of these areas had been well described, thus simplifying the investigation of plastic changes. The following section will review the research on plasticity of the primary motor cortex, the area most relevant to motor learning.

Plasticity in animal and human M1

Several animal studies have demonstrated that the representations of muscles or movements in adult primary motor cortex can undergo plastic changes in response to peripheral or central lesions or altered experience. Motor maps have been shown to change in response to peripheral motor nerve lesions in the rat (Donoghue, Suner, & Sanes, 1990), repetitive cortical stimulation in the monkey (Nudo, Jenkins, & Merzenich, 1990), pharmacological modulation of intracortical inhibition in the rat (Jacobs & Donoghue, 1991), change of rat limb configuration (Sanes, Wang, & Donoghue, 1992), motor practice (Nudo, Wise, SiFuentes, & Milliken, 1996), or cortical lesions in the monkey (Nudo & Milliken, 1996; Nudo, Milliken, Jenkins, & Merzenich, 1996) found expansion of the motor cortical representations of muscles/movements that were used during a several week long session when monkeys learned to retrieve food pellets from small wells. In another primate study with long-term movement practice, M1 neurons that have been initially silent begin firing (Kennedy & Bakay, 1997). The extent of newly emerged cortical finger representation was correlated with recovery after stroke destroying the original finger representation (Nudo et al., 1996).

Several cellular mechanisms have been implicated to explain the observed plasticity, including unmasking or potentiation of existing but normally ineffective neural connections, axonal sprouting with new synapse formation, or a combination of these. Changes in motor maps after the application of bicuculline, an antagonist of the inhibitory neurotransmitter GABA (Jacobs & Donoghue, 1991), have been taken as evidence that a part of the wide network of available neural connections is functionally suppressed through intracortical inhibition. Long-term potentiation of cortico-cortical synapses has been observed in cat motor cortex (Keller, Arissian, & Asanuma, 1990), as has the appearance of new synapses after damage to deep cerebellar nuclei (Keller, Iriki, & Asanuma, 1990) or long-term thalamic stimulation (Keller, Arissian, & Asanuma, 1992). Increased synaptogenesis and early immediate gene c-fos expression have been associated

with motor acrobatic learning in rat motor cortex (Kleim et al., 1996). Furthermore, the strength of intrinsic connections in M1 is dynamically modifiable through long-term potentiation (Aroniadou & Keller, 1995; Hess & Donoghue, 1994). Finally, the extent of horizontal connections has been shown to correlate well with the extent of plastic changes in motor cortical representations after transsection of efferent connections in the rat (Huntley, 1997).

Human motor plasticity

Changes of primary motor cortical organization have also been observed in adult humans. Expansion and shifts in motor maps occur after central or peripheral neurological lesion such as stroke (Weiller et al., 1993), amyotrophic lateral sclerosis (Kew et al., 1994), arm amputation (Kew et al., 1994; Pascual-Leone et al., 1996) and facial paralysis (Rijntjes et al., 1997). Remapping within M1 was suggested as one possible mechanism of motor function recovery after stroke (Weiller et al., 1993). One type of map change observed within M1 as a result of brain injury or disease was a shift of hand area laterally and ventrally, into the presumed face area, over a distance of up to 10 mm (Kew et al., 1994; Rijntjes et al., 1997; Weiller et al., 1993).

Similar changes have been described in the absence of motor system injury. Practice of Braille reading and motor learning caused expansion of scalp area from which movement could be evoked by transcranial stimulation (Pascual-Leone et al., 1993; Pascual-Leone, Grafman, & Hallett, 1994). Prolonged leg immobilization, on the other hand, caused shrinking of the scalp area for excitation of a leg muscle (Liepert, Tegenthoff, & Malin, 1995). Several studies of human motor learning have observed changes within M1 (Karni et al., 1995; Kawashima, Roland, & O'Sullivan, 1994; Pascual-Leone et al., 1995), even though M1 is only one of the multiple cerebral areas supposedly involved in motor learning (Halsband & Freund, 1993b). A newly acquired motor skill may take advantage of movement segments that are formed by combining neural units of M1 (segmental learning) and retrieved during the execution of the acquired skill (Asanuma & Keller, 1991). The possible anatomical substrate for the co-activation of an ensemble of neurons during skilled movement is the network of horizontal corticocortical connections observed within monkey M1 (Huntley & Jones, 1991).

Cortical activation size and learning

If one accepts the assumption that increasing skill and automaticity for a specific movement originates from changes of cortical motor function, the next question regards the character and direction of such changes. There is an intuitive concept that skill reflects efficiency at the cortical level and that such skill would translate into less cortical activation during functional imaging, implying either that neural units are firing less, fewer neural units are firing action potentials, or both. On the other hand, there is

both nonhuman primate (see above) and human evidence that practice increases, rather than decreases the area of cortex associated with the practiced movement (at least in the time frame of several weeks).

Human motor learning studies have commonly reported that movement practice leads to recruitment of additional motor cortex, with the appearance of new active cortical fields (Kawashima et al., 1994), and expansion of the cortical territory corresponding to the practiced muscles/movements of several millimeters up to several centimeters (Karni et al., 1995; Pascual-Leone et al., 1995). Subjects who practiced a five-finger piano exercise for 2 hours a day for 5 days showed an enlarging motor cortical area targeting the long finger flexors and extensors, followed by a decreased threshold for activation as they learned the skill (Pascual-Leone et al., 1993).

Karni et al. (1995), compared fMRI activation caused by two sequential finger movements involving the same fingers. The sequences had five components and each involved fingers 2–5 touching the thumb in a particular order. One of the sequences was repeatedly practiced over several weeks. While the extent of cortex activated with either sequence was similar at the beginning of the study, after training the primary cortical activation by the practiced finger sequence was significantly larger than activation caused by the non-practiced sequence. The area of evoked response in M1 for the trained sequence did not extend beyond the hand representation, which was mapped in a subset of the subjects by independent finger movements. However, the amount of change in the rest of the motor map was not addressed to establish whether the learning was competing for cortical output neurons or instead whether it enhanced sharing of neurons. The relationship between the observed expansion and the localization of other hand movements was also not described. Finally, the study was limited to M1, although there is evidence that other motor and somatosensory regions participate in learning of new motor skills (see below).

In addition to investigating the effect of short- and medium-term experimental motor training on the motor cortex, correlation has also been sought between very long-term practice of skilled movements and the motor system. Although right-hand dominance for skilled movements is typical for humans, hand preference has also been observed in monkeys (Nudo et al., 1992). The monkey motor cortex controlling the preferred hand has been found to contain a larger and more complex hand area when studied with intracortical microstimulation (Nudo et al., 1992). Studies of human M1 structural asymmetry related to handedness have found asymmetry in the depth of the central sulcus, with the left hemisphere bigger than the right in right-handers, and a less prominent opposite asymmetry in left-handers (Amunts et al., 1996; White & Hardy, 1995). Microstructural asymmetry has been found in post-mortem brains, with a larger neuropil compartment (containing dendrites, axons, and synapses) in the left (dominant) motor cortex (Amunts et al., 1996). The

authors suggest that this finding reflects a greater density of intracortical horizontal connections in the cortex serving the dominant hand (Amunts et al., 1996). Callosal connections from the opposite motor cortex comprise another possible source of increased connectivity, but callosal connection density is very low in the monkey motor hand areas and seems to be inversely related to the development of independent fine movements (Zant & Strick, 1978). Callosal connections have also been suggested to be a potential hindrance for independent movements of one hand (Gould et al., 1986). Another anatomical study did not find any asymmetry in the size of the precentral motor cortex in post-mortem human brains (White et al., 1997).

The effect of long-term bimanual practice (i.e., playing a musical keyboard instrument) on brain structure was studied by Amunts et al. (1997). The asymmetry of central sulcus depth observed in control subjects was diminished in musicians and this effect was proportional to the age of inception of music training. Similarly, finger-tapping performance of musicians was more symmetrical, due to significantly better performance of the nondominant left hand. A right-larger-than-left difference was found in the strength of cortical magnetic fields evoked by moving left versus right fingers in the primary motor cortex of string players (Elbert et al., 1995). All this evidence seems to further support the notion that long-term practice changes the motor cortex on both microscopic and macroscopic levels.

Contribution of other motor and somatosensory areas to motor learning

Regions other than M1 have also been implicated in motor learning and motor plasticity. Changes in the supplementary motor area (SMA), premotor cortex (LPMC), cingulate motor area (CMA), and areas of the parietal lobe have all been associated with motor skill acquisition (Halsband & Freund, 1993a).

Primate SMA neurons participate in preparatory rather than movement-related activity (Aizawa & Tanji, 1994; Wiesendanger, 1986) and their activity is modulated by learning. After a motor task (keypress movement in response to a visual trigger) had been extensively overtrained (12 months) in monkeys, very few, if any, SMA neurons remained active before movement onset (Aizawa et al., 1991). The authors suggest that SMA neuronal activity during a simple task is redundant and therefore eliminated over time to increase efficiency through division of labor. It might be inferred that even during a complex motor task, non-primary motor activation can be gradually eliminated at the same time-scale as the movement is increasingly encoded in M1. However, after M1 damage, SMA activity reappears (Aizawa et al., 1991). Similarly, in a human study of motor learning, SMA was active early during motor skill acquisition (Grafton, Hazeltine, & Ivry, 1998) but not later during transfer of skill from hand to arm. In contrast to these results and the theoret-

ical model they suggest, Jenkins et al. (1994) found SMA activation in a human study of motor sequence learning to be stronger during performance of a pre-learned sequence than during new learning. It is thus possible that some type of movement sequences becomes represented in the SMA rather than M1 over the course of learning. Human imaging studies using PET has also shown prominent activation of LPMC and parietal association cortex in early stages of motor learning (Jenkins et al., 1994).

Participation of primary somatosensory cortex in motor cortical plasticity

Primary somatosensory cortex is also thought to play a role in the plasticity of M1. While ablation of somatosensory cortex does not markedly worsen motor performance in the monkey (Asanuma & Arissian, 1984), it prevents learning of new motor skills (Pavlides, Miyashita, & Asanuma, 1993). The importance of S1 for motor learning is most likely due to processing of proprioceptive feedback, the absence of which degrades skilled movements (Bossom, 1974) and slows or blocks the acquisition of new motor skills (Rothwell et al., 1982). Changes in forelimb configuration have caused expansion of the M1 forelimb motor area into the representation of face in the rat (Sanes, Wang, & Donoghue, 1992).

As mentioned above, proprioceptive afferent information mainly reaches area 3a (Jones, 1983) and, to a lesser degree, area 3b (Heath, Hore, & Phillips, 1976), with further processing in area 2. It has been suggested that each of these areas has a separate somatotopic map in the monkey (Kaas et al., 1979) and these maps have been found to show plastic changes in response to manipulation of the periphery or cortex (Courtemanche, Sun, & Lamarre, 1997; Kaas, Florence, & Neeraj, 1997; Merzenich et al., 1984). Changes in the 3a map have been studied with training of fine touch on the skin (Recanzone, Merzenich, & Dinse, 1992) and after experimental cortical stroke in area 3b (Xerri et al., 1998). Acquisition of a motor skill dependent on fine touch caused reorganization in area 3b (Xerri et al., 1999), but it is not known whether area 3a also reorganizes during motor skill acquisition and whether it thus possibly contributes to the reorganization in M1.

The Neural Basis of Affective and Social Behavior

RALPH ADOLPHS AND MICHAEL L. SPEZIO

INTRODUCTION

The processing of affectively and socially relevant information, long the purview of social psychology and psychiatry, has recently become a primary focus for cognitive neuroscience. The reasons for this are twofold: (1) the maturation of theoretical frameworks for understanding such information processing provided specific hypotheses that made neuroanatomical predictions; and (2) the advent of modern neuroscience methods, in particular functional neuroimaging, provided ways of testing those predictions. Of course, the predictions were not all formulated first and then simply tested, but as the data from neuroscience began to trickle in, major revisions in the theoretical framework and the hypotheses were undertaken at the same time. This has resulted in one of the most dynamic and interesting fields of scientific research, really a paradigm study in the philosophy of science, in which hypotheses and data continuously update one another.

Two historical texts, one by Charles Darwin (Darwin, 1872/1965) and the other by William James (James, 1884), have provided the impetus for many of the questions modern affective neuroscience has thought it has had to address. Darwin's book, *The Expression of the Emotions in Man and Animals*, provided three famous principles for understanding emotion and its relation to social communication: the idea that emotional expressions had evolutionarily antecedent bodily reactions whose primary adaptive nature had been co-opted for social purposes; the idea that emotions have an internal structure (specifically, his principle of antithesis); and, last but not least, the idea that emotions are a direct result of the nervous system, which mediates interactions between the brain and bodily affect in the expression of emotions (cf., Bernard, 1866).

James departed from Darwin's third principle – which emphasized the interaction between brain and bodily affect – to answer the question "What is an emotion?" in an eponymously entitled paper (James 1884). His answer was counterintuitive, and reactions to it have influenced the

theoretical positions on emotion to this day. James proposed that bodily changes, or affects, directly follow the perception of some emotionally evocative stimulus ("exciting fact"), and that the perceptions of these bodily changes are simply identified as the emotion or feeling. James thought that the emotion/feeling only happened *after* the bodily changes had occurred, arguing against the idea that neural activity in preparation for the bodily changes could itself be perceived and give rise to emotion/feeling prior to or at the same time as the bodily changes.

Cognitive neuroscience has used the interactionist perspective Darwin proposed in investigating the mechanisms by which the brain processes both environmental stimuli in the generation of emotions and the concomitant physiological responses as they influence not only further emotional processing, but also higher order cognitive functions. The goal of incorporating emotional processing into a rigorous mechanistic understanding of cognition (Simon, 1979) is being actively pursued in cognitive neuroscience. Recent reviews on the relationship of emotion to memory (LaBar, 2003; Richter-Levin, 2004; Kensinger, 2004; McGaugh, 2004), to attention (Pessoa, Kastner, & Ungerleider, 2002; Pessoa & Ungerleider, 2004), and to decision making (Bechara, 2004; Bechara, Damasio, & Damasio 2003) illustrate the wide reach of emotional processing research within cognitive neuroscience. Some of the most surprising results in relating emotion to complex cognition, however, have come from the cognitive neuroscience of social behavior. Here, not only has emotional processing within localized brain networks been shown to strongly modulate social behavior, but there is evidence that emotional processing is in fact constitutive of and required for normal social behavior (Adolphs, Tranel, & Damasio, 2003; Adolphs, 2003, 2003; Anderson et al., 2000). That is, damage to key brain areas important for emotional processing impairs a range of social abilities, from judging emotion from faces or voices or bodily motion to profound social dysfunction.

Indeed, most structures that have been shown to be important in processing emotions have turned out to be important also for social behavior. These include (a) higher-order

sensory cortices; (b) amygdala, ventral striatum, and orbitofrontal cortex; and (c) additional cortical regions such as the left prefrontal, right parietal, and anterior as well as posterior cingulate cortices. One can relate these three sets of regions, respectively, as implementing different sets of processes: (a) a perceptual representation of the stimuli and their constituent features, (b) an association of this perceptual representation with emotional response, cognitive processing, and behavioral motivation, and (c) the construction of an internal model of the social environment, involving representation of other people, their social relationships with oneself, and the value of one's actions in the context of a social group. To some extent these three sets of processes build on one another, although their interactions are complex.

SENSORY PROCESSING

Faces: visual cortex and the amygdala. A large literature has shown that humans pay attention to, make eye movements to, discriminate, categorize and recognize faces differently than other visual stimuli (Adolphs, 2002). These differences in processing at multiple levels are driven by the computational demands that faces present: they constitute a large class of stimuli that are all visually very similar, yet require rapid and accurate subordinate-level categorization and recognition. Their social significance and ubiquity also makes everyone an expert at such processing, at least for large classes of faces. While debate continues regarding the extent to which face processing is domain-specific (Kanwisher, 2000; Tarr & Gauthier 2000), it is clear that it differs from processing of other visual stimuli, whether in kind or degree, and that it consequently correlates with disproportionate engagement of certain neural structures.

In addition to processing the identity, age, and gender of faces, one socially very important aspect of face processing is emotional expression (Darwin, 1872/1965) including direction of eye gaze (Emery, 2000). Although it remains a rich topic in psychology and philosophy how to conceptualize the terms "emotion" and "expression" (Russell, Bachorowski, & Fernandez-Dols, 2003), and there is continuing debate regarding how best to classify the different emotional facial expressions, most investigators within cognitive neuroscience have followed the scheme pioneered by Paul Ekman. He and others identified happiness, fear, anger, disgust, and sadness, with possibly also surprise and contempt, as so-called "basic" emotions that could be reliably signaled by the face (Ekman, 1972, 1973; Tomkins 1962), and his stimuli remain the most widely used set (Ekman & Friesen, 1976).

More contentious has been a second argument of Ekman's: that these basic emotions are cultural universals. Based on cross-cultural studies, some investigators argued that the set of basic emotions can be recognized as such across all cultures, and furthermore that this is evidence for their innate basis (Ekman, 1972; Izard, 1971). More

recent studies and meta-analyses have provided clear evidence that both culturally universal and specific factors contribute to recognition of emotional facial expressions: viewers from all cultures perform above chance levels in their ability to classify facial displays into emotion categories, but there is a further advantage if the race of the face shown in the stimulus matches that of the viewer (Russell & Fernandez-Dols, 1997; Elfenbein & Ambady 2002, 2002). There appears to be cultural learning (Sporer, 2001), such that increasing familiarity with the ethnicity of the faces shown as stimuli results in a graded increase in the accuracy with which they are recognized (Elfenbein, & Ambady, 2003).

Gender differences in the recognition of emotional facial expressions have also been reported, in line with the large literature on gender differences in processing emotional information more generally. Across studies, there is a consensus that females are more accurate than males, that such differences develop early (McClure, 2000), and that they depend also on the gender of the face shown in the stimulus (Erwin et al., 1992). There is even preliminary evidence that developmental gender differences in facial emotion processing are reflected in differences in the activation of certain brain structures, such as the amygdala (Killgore, Oki, & Yurgelun-Todd, 2001).

A large literature from functional imaging studies exists on face processing in extrastriate visual cortices; such work has shown, for example, that there are regions specialized to process different kinds of information from faces, such as information about identity and emotional expression (Hoffman & Haxby, 2000); that such processing draws on a distributed set of brain regions even though there is also specialization (Haxby et al., 2001); that facial expression and direction of gaze interact (Adams et al., 2003), and that such processing operates at several temporal scales (Adolphs, 2002). The amygdala is arguably the brain structure whose specific role in processing facial emotion has been investigated most intensely. Functional imaging studies have provided evidence that viewing facial expressions, especially fear, automatically engages the amygdala in normal individuals (Vuilleumier et al., 2001), and that abnormal amygdala activation can be seen in certain psychiatric populations with disorders of emotion (Rauch et al., 2000; Sheline et al., 2001; Davidson, 2002; Drevets, 2001). A large number of studies have reported disproportionate amygdala activation when viewing expressions of fear (Morris et al., 1996; Breiter et al., 1996; Phillips et al., 1998; Whalen et al., 2001). However, as in the case of the lesion studies (cf. below), other investigations have found evidence for amygdala processing of expressions other than fear, including either activations (Breiter et al., 1996) or deactivations (Morris et al., 1996) to happy faces, as well as activations to sad faces (Blair et al., 1999). At least some of these discrepancies in the literature may have arisen due to the interaction of facial emotion with other factors, such as context or direction of eye gaze, a topic that has been explored very recently.

The direction of eye gaze is an important source of information about individuals intention, and likely future behavior. Eye gaze is a key social signal in many species (Emery, 2000), especially apes and humans, whose white sclera makes the pupil more easily visible and permits better discrimination of gaze. Human viewers make preferential fixations onto the eye region of others' faces (Janik et al., 1978), a behavior that appears early in development and may contribute to the socioemotional impairments seen in developmental disorders like autism (Baron-Cohen, 1995). Eyes signal important information about emotional states, and there is evidence from functional imaging studies that at least some of this processing recruits the amygdala (Baron-Cohen et al., 1999; Kawashima et al., 1999; Wicker, Perrett et al., 2003). The interaction between facial emotion and direction of eye gaze has been explored only very recently. It was found that direct gaze facilitated processing of approach-oriented emotions such as anger, whereas averted gaze facilitated the processing of avoidance-oriented emotions such as fear (Adams & Kleck, 2003), and that this processing facilitation correlated with increased activation of the amygdala in a functional imaging study (Adams et al., 2003).

Some of the amygdala's contribution to the processing of facial emotion may rely on an initial, rapid evaluation of the stimulus, possibly in part via subcortical inputs (Morris, Ohman, & Dolan, 1999; Morris et al., 2001), followed by feedback modulation of visual cortex. The amygdala is known to receive input from visual cortex and to project back to temporal and occipital visual cortices, including striate cortex, in primates (Amaral & Price, 1984; Amaral, Behniea, & Kelly, 2003; Stefanacci & Amaral, 2000) probably including humans (Catani et al., 2003). A possible functional role for this anatomical connectivity is suggested by electrophysiological data: intracranial recordings from the human brain show that field potentials in both the amygdala (Krolak-Salmon et al., 2004; Oya et al., 2002) and in temporal visual cortex (Puce, Allison, and McCarthy, 1999) are modulated by emotional and/or social information. The time course of this field potential modulation – amygdala first, visual cortex next – is consistent with amygdala input giving rise to emotional modulation seen in the visual cortex. Dependence upon the amygdala for emotional discrimination in the temporal visual cortex is also suggested by recordings from single neurons in monkey temporal cortex (Sugase et al., 1999). In monkey temporal visual cortex, neurons encode discriminations between superordinate categories (e.g., face vs. non-face objects) earlier than they encode discrimination between facial emotions.

Some of the most convincing evidence for the amygdala's role in the emotional modulation of visual cortex comes from studying people who have amygdala lesions. Amygdala lesions eliminate the ability of fear faces to modulate activation in visual cortex, including the fusiform gyrus and occipital cortex (Vuilleumier et al., 2004). People with-

out lesions to the amygdala and people who have lesions of the hippocampus alone continue to show modulation of brain activation in visual cortex by fear faces, compared to neutral faces. Thus, the amygdala appears to be required for robust modulation of visual cortex activation by facial emotions.

The requirement of the amygdala for face processing in normal social behavior is confirmed by lesion studies, many of which were actually carried out first and provided the impetus for the functional imaging studies. Several recent lesion studies reported rare patients with bilateral damage to the amygdala. Most of the impairments found were not seen in the more common unilateral cases, typically patients with neurosurgical temporal lobectomy for the treatment of epilepsy. The bilateral amygdala patients fell into three classes: most common (albeit still rare) were those who had complete bilateral amygdala damage as well as damage to surrounding structures from encephalitis. Yet more rare were those with bilateral but incomplete damage relatively restricted to the amygdala.

Following earlier indications that bilateral amygdala damage might impair aspects of face processing (Jacobson, 1986), the first study to demonstrate a selective impairment in recognition of emotion from faces also found this impairment to be relatively restricted to certain highly arousing emotions, especially fear (Adolphs et al., 1994). Some subsequent studies found a disproportionately severe impairment in recognizing fear (Adolphs, Tranel et al., 1995; Broks et al., 1998; Calder et al., 1996; Anderson & Phelps, 2000; Sprengelmeyer et al., 1999), whereas others found evidence for a broader or more variable impairment in recognizing multiple emotions of negative valence in the face, including fear, anger, disgust, and sadness (Adolphs et al., 1999; Adolphs, 1999; Schmolck & Squire, 2001) (Siebert, Markowitsch, & Bartel, 2003). Impairments in processing the direction of eye gaze have also been reported (Young et al., 1995).

Across the majority of studies, impairments in recognition of emotion have been found despite an often normal ability to discriminate perceptually among the same stimuli. Many patients with bilateral amygdala damage perform in the normal range on the Benton Face Matching Task (Benton et al., 1983), in which subjects are asked to match different views of the same, unfamiliar person's face, and they also perform normally in discriminating subtle changes in facial expression, even for facial expressions that they are nonetheless unable to recognize (Adolphs, Tranel, & Damasio, 1998; Adolphs & Tranel, 2000). A final piece of evidence for normal face perception is that some of the subjects with amygdala lesions are able to recognize a person's identity (Adolphs et al., 1994), as well as gender and age (Anderson & Phelps, 2000) from the face, even though they fail to recognize aspects of its emotional expression.

A single case to date, subject SM, has complete bilateral damage that is restricted to the amygdala (Adolphs et al., 1994). This subject has been especially informative

because of the specificity of both her lesion and her impairment (Tranel & Hyman, 1990; Adolphs & Tranel, 2000). SM is a 40-year-old woman who has complete bilateral amygdala damage resulting from a rare disease (Urbach-Wiethe disease (Hofer, 1973)). On a series of tasks, she shows a relatively disproportionate impairment in recognizing the intensity of fear from faces alone, and a lesser impairment also in recognizing the intensity of related emotions such as surprise and anger (Adolphs et al., 1994). Her impairment is restricted to this class of emotions when asked to rate the intensity of basic emotions; however she also has a broader impairment in rating the degree of arousal of all negatively valenced emotions (Adolphs, Russell, & Tranel, 1999), as well as in making social judgments concerning the trustworthiness and approachability of people from their faces (Adolphs, Tranel, & Damasio, 1998), displaying a strong bias to issue judgments of trustworthiness independent of facial characteristics. SM also shows a distinct failure to make use of the eyes when judging emotion from faces, and an impairment in overt attention to fear faces (Adolphs et al., 2005). These results are consistent with the notion that the amygdala is required for effective processing of salient information signaling emotion in a face, and support theories implicating the amygdala in visual processing of emotion from the eyes.

Several different theories have been offered to explain the data thus far. We have suggested that the amygdala is involved principally in processing stimuli related to threat and danger (Adolphs & Tranel, 2000; Adolphs et al., 1999). Others have suggested that it instead triggers cognitive resources to help resolve ambiguity in the environment – under this explanation, both facial expressions of fear and of anger signal threat/danger, but fear differs from anger in that the source of the threat is ambiguous. It would then be the imperative to resolve this ambiguity that engages the amygdala (Whalen, 1999). This latter explanation would fit also with the substantial evidence for the amygdala's modulation of attentional processes in both animals (Holland & Gallagher, 1999) and humans (Holland & Gallagher, 1999; Anderson and Phelps, 2001), including a possible role for modulating spatial attention to facial expressions (Vuilleumier & Schwartz, 2001). It also fits with some reports (Whalen et al., 2001) that the amygdala is more important for recognizing fear from facial expressions than it is for recognizing anger, and with recent findings that the amygdala activation by fear and anger faces depends on the direction of gaze (Adams et al., 2003). Another explanation is that the amygdala is involved in processing a class of emotions that are of negative valence and high arousal (Adolphs, Russell, & Tranel, 1999), which may carve out an ecologically salient emotion category of which threat/danger is a subset. Yet a further possibility is that the emotions whose recognition depends most on the amygdala are related to behavioral withdrawal (Anderson, Spencer et al., 2000), where again threat/danger or fear are a subset of this class. Given these multiple interpretations, it seems plausible that the amygdala may instead

participate primarily in a set of more basic processes that can all come into play in emotion recognition, but that do not translate neatly into any particular categories of emotion. One such more basic process, the one investigated in the present application's proposed studies, is that the amygdala is relatively specialized to process information from a particular feature, or set of features in the face – features that are particularly important for detecting threat, resolving ambiguity, and eliciting behavioral withdrawal when recognized. The expression and direction of gaze of the eyes would be one such candidate feature.

Unilateral damage to the amygdala results in a smaller magnitude of impaired recognition of emotion than does bilateral damage (Adolphs, Tranel et al., 1995). However, when larger samples of subjects are tested, impairments are also found: an impaired ability to learn new emotional facial expressions correlated with the extent of unilateral amygdala damage (Boucsein et al., 2001), and both (Adolphs et al. (2001) (sample N = 26) and (Anderson et al. (2000) (sample N = 23)) found evidence that subjects with unilateral damage due to temporal lobectomy were impaired, as a group, in their recognition of some negative emotions from facial expressions, despite intact basic visual perception (Mendola et al., 1999). The impairment was especially striking for fear (Adolphs, Tranel, & Damasio, 2001) but may extend to emotions related to withdrawal in general (Anderson, Spencer et al., 2000).

The studies of other patients with bilateral amygdala damage, as well as further considerations of data just from patient SM, raised important additional questions. One puzzling finding was that some patients who had complete, non-selective bilateral amygdala damage nonetheless appeared to perform normally on the same tasks that SM failed. This was puzzling because the lesions of these other patients included the entirety of the lesion present in SM, plus additional tissue. Several explanations could be entertained: first, it is important to note that SM's lesion was likely acquired developmentally, quite early in life, whereas the lesions of the other subjects were acquired in adulthood. Second, it is certainly possible to construct a model whereby additional brain damage actually improves performance due to a primary lesion (Kapur, 1996). Third, the patients were very rare and all different in many respects, so that performance differences might be due to other neuropsychological or demographic differences. In the end, while any of these possibilities might still be important, it turned out that (a) subjects perform variably from trial to trial, and (b) when data were reanalyzed, general impairments in emotion recognition were found to be present in all the subjects, although they did not appear to show up in exactly the same way (Schmolck & Squire, 2001). The picture that emerged should not have been unexpected, since it is the standard picture for thinking about how risk factors contribute to pathology: lesions of the amygdala interfere with certain basic emotional

processes, and hence compromise recognition of fear from faces. But this effect interacts with damage to any other parts of the brain, age of acquisition of the lesion, background neuropsychology and personality of the subject, and indeed the particular context and task used to assess emotion recognition.

We can summarize the basic impairment that follows lesions of the human amygdala. Since subjects with amygdala lesions do not have basic discriminatory visuoceptual impairments, it cannot be that they simply cannot discriminate certain visual features. Since they also don't have general conceptual/semantic impairments about emotions, it cannot be that they simply don't know what certain emotions mean. What patients with amygdala damage lack is the ability to link these two: the mechanism for using visual changes in a particular facial feature to obtain information about a particular emotion.

Voices: cortical and subcortical substrates. As in Darwin's work on human emotional expression (Darwin, 1872/1965), the quantity of cognitive neuroscience research into emotional processing in the facial/visual domain dwarfs that on processing emotion from the vocal/auditory domain. Yet there is an extensive literature on emotional cues in and processing of vocalizations in social contexts, and like the work on emotional processing from faces, the work on vocalizations utilizes an evolutionarily informed approach (cf., Scherer, 1988; Marler, 1984).

Study of emotional processing in the vocal/auditory domain focuses primarily on prosody in the voice. Prosody is defined as vocal information that cannot be ascertained from lexical information, and includes measures of pitch, duration, and amplitude (Monrad-Kohn, 1947). Acoustic measurements of prosodic components can be used in combinatorial algorithms to categorize basic emotions from voices alone with an accuracy of 60–70% (Scherer et al., 1991; van Bezooijen, Otto, & Heenan, 1983; van Bezooijen, 1984; Yildirim et al., 2004; Scherer, 1995), where chance performance is in the 10–20% range. Yet the categorization accuracy of human judges is higher than this, and it is of interest to determine the mechanism used by the brain to yield such effective emotional judgment from the voice.

Although the amygdala was seen to be required for effective processing of emotion from faces, the evidence for the amygdala's involvement in judgment of vocal emotion is less clear. While there is evidence for the activation of the amygdala by emotional prosody (Morris, Scott, & Dolan, 1999), and for the impairment of vocal emotion judgment after bilateral amygdala lesion (Scott et al., 1997), there is also evidence that bilateral lesions of the amygdala have no effect on such judgment (Adolphs & Tranel 1999).

However, an extensive study of patients with cortical lesions revealed several cortical areas that are important for such judgment (Adolphs, Tranel, & Damasio, 2002). The cortical areas whose lesions most affected emotional judgment from the voice include the frontal pole,

the frontal operculum (including Broca's area), and the right frontal and anterior parietal cortex, including right somatosensory cortex. Impairments were worst for the emotions of fear, anger, and surprise, compared to happiness and sadness. In an important study of a single patient, a lesion to the right ventromedial prefrontal cortex eliminated the ability to judge vocal emotion while preserving propositional speech and syntactic prosody (Heilman, Leon, & Rosenbek, 2004).

Results from neuroimaging experiments are largely consistent with results from lesioned patients. Activations to vocal emotion are primarily right lateralized and have been seen in right frontoparietal areas (Buchanan et al., 2000), including the right frontal gyrus, the right inferior parietal lobule, the right middle temporal gyrus (Mitchell et al., 2003), the right ventromedial prefrontal cortex (Wildgruber et al., 2005), and both the left (Mitchell et al., 2003) and right (Wildgruber et al., 2005) superior temporal gyri. Superior temporal regions have also been implicated in discriminating angry vs. neutral prosody, absent semantic content of speech (Grandjean et al., 2005). As yet the mechanism for how emotional information from the voice is processed within these areas, and the temporal order by which these areas are brought online for judgment of vocal emotion, remains obscure. Nevertheless, the work thus far focuses increasing attention on the right hemisphere of the brain, particularly in the frontal and frontoparietal regions. The implication of superior temporal regions is somewhat more recent, and it will be important for future cognitive neuroscientific work on the judgment of vocal emotion to delineate what the specific function is of this area in emotional processing of voices.

Several of the areas implicated by lesion analysis and neuroimaging for judging vocal emotion (e.g., ventromedial prefrontal cortex, right somatosensory cortex) are known to be critical for normal social behavior (see below). In fact, psychopaths who show severely abnormal social behavior also exhibit impairments in judging emotion in the voice, and they are especially impaired at judging vocal fear (Blair et al., 2002). This observation is consistent with the notion that brain centers required for emotional processing, in this case of vocal emotion, are also required for normal social behavior.

SOCIAL JUDGMENT AND DECISION-MAKING

Orbitofrontal cortex. We now consider explicitly the importance for social judgment and decision making of brain areas that are strongly implicated in emotional processing. Probably the best example here is the orbitofrontal cortex, a region of the brain located on the ventral surface of the frontal lobes. The studies of orbitofrontal cortex began with a famous historical case, that of Phineas Gage (Damasio, 1994). Gage, a foreman working on the railway in Vermont, sustained a traumatic brain injury due to a tamping iron that exploded through his head. It was amazing that he survived the accident at all, but no less amazing

were the specific cognitive changes that ensued. His basic intellect appeared unchanged, but long-term behaviors and dispositions relating to emotional responses to his environment and to other people had been dramatically altered. Whereas before the accident he was a respected, well liked, courteous, and amiable person, after the accident he became uncaring, rude, profane, and exhibited a gross disregard both for his own personal future and for other people. What had changed were emotional processes that contribute substantially to our concept of a personality.

Gage's case was notably resurrected in recent times by a further analysis of his likely brain lesion (Damasio et al., 1994), and by supplementation with data from modern patients who had sustained similar damage – not because of the passage of an iron rod through their head, but typically because of tumor resections of the frontal lobe or aneurysms of the anterior communicating artery (Damasio, 1994). These modern case studies permitted more controlled experimental investigations of the impairment, and eventually accrued to comprise a group of subjects that shared damage to ventral and medial sectors of the prefrontal cortex, all of whom exhibited a remarkably similar constellation of findings. They failed to elicit emotional psychophysiological responses to stimuli (Damasio, Tranel, and Damasio, 1990), they failed to elicit such responses in anticipation of future punishment (Bechara et al., 1996), and they failed to guide their behavior so as to avoid future punishment (or seek future reward) (Bechara et al., 1994). Their behavior was driven by what was immediately present, and did not take into account planning for the future. One of the major current theories of the function of this region of prefrontal cortex, Antonio Damasio's somatic marker hypothesis, draws on these findings and proposes that they are causally related (Damasio, 1994). In real life, all these patients fail to maintain lasting social relationships or jobs, a reflection of their dysfunction in this particular mechanism.

As the investigations of orbitofrontal cortex have accrued a sufficient number of cases, they have permitted some further specification of the neuroanatomy and the processes. For instance, dissociations have been found between damage in dorsolateral and ventromedial prefrontal cortex in relation to working memory and decision-making, respectively (Bechara et al., 1998). Damage to the right prefrontal cortex has been shown to result in more severe impairments in emotion processing than damage to left (Tranel, Bechara, & Denburg, 2002). And the impairments following damage to ventromedial prefrontal cortex have been shown to be distinct from any impairment in IQ, language function, or perception.

The above summarized findings are consistent with what is known about the connectivity of this region of the brain. Medial and ventral sectors of prefrontal cortex have been shown to constitute a densely interconnected network that obtains polysensory information, taste and smell information, and visceral information, and projects

to autonomic control structures, such as the hypothalamus and periaqueductal grey area (Öngür & Price, 2000). They are consistent also with other data from functional imaging studies in humans, as well as from lesion and electrophysiological studies in animals.

The orbitofrontal cortex has also been implicated in social reasoning. Damage to this region impairs the ability to figure out that other people are being deceptive (Stuss, Gallup, & Alexander, 2001), and results in impaired performance in reasoning about social exchange using the Wason selection task (Stone et al., 2002; Adolphs, Bechara et al., 1995). These findings may reflect the above mentioned role for the orbitofrontal cortex in guiding social cognition by the elicitation of emotional states that serve to bias cognition, a role further supported by investigations of moral reasoning.

The role of specific brain structures in moral behavior has been investigated using social and moral dilemmas – choice options structured so that they conflict (Greene & Haidt, 2002). Such conflict may arise from short-term versus long-term goals, or from goals advantageous to oneself versus those advantageous for others or society as a whole. It is thus closely related to altruistic behavior, social cooperativity, and the cognitive processes that guide behavior in markets and that are described by economics. A subset of moral dilemmas involve one's own agency and trigger strong emotions in their consideration; these have been found to engage structures involved in emotion processing, such as the superior temporal sulcus, cingulate, and medial prefrontal cortices (Greene et al., 2001). Social cooperation in the prisoner's dilemma engages a similar set of structures, including orbitofrontal and anterior cingulate cortices as well as ventral striatum (Rilling et al., 2002). All of the above data on medial and orbital prefrontal cortex are consistent with a role for this region in guiding the strategic adoption of someone else's point of view – perhaps by triggering emotional states, by engaging simulation routines, or by more cognitive strategies.

The amygdala, take two. We encountered the amygdala earlier, when we discussed the recognition of emotions from faces. But the amygdala also plays a complex and more ubiquitous role in emotional aspects of social behavior (Aggleton, 2000). The mechanisms that underlie this role are best understood in animals, especially rodents, where they have been shown to draw on the amygdala's ability to modulate a large variety of response components and cognitive processes based on the emotional significance of the stimulus. Thus, the amygdala modulates attention, memory, and decision making, as well as many components of an emotional response (including behavioral, autonomic, and endocrine components), and all of these are highly relevant to regulating social behavior. It is still an open question to what extent the amygdala might actually be specialized to subserve social behavior as such, or whether it is simply involved in domain-general

emotional processing that happens also to be important to social behavior.

The amygdala's functional complexity is mirrored in its vast array of connections with other brain structures: high-level sensory neocortices provide information about the stimulus, primarily to the lateral nucleus, and the amygdala projects back to much of neocortex, as well as to basal forebrain, hippocampus, and basal ganglia to modulate cognition, and to hypothalamic and brainstem nuclei to modulate emotional response (Amaral et al., 1992). It is precisely because of the complexity of the various processes in which the amygdala participates that it can effect a concerted change in cognition and behavior that plays out as an organized emotional reaction.

Beyond its role in recognition of basic emotions, the amygdala shows differential habituation of activation to faces of people of another race (Hart et al., 2000), and amygdala activation has been found to correlate with race stereotypes of which the viewer may be unaware (Phelps et al., 2000). However, the amygdala's role in processing information about race is still unclear: other brain regions, in extrastriate visual cortex, are also activated differentially as a function of race (Golby et al., 2001), and lesions of the amygdala do not appear to impair race judgments (Phelps, Cannistraci, & Cunningham, 2003).

Other kinds of social judgments also appear to involve the amygdala. In one study, patients with bilateral amygdala damage were found to be impaired in judging how much to trust another person from viewing their face: they all judged other people to look more trustworthy and more approachable than do normal viewers (Adolphs, Tranel, & Damasio, 1998), a pattern of impairment that is also consistent with the often indiscriminately friendly behavior of such patients in real life. The amygdala's role in processing stimuli related to potential threat or danger thus extends to the complex judgments on the basis of which we come to approach or trust other people.

Lesion studies of the amygdala's role in judging trustworthiness have been complemented by functional imaging studies. When normal subjects view faces of people judged to appear untrustworthy, activation is found in superior temporal sulcus, amygdala, orbitofrontal cortex as well as insular cortex (Winston et al., 2002), perhaps outlining a sequence of processes encompassing perception, judgment, and aspects of emotional response. Interestingly, some of the amygdala activation by untrustworthy looking faces is independent of factors such as gender, eye gaze, race, or emotional expression of the face (Winston et al., 2002). Given that much of the variance in the physical dimensions along which faces vary can be eliminated, yet still drive amygdala activation, one is led to assume that the amygdala activation reflects the judgments and inferences that subjects make about the face, rather than its perceptual properties. It will be important to test this idea directly by systematically manipulating the attributions that viewers make to a fixed set of social stimuli. An important future direction will be to examine

the variance in viewers' personality traits in these social judgments, as has been done in two recent studies correlating amygdala activation to emotional expressions with viewers' extraversion (Canli et al., 2002) or anxious temperament due to polymorphism in the serotonin transporter promoter (Hariri et al., 2002). To the extent that amygdala activation covaries with differences in the personality of the viewer, rather than the physical composition of the stimulus, we may conclude that we are tapping processes more distal to perception and closer to judgment, decision making, and the interpersonal behaviors based on them.

Another class of social judgment made from faces is attractiveness, which can be manipulated by specific properties of faces. For instance, faces are perceived to look more attractive the more average or symmetrical they are, or with greater exaggeration of robusticity and neoteny features, all of which have been proposed to signal differential fitness. Moreover, such preferences by women can vary across the menstrual cycle (Penton-Voak et al., 1999), as do other aspects of their categorization of men (Macrae et al., 2002), possibly providing a link between mate preference and probability of conception. Judgments of attractiveness can reflect both aesthetic judgments (e.g., males can judge faces of both males and females to look beautiful) as well as motivational aspects (e.g., males prefer to look at beautiful female rather than beautiful male faces), two aspects that have been dissociated in functional imaging studies (Aharon et al., 2001). The motivational aspects of facial attractiveness appear to activate the ventral striatum (Kampe et al., 2001; Aharon et al. 2001) as well as orbitofrontal cortex (O'Doherty et al., 2003). These structures likely play a broad role in processing the motivational properties of stimuli: for instance, they are activated also when males find pictures of sportscars more rewarding than pictures of limousines or small cars (Erk et al., 2002). Ventral striatum and orbitofrontal cortex are reciprocally connected with the amygdala; all three structures can be thought of as components of a neural system that links sensory representations of stimuli with the social judgments we make about them on the basis of their motivational value. Given that the same structures that mediate social judgments also mediate more basic reward processing, one is led to wonder whether the former might be reducible to the latter, an issue taken up in the concluding section of this review.

SIMULATION AND SOCIAL COGNITION

"Simulation theory" advances the notion that processing involved in the perception of one's own bodily states is required for the accurate judgment of others' emotional states, via a partial simulation of those states within the person doing the judging (Goldman, 1992; Goldman & Sripada, 2005). Simulation theory has gained support from the discovery of "mirror neurons" in Rhesus monkeys and putative homologous neural functions in humans (Iacoboni et al., 2005; Rizzolatti & Craighero,

2004; Gallese, Keysers, & Rizzolatti, 2004). Mirror neurons were originally reported from recordings from single neurons in monkey motor area F5, and the unifying principle in their identification was that they showed nearly identical neuronal firing both when a monkey performed an action and when the monkey observed the same or a similar action performed by a human experimenter or another monkey (Gallese et al., 1996). They constitute approximately 20% of neurons in F5 (Gallese et al., 1996). Mirror neurons are classified as “strictly congruent” and “broadly congruent” based on the similarity between performed and observed action in generating neuronal firing, and approximately 1/3 of all mirror neurons in F5 were strictly congruent, with the remainder being broadly congruent. This class of neurons is not only observed in F5, but also in area 7b in the monkey parietal cortex (probably Von Economo’s area PF, see Von Economo, 1929; Seltzer & Pandya, 1980; Seltzer & Pandya, 1994), which sends projections to area F5. Approximately 30% of area 7b neurons are active during performance and observations of similar actions (Rizzolatti & Craighero, 2004).

While there is only limited evidence of mirror neurons in the human brain (Hutchison et al., 1999), there is evidence of broadly overlapping neural tissue involved in both the sensation and in the judgment of emotion. This evidence comes from studies of the effects of lesions, from neuroimaging studies, and from studies examining the interference with emotional judgment due to transcranial magnetic stimulation. In all of these studies, it is not possible to speak strictly of mirror neurons, for although the studies identify large-scale similarity of brain areas involved in emotional sensation and judgment, in all cases the degree of overlap is partial only. This observation may be important in elucidating a mechanism of emotional judgment that prevents confusion between one’s own emotional states and the inferred emotional states of others, something that strict mirroring in all areas could not allow. It is useful to keep in mind that simulation theory does not require nor postulate identity, but only a degree of overlap, between the neural processing involved in sensing and judging emotion.

The clearest evidence in support of the simulation theory of emotional judgment comes from studies involving the somatosensory cortex and insula. An intensive study of the cortical areas involved in the judgment of emotions from faces involved 108 subjects with focal brain lesions (Adolphs et al., 2000). All 108 lesions were mapped onto a single normal reference brain, so that their lesions could be directly compared and lesion density overlap images could be constructed. When one examined the subjects who had the lowest performance scores on each emotion, regardless of absolute performance, a consistent pattern emerged for all emotions: lesions in right ventral parietal cortex and right frontal cortex were systematically and significantly associated with impaired recognition of emotion. The sites within which lesions systematically resulted in impaired emotion recognition focused on ventral S-I

and S-II (i.e., somatosensory cortex), with involvement in insula and anterior supramarginal gyrus, as well.

The requirement of somatosensory cortex for emotional judgment from faces alone has been confirmed by transcranial magnetic stimulation (TMS) (Pourtois et al., 2004). Judgments of fearful faces took longer when single pulse TMS was applied over right somatosensory cortex. The application of the TMS pulse occurred between 100 msec and 200 msec following onset of the facial image, suggesting that the processing of facial emotion in somatosensory cortex occurs very early on, perhaps in parallel with processing in the amygdala (see above).

The most straightforward interpretation of these findings is one that invokes simulation theory: we construct central images of the body state that would be associated with the visually observed emotion; that is, we imagine how the other person would feel by simulating some of the neural network activation involved in the feeling that way. Just as the brain recruits visual cortex both during visual perception and during visual imagery (Kosslyn, Ganis, & Thompson, 2003; Klein et al., 2004; Ganis, Thompson, & Kosslyn, 2004; Slotnick, Thompson, & Kosslyn, 2005), it recruits somatosensory cortex both during perception of one’s own body state as well as during imagining how someone else feels.

The extensive study of lesioned patients described above also identified the right insula as important for emotional judgment from faces. The insula is also known to be strongly involved in sensations of disgust (Fitzgerald et al., 2004) and it strongly responds to images depicting bodily mutilation and contamination (Wright et al., 2004). A focused study of one patient, B., with extensive bilateral lesions including the anterior insula showed that the insula is required for the accurate judgment of disgust from faces. B. was not only impaired in the ability to judge disgust from gustatory stimuli (e.g., high salinity solution) or visual stimuli (e.g., images of food covered with cockroaches), he was unable to judge disgust from dynamic facial stimuli and he could not infer another person’s disgust from events in a descriptive narrative (Adolphs, Tranel, & Damasio, 2003). These results are consistent with neuroimaging studies that robustly and repeatedly show insula activation when viewing facial expressions of disgust (Phillips et al., 1997; Wicker, Keysers et al., 2003). In the case of Wicker et al. (2003), the same participants were imaged either during olfaction with disgusting odors or during viewing of movies of facial disgust. An approximate 40% overlap in active brain voxels in the left insula and inferior frontal gyrus was seen in comparing the two conditions (olfaction vs. viewing), again providing support for the simulation of emotional states in the judgment of the emotional states of others.

The primary conclusion from the findings reviewed here is that there is a great deal of evidence for a simulation theory of judging others’ emotions, although there is also debate regarding the scope of simulation in cognition (Saxe, 2005). The findings discussed here also fall

under the theme already seen for the involvement of the amygdala and orbitofrontal cortex in social behavior. That is, brain areas important for emotional processing are also crucial for social cognition and therefore for normal social behavior. Simulation theory can also be extended to areas of social cognition that incorporate but go beyond emotional judgment, such as imitation, empathy, and theory of mind. We turn next to a consideration of these important topics in the cognitive neuroscience of social behavior.

IMITATION, EMPATHY, AND THEORY OF MIND

Within cognitive neuroscience, it is now possible to see a clear relationship between areas for emotional processing and key aspects of social behavior, such as imitation, empathy and theory of mind. Imitative behavior in humans is known to occur early in development and is thought to be critical for the normal development of social referencing, empathy, and theory of mind (Meltzoff & Moore, 1977; Meltzoff & Decety, 2003). Indeed, the mental imitation, or simulation, of another's actions and/or states is sometimes taken to be necessary for a full understanding of the other (Lipps, 1907; Lipps, 1903; Barresi & Moore, 1996). Imitation has been linked with emotional processing using two lines of evidence. The first is the observation that people with social behavior dysfunction that includes difficulty in judging another's emotion also show impairments in imitative behavior. One of the most striking examples of this association occurs in autism (Meltzoff & Decety, 2003; Sigman et al., 2004; Rogers et al., 1996; Rogers et al., 2003; Roeyers, Van Oost, & Bothuyne, 1998; Williams et al., 2001; Williams, Whiten, & Singh, 2004). Indeed, deficits in imitation are among the most robust and replicable social deficits observed in autism, from very early in development to late adulthood, along with deficits in understanding the emotional states of other people. The fact that autism leads to deficits in emotional understanding and in imitative behavior led theorists to propose that there is a relationship between the neural circuitry underlying both of these aspects of social behavior.

The second line of evidence associating emotion with imitation in social behavior comes from studies of empathic processing. Chartrand and Bargh (1999) showed that people who exhibit a greater ability to take the perspective of another person show a greater propensity for nonconscious imitative behavior (i.e., the "Chameleon Effect") and also that imitative behavior led to higher positive ratings of social behavior. It is important to distinguish the nonconscious imitation typically thought to be involved in emotional understanding and empathy from overt imitation without emotional overtones, since the latter may actually reduce activity in emotional processing (Leslie, Johnson-Frey, & Grafton, 2004). Both Carr et al. (2003) and Leslie, Johnson-Frey, and Grafton (2004) observed activation in the right inferior frontal cortex, and Carr et al. (2003) observed activation in the insula, during passive viewing of static and dynamic facial expressions

of emotion, respectively. Importantly, they saw increases of activation in these areas during imitation, compared to simply passive viewing. Since we have already seen these areas involved in emotional judgment, this evidence is consistent with the notion that imitative social behavior recruits areas necessary for the processing of emotion in social behavior.

A direct assessment of emotional processing within empathy is possible by studying people during the passive viewing of another person's pain. In one such study, women were imaged using fMRI both while they watched their significant others receive painful stimulation to the right hand and while they themselves received the same painful stimulation (Singer et al., 2004). A comparison of the observation vs. stimulation conditions revealed that observation alone activated those brain areas strongly associated with the emotional response to painful stimuli as opposed to somatosensory areas associated only with the perception of the stimulus itself. This result was extended by a recent study that examined brain activation during the viewing and assessment of pictures of hands and feet in painful positions (Jackson, Meltzoff, & Decety, 2005). Here, the network of brain areas active during the viewing of painful bodily positions was very similar to that identified by viewing a significant other undergoing painful stimulation. Areas included the anterior insular cortex and posterior part of the anterior cingulate, both known to associate with the affective response to pain. A strong correlation was observed between subjective ratings of pain in the images and activation of the posterior part of the anterior cingulate ($r = 0.83$).

Constructing an affective theory of mind about another person is necessary for social adaptive behavior. The work on the cognitive neuroscience of social behavior reviewed thus far provides strong evidence that neural networks for emotional processing are strongly involved in, and in several cases are required for, normal operation of an affective theory of mind. Normal emotional processing contributes to the accurate perception of emotions and emotional states relating to particular conditions, such as being in pain. The way in which this occurs appears to be via nonconscious imitative processes long postulated by simulation theories of the theory of mind. Moreover, it is possible that these imitative/simulative processes engage motivational systems for the deployment of resources for seeking out and processing of social information, and thus normal emotional processing could be implicated in mechanisms responsible for the strong social orientation in humans.

THE ROLE OF PSYCHOPHYSIOLOGY IN COGNITION

In this last section, we return to the question raised by William James in the Introduction and to his novel answer to it. It is notable that several of the structures discussed above play dual roles in social cognition and in triggering psychophysiological concomitants of emotional response in the body. For instance, we discussed the role of the

amygdala in recognition of emotion from viewing other people's facial expressions, and its role in social judgments such as trustworthiness. But there is also a large literature documenting its role (specifically, that of the central nucleus of the amygdala) in autonomic responses, including changes in skin conductance, heart rate, blood pressure, and endocrine regulation. Similarly, in the case of orbitofrontal cortex, we pointed out that this structure plays roles in decision making as well as psychophysiological responses, and that in fact the latter have been postulated to play a direct causal role in the former. These observations raise a deep and unresolved issue that brings us right back to the question of James we had mentioned at the beginning of this chapter. Are psychophysiological responses involved in cognition as such, or are they merely epiphenomenal with respect to it? There is no question that thinking, remembering, deciding are often, perhaps even typically, associated with physiological changes in our bodies – but are the latter merely a consequence of the former, or, as Darwin suggested and William James emphasized, might the latter be antecedent to some components of the former?

The issue is very difficult to resolve empirically, but that has not stopped hypotheses. Foremost among these is the somatic marker hypothesis we discussed above. In its most general form, that hypothesis argues that subjective utility (value) is ultimately to be identified with actual or represented changes in the homeostatic parameters of an organism's body. So far, there is evidence in favor as well as against this idea, but none of it is at all decisive at this stage. Our own view is that the somatic marker hypothesis, in its general form, is extremely likely to be correct, even though some of its more specific interpretations (which in some cases are actually not the interpretations of its author) are very likely to be false.

Rather than debate the details of the somatic marker hypothesis here, which has been done substantially in several recent publications, we would like to add to it in providing perhaps an even more general conception of the role of the body in cognition. That conception is a fairly straightforward extension of the somatic marker hypothesis as originally stated: parameters of body states are computational. That is, just as parameters specifying electrical and neurotransmitter-related changes within the brain can be said to process information, so can parameters specifying changes in autonomic, endocrine, and musculoskeletal states of the body. The body, as well as the brain, performs computations and information processing.

In making sense of this speculation, two observations are important. First, the body does not process information in isolation, but as an adjunct to the information processing that occurs in the brain. Seen this way, the body might provide the brain with computational resources in the same way that the external environment might – just as we use pencil and paper to calculate math problems by relying on structured processes outside ourselves, so our brains might make use of changes in bodily parameters as

a kind of "somatic scratchpad." One might imagine that the brain triggers autonomic changes in the body, but that those triggers themselves do not yet make explicit the information required, just like the visual array at the level of the retina is sufficient to trigger visual representations, but not yet sufficiently explicit to constitute them. Once those psychophysiological changes have been triggered, they play out within the body, subject to the causal role and constraints of various organs and their interaction. That is a form of computation, provided it can be read out again and made use of by the brain.

Which brings us to the second important observation. The kind of computations in which the body might engage do differ, if not qualitatively then at least quantitatively, from those in which the brain typically engaged: they are analog rather than digital. Some (perhaps more than we usually acknowledge) neural computations are also analog, so this difference may not be as dramatic as we are at first inclined to think. Nonetheless, it is clear that at least a good portion of the information processing within the brain relies on the digital nature of action potentials, whereas essentially all of the information processing within the body relies on the analog interactions of joints, muscles, and hormones.

We take it that all of this sounds reasonable enough, except for one key point on which many readers are likely to get stuck in doubt. What kind of information, pray tell, is the body processing? Certainly, one would think, not visual information, or auditory information, or representations of abstract concepts (however those might be instantiated). Well, of course it processes somatic information, but that sounds like we are claiming the body processes somatic information in the same sense that the lens of the eye processes visual information; and that is not our claim here. The claim, rather, is that the body's somatic information processing is used by the brain to compute value. That is, somatic representations can be used to point to the value that events and situations in the environment provide, an idea that finds resonance in some recent philosophical theories (e.g., Prinz, 2004). That value, in turn, comes into play in guiding social behavior, and in decision making of all kinds.

24 Language

MARTA KUTAS, KARA D. FEDERMEIER, JENNY STAAB, AND ROBERT KLUENDER

The Brain – is wider than the sky –
For – put them side by side –
The one the other will contain –
With ease and you beside

The Brain is deeper than the sea –
For – hold them – Blue to Blue –
The one the other will absorb –
As Sponges – Buckets – do

The Brain is just the weight of God –
For – Heft them – Pound for Pound –
And they will differ – if they do –
As Syllable from Sound

– Emily Dickinson, 1896

1. HISTORICAL CONTEXT

As Dickinson notes, the brain has a remarkable capacity that differentiates it from other sorts of material substances: the ability to intentionally represent, to impose its own internal order on perceptions of the outside world supplied to it via the senses. Although we often take this capacity for granted, it is no small feat that we are able to access, decipher, and interpret the thoughts of a woman who died well over a century ago. While many consider Dickinson to be an exceptionally gifted poet, her ability to exploit the representational capacity afforded by the brain through language is shared by all humans. This capacity allows us to analyze our own internal thought processes, to communicate with one another across distances of time and space, and to alter our environment by influencing one another's behavior.

It is this ability that intrigues language researchers and inspires them to plumb the depths of the language system in hopes of unmasking its intrinsic principles and underlying mechanisms. With the onset roughly half a century ago of the cognitive revolution, language quickly came into focus as one of the main puzzles of human cognition. The most fundamental reason for this puzzlement is that, at least *prima facie*, language is a behavioral phenomenon not found in any species other than our own. Moreover, lan-

guage mediates virtually every aspect of human social and cultural interaction. Human beings are the only species in which language plays a role not just in the formation of mental representations, but in the interrelationships of such representations with each other and with the external environment as well. By understanding language, we thus not only gain a privileged window into the internal workings of the human mind, but also a way to comprehend how it relates to the outside world.

At this point in history, we already know something of the intrinsic principles and mechanisms of language. For example, we know that language is a multi-layered system, with principles that apply at different levels of organization, namely those of sound (phonetics and phonology), the word (morphology), the phrase and the sentence (syntax), the entire text, be it written or spoken (discourse and information structure), and meaning (semantics and pragmatics) – cf. section 3. We further know that because language is a serialized signal that unfolds sequentially in time and space, it must rely on the support of other cognitive systems, including attention and memory, both working and long-term.

Long-term memory provides a useful illustration of the difference between principles and mechanisms of language and between the often complementary interests of linguists and psycholinguists. Long-term memory plays an important role in the pairing of sound patterns with associated meanings at the level of individual lexical items, which must be accessed and retrieved during on-line processing. This process of “lexical access” is a major focus of investigation with respect to both psychological and neural mechanisms (see section 4). However, it is largely absent from purely linguistic discussions because, among the linguist’s inventory of ontological primitives, the word is the most poorly defined. Even though linguists know a great deal about the principles governing word formation (morphology), they merely assume that words are taken from the lexicon when inserted into syntactic structures, as the mechanism(s) of lexical insertion remains largely unspecified.

More generally, the ontological status of linguistic principles, levels of organization, and mechanisms lies

at the heart of three related but logically independent debates within linguistics and psycholinguistics, commonly referred to as competence versus performance, modularity, and psychological reality. With regard to the first, Chomsky (1965) has taken great pains to distinguish a language user's inherent knowledge of his or her native language (competence) from its implementation in real time and space (performance). The former is an abstract, idealized, almost Platonic set of mental representations distributed across a speech or sign community, whereas the latter is an imperfect individual reflection of this, subject to human cognitive limitations on attention and memory, etc. The prevailing view within linguistics for the past half century has been that competence rather than performance is the proper subject of the language researcher's investigation. This is because competence remains relatively stable over time – though subject to changes across generations as innovations make their way into the system – whereas performance is subject to the moment-to-moment vagaries of on-line processing. This is another reason why linguists have traditionally paid little attention to the mechanics of processes like lexical access: everyone is familiar with the effects of impaired memory on lexical access in the individual brain, but this has no impact whatsoever on the collective repository of lexical items in any given language.

However, while many linguists still adhere to a strict dichotomy between competence and performance, others have begun to challenge it: in recent years, performance-based accounts of a number of core linguistic facts usually attributed to competence – such as basic word order (Hawkins, 1994), and dependencies between discontinuous sentence elements, so-called “unbounded dependencies” (Hawkins, 1999; Kluender, 1998, 2005) – have emerged. During this same time period, a number of event-related brain potential (ERP), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) studies have investigated the precise role of working memory in the processing of unbounded dependencies (see section 4.3.2.1). The aim of these studies has been to determine whether syntactic mechanisms play a role over and above that of working memory in the processing of such structures, or whether the two are largely co-extensive.

The second debate centers around Fodor's (1983) claim that cognition is the result of a large number of autonomously functioning, highly specialized input modules feeding into a more general-purpose central processor. The role of input modules is to transform specific inputs from the sensory periphery into representations that can be handled by this central processor. Since an input system is dedicated to processing only one type of input, it is said to be “informationally encapsulated,” i.e., insensitive to any source of information that falls outside its particular domain of specialization. It is also argued that the central processor has access only to the outputs of such modules and not to any intermediate representations that they may compute for their own internal purposes. Perhaps most

importantly for present purposes, each input module is said to be associated with a fixed neural architecture.

This series of claims has had two major consequences for the study of language. First, language itself is taken to be a sort of macro-module, independent of other cognitive systems like attention and memory; this is essentially a reification of the competence/performance distinction. Second, levels of organization within the language system are often taken to be sub-modules that are informationally encapsulated from each other. This claim has been made most frequently with respect to lexical and syntactic levels of processing, which are argued to be impervious, during lexical access and initial syntactic parsing operations, to semantic and pragmatic factors, in turn argued to engage higher-level processes of interpretation solely under the purview of the central processor. On this view, contextual meaning should not initially influence how a word is identified by the lexical access module or how a string is parsed by the syntactic module. Lexical access and syntactic parsing operations are thus expected to be subserved by brain regions different from those that figure in semantic or pragmatic interpretation.

Psychophysiologicaly, this expectation has been investigated most thoroughly with respect to comparisons and interactions of syntactic and semantic processing (see section 4.3.2.2.2), although it is not always obvious how to isolate syntactic processing from the influence of other levels of organization. For example, a common experimental manipulation compares active and passive versions of the same sentence, the general assumption being that the two versions differ in syntactic structure alone. However, passivization affects not only the alignment of semantic (or “thematic”; cf. section 3) roles with syntactic positions (either agent or undergoer (patient) as subject of the sentence in active vs. passive sentences, respectively), but also the underlying information structure of the sentence. To illustrate, the “team of authors” is not only the subject, but also the topic of the active sentence *A team of authors wrote the chapter*, while “the chapter” forms part of the informational focus, or new information about the topic. These information structural statuses are reversed in the passive sentence *The chapter was written by a team of authors*, in which “the chapter” is the topic and the “team of authors” is part of the new informational focus. Linguists are not sure whether to assimilate information structure to syntactic or semantic levels of representation or to consider it a completely independent level of representation on its own, although it is recognized to play a role in sentence structure over and above purely syntactic considerations.

Information structure is not the only level of linguistic organization for which it is difficult to entertain claims of modularity. As mentioned above, processes of word formation are quite well understood by linguists, but the notion that morphology should constitute an independent, autonomous, informationally encapsulated level of organization (and/or processing) within the language system

is almost certainly wrong. Morphological processes of word formation are known to interact extensively both with “lower” level phonological processes, as well as with “higher” level syntactic processes; for this reason, linguists refer to – and distinguish between – “morphophonological” and “morphosyntactic” processes. Phonological processes similarly play a role in both morphology and syntax; aside from the subdiscipline of morphophonology just mentioned, a very popular topic in psycholinguistics at the time of writing is the role that prosody plays in word segmentation and in syntactic parsing. It is even difficult to see how morphology could be entirely dissociated from semantics, as affixes typically involve a concomitant change in word meaning: *lion* vs. *lioness*, *child* vs. *children*, *rational* vs. *irrational*, *write* vs. *rewrite*.

Nevertheless, there is a long-standing controversy within morphology itself that does bear on issues of modularity: the difference between regular (rule-based) and irregular (more or less idiosyncratic) processes of word formation. Note that here the claim for modularity is based on a sub-sub-module of the language system. The controversy centers around whether regular and irregular processes of word formation constitute separate subsystems, each with unique principles and mechanisms (the “dual route” model), or whether these two processes share the same resources (the “single route” model). There is an extensive behavioral and computational literature devoted to this topic, and there have been a number of psychophysiological studies as well (section 4.2.1).

The third debate in linguistics is referred to as psychological reality: is there any evidence to be found for the levels of organization posited by linguists, and the principles claimed to apply to them, in the on-line processing of language, or are they merely explanatorily convenient, abstract constructs? First raised by Sapir (1933), nowadays this issue is generally cast more in terms of finding behavioral evidence for linguistic constructs, and thus has been rejected by some as irrelevant to issues of competence (Chomsky, 1980). Nonetheless, the current prevalent trend in linguistic departments in the United States is to add positions in psycho- and neurolinguistics, pointing to at least tacit recognition of the fact that linguistic theory construction in the 21st century requires a broader empirical base that also addresses questions of psychological reality.

To this end, research on the psychophysiology of language processing – using techniques such as ERPs, PET, and fMRI – has attempted to monitor how the brain reacts to experimental manipulations at various levels of linguistic organization. As noted above, the assumption is that language subprocesses are subserved by different anatomical and physiological substrates that generate distinct patterns of biological activity – and this assumption is neutral with respect to issues of competence vs. performance, modularity, and psychological reality. These patterns of biological activity can then be picked up by methods sensitive to fluctuations in electromagnetic and hemodynamic activity.

Psychophysiological studies of language processing are well-suited to examine issues of both representation and processing. Techniques with high spatial resolution, such as PET and fMRI, can help pinpoint brain areas important for language processing. Techniques with high temporal resolution, such as ERPs and eye-tracking, can help reveal how language processing unfolds over time; they can be used to track the availability of different sorts of linguistic information and the temporal course of their interactions. Additionally, studies of brain-damaged patients, in conjunction with the use of psychophysiological measures, can provide important insights about which brain areas are necessary and/or sufficient for certain types of linguistic processes, and about the relationship between language processing and other cognitive abilities. In this chapter, then, we consider the role of the brain in understanding and producing natural language utterances. We review how psychophysicologists have addressed this issue in the past and consider how these methods might best be employed in the future.

2. PHYSICAL CONTEXT

The physical context for language is the human brain – the only known physical system capable of language. And, although some parts of the brain have been more closely tied to language than others, nearly the whole brain seems to be involved to some extent. Language comprehension, for example, depends on subcortical and cortical neural systems that transduce, process, and identify the sensory information that constitutes language input. Language production, in turn, ultimately makes use of the motor cortical, basal ganglia, and cerebellar systems that enervate the muscles and coordinate the movements of the diaphragm, intercostal muscles, vocal folds, jaw, tongue, and lips (and/or arms, hands, and face). Both comprehension and production require that information be attended, held in working memory, and accessed from long-term memory, thereby involving hippocampal, medial temporal, frontal and parietal areas. These brain areas show varying degrees of specialization for various linguistic processes, and many appear to perform general functions – like sequencing or mapping between inputs/outputs and knowledge – that are necessary for language without being unique to it.

Of course, some parts of the brain are considered by most neuroscientists to be particularly concerned with the processing of language. One of these is an area of left frontal cortex (Brodmann's area, or BA 44 and 45) known as Broca's area, damage to which (often including underlying subcortical tissue and white matter) causes an aphasia characterized by halting, “telegraphic” speech (lacking in function words) but with reasonably good comprehension. Despite its obvious import in language production and the control of articulation, there has been some controversy over whether the apraxia of speech is due to malfunction of Broca's area (Hillis et al., 2004) or the

underlying insula (Dronkers, 1996; Ackermann & Riecker, 2004). Whatever its precise role, there is ample evidence not only for its involvement in language processing but for functional subdivisions of this area (see Bookheimer, 2002).

For example, imaging studies have found activation in posterior aspects of the left frontal operculum (especially BA 44) associated with phonological encoding in production (see meta-analysis by Indefrey & Levelt, 2004) as well as with phoneme discrimination (Zatorre et al., 1996) and sequencing (Demonet et al., 1994) during comprehension. Some have suggested that the primary role of this area is to subserve articulatory-based working memory processes (Hickok & Poeppel, 2004). Similar arguments have been made for the role of the more medial portion of Broca's area in syntax. Lesions to Broca's area cause problems with the production (Friedman & Grodzinsky, 1997) and interpretation (Grodzinsky, 2000) of syntactically complex sentences, and this area has shown activation in many imaging studies comparing relatively simple to more complex syntactic structures (see 4.3.2.1). While some have taken this to mean that syntactic processing is mediated by Broca's area (e.g., Grodzinsky, 2000), others have suggested that it subserves general or syntax-specific aspects of working memory (Caplan & Waters, 1999; Caplan & Waters, 1999; Fiebach, Schlesewsky, & Friederici, 2001; Kan and Swaab, 2002; Friederici, 2002).

Finally, anterior portions of Broca's area (BA 47, and the inferior part of BA 45) have been linked to semantic processing (reviewed in Bookheimer, 2002; Gabrieli, Poldrack, & Desmond, 1998). Thompson-Schill and colleagues have argued that this area is not specific to semantics but rather is involved in selection more generally, showing increased activation when competing, irrelevant information engenders high selection demands (1999; Kan & Thompson-Schill, 2004) and deficits in selection when damaged (Thompson-Schill et al., 1998). Others, however, have suggested that it is a more superior and posterior area that mediates selection (Martin & Chao, 2001; Wagner et al., 2001), linking the anterior portion of Broca's area with controlled semantic retrieval.

The functionally specific sub-areas that seem to make up the original "Broca's area" have thus been linked to language at the sound, structure, and meaning levels, especially for production but, to some extent, also for comprehension. What remains more controversial is whether the computations this brain area performs are language-specific or more general. Both lesion and imaging work suggest that Broca's area is especially critical for language functions, yet activity in this area has also been observed during non-linguistic tasks such as tone discrimination (Müller & Basho, 2004), motor imagery (Binkofski et al., 2000; Hanakawa et al., 2003), and imitation (Iacoboni et al., 1999; Leslie, Johnson-Frey, & Grafton, 2004), consistent with its being part of more general brain systems concerned with segmentation, planning, working memory, and/or selection processes, among others.

Another brain area closely linked to language is Wernicke's area (BA 22) in the left temporal/parietal cortex. Damage to this area produces a "fluent" aphasia and impaired comprehension; patients' speech has normal rate and rhythm together with many paraphasias (incorrect word substitutions) that render it nearly incomprehensible. Wernicke's area has traditionally been associated with language comprehension and semantics, though it too has been subdivided into functionally specific subareas.

The traditional "Wernicke's area," the posterior superior temporal gyrus (STG), has become closely linked to phonological decoding. Lesions to this area cause word deafness (especially, or even perhaps only, when bilateral: Poeppel, 2001; Buchman et al., 1986), and bilateral STG activation is consistently observed in speech comprehension tasks (Hickok & Poeppel, 2000, 2004). This area is also sensitive to the acoustic properties of speech (Binder et al., 2000; Scott et al., 2000), although left and right STG may mediate somewhat different aspects of acoustic processing (Ivry & Robertson, 1998). The left posterior STG seems to play a more crucial role for language *production*, as damage to this area causes a conduction aphasia marked by phonemic production difficulties at all levels (Anderson et al., 1999; Boatman, 2004). The anterior portion of the STG is also important for the analysis of speech (Scott & Wise, 2004), but it seems to play an additional role in the processing of language structure. Lesions to this portion of the STG are associated with syntactic processing deficits (Friederici, 2002; Dronkers et al., 2004), and imaging studies find increased activation in this area for sentences versus word lists (Stowe et al., 1999), for ungrammatical versus grammatical sentences (Meyer et al., 2002), as well as activation changes linked to syntactic priming (Noppeney & Price, 2004).

More inferior parts of the temporal lobe have come to be associated with processing at the interface between sound and meaning. Damage to the posterior portion of the middle temporal gyrus (MTG) has been associated with severe word comprehension and naming deficits (Dronkers et al., 2004). Activations in this area have been observed during word comprehension (Binder et al., 1997) and the processing of environmental sounds (Lewis et al., 2004), as well as in a meta-analysis of production imaging studies, where it has been linked to "conceptually driven lexical retrieval" (Levelt & Indefrey, 2004). Still more inferior areas, in the inferior temporal gyrus (ITG) and fusiform gyrus, seem to play a role in reading, naming, and concept retrieval. Stimulation of this "basal temporal language area" (in epileptic patients undergoing surgery) results in language deficits ranging from anomia to global expressive and receptive aphasias (Lüders et al., 1991). The fact that only transient aphasia results from damage to the basal temporal language area suggests that its functions are or can be duplicated by other brain areas (or, perhaps, that stimulation of this area disrupts language primarily through its connections with other language areas). Nevertheless, imaging studies suggest that activity in this area accompanies

normal semantic-linguistic processing (Thompson-Schill et al., 1999; Chao, Haxby, & Martin, 1999). The “visual word form area” in the posterior fusiform is consistently activated in reading tasks (review in Cohen et al., 2002) and is sensitive to abstract orthographic properties (Polk & Farah, 2002). It has been hypothesized to be involved in the prelexical processing of letter strings, though it also becomes active in a variety of other (even non-visual) tasks (Price & Devlin, 2003).

The aforementioned brain areas classically associated with aphasia, and thus with language – Broca’s area and Wernicke’s area – are in the left cerebral hemisphere, leading to the now widely accepted view that the left hemisphere is the “verbal” hemisphere and the right is the “nonverbal hemisphere.” However, it now seems that left-lateralization may be strong only for language production, with the right hemisphere playing a more important role in the integrative and pragmatic aspects of comprehension (for reviews see Joanette, Goulet, & Hannequin, 1990; Beeman & Chiarello, 1998). Right hemisphere damage has been associated with difficulties producing and comprehending both affective and linguistic prosody (Wymer, Lindman, & Booksh, 2002; Baum & Dwivedi, 2003) as well as with impairment in processing a variety of types of non-literal language, including indirect requests, sarcasm and speech acts (Kaplan et al., 1990; Champagne et al., 2003), connotations, jokes and humor. Right hemisphere damage has also been associated with more general problems drawing inferences and processing language at a discourse level. Correspondingly, imaging studies often observe bilateral – or even in some cases right-lateralized – activity in a variety of language tasks. For example, activity in right hemisphere homologues of left hemisphere language areas (inferior frontal gyrus, posterior superior temporal sulcus) has been seen in tasks requiring judgments of metaphorical meaning (Bottini et al., 1994), use of higher-level linguistic context (Kircher et al., 2001; St. George et al., 1999; Robertson et al., 2000), use of metalinguistic knowledge (Meyer, Friederici, & von Cramon, 2000), and monitoring of emotional prosody (Buchanan et al., 2000).

Overall, recent neuropsychological and imaging data suggest that a complex network of brain areas, including frontal, temporal, and parietal cortical areas in both hemispheres, along with associated subcortical structures, subserve normal language processing. A small set of these areas subserves functions that are so particular and so critical for language that damaging them causes severe and sometimes permanent language deficits. However, a larger set of areas also seems to make important contributions to language, albeit contributions whose loss can more readily be compensated for. As a result, the precise network involved in any given situation will depend heavily on the choice of experimental and control tasks and the methods used to process and analyze the data. When drawing conclusions from neuroimaging data, as from all types of psychophysiological data, it is thus important to recognize the inferential leaps required by and the inferential limita-

tions inherent in mappings from physiology to psychology (see Chapter 1 and Sarter et al., 1996).

3. SOCIAL/COGNITIVE CONTEXT

For at least 100,000 years our species has used language to describe – and construct – the world around us. First, and perhaps most obviously, language provides a medium for the communication of thoughts via a structured stream of sound, or, in signed language, manual and facial gesture. Upon hearing or seeing language, comprehenders are somehow able to formulate a mental representation of the conceptual content of the spoken, written, or signed message, which can alter the comprehenders’ mental state and affect subsequent behavior. Language thus provides the primary means of social interaction, enables the coordination of group action, and plays an organizing role in social relationships. Second, language enables us to transmit cultural knowledge such as customs and values.

The cognitive basis of this complex human skill involves representations and processes at a number of different levels, the regularities of which are investigated by subdisciplines within linguistics. Moving from sound to meaning, these disciplines include phonology, the study of linguistic sound patterns; morphology, the study of word formation; syntax, the study of hierarchical structure in individual utterances; information structure, the study of structure in spoken and written discourse; semantics, the study of context-invariant aspects of meaning; and pragmatics, the study of meaning in use. Although it is still unclear how traditional linguistic categories map onto brain structures and functions, it is important to consider the work of linguists as a relevant starting point for exploration of these issues.

Although our intuition may suggest that the fundamental unit of language is the word, linguistic research has shown that words are composed of more fundamental units known as phonemes and morphemes. Phonemes are categories of sounds considered equivalent to each other in a language and that distinguish one word from another: in *The cat sat on the mat*, the phonemes /k/, /s/, and /m/ recombine with the phonemes /æ/ and /t/ to form three different English words. Morphemes are the smallest units of meaning in a language: *cat* consists of three phonemes but only one morpheme, while *anti-dis-establish-ment-arianism* consists of seven morphemes, each contributing to the meaning of the word as a whole. This idea of building up meanings by combining representations at different levels is a recurrent one in linguistics because it helps explain the fact that we can express an infinite number of different meanings with a limited repertoire of speech sounds. Thus, phonemes are combined into morphemes, morphemes into lexemes (words), words into phrases, phrases into sentences, and sentences into discourses.

Just as words are built up out of individual sounds, sentences are built up from individual words. The relationship between words and sentences is complex and involves

structure at a number of different levels. “Parsing” is the process of analyzing the input into a series of lexical units and mapping higher order structures onto those units in a consistent and eventually meaningful way.

Words are divided into “grammatical categories” (traditional parts of speech: noun, verb, etc.), and syntax is the study of the relations among them – grammatical, phrase structural, subcategorization, and thematic. “Grammatical relations” include the traditional parts of a sentence: subject, object, etc. Words combine to form phrases in hierarchical configurations (“phrase/tree structures”) that encode grammatical relations. For example, the direct object of a verb is the noun phrase (NP) sister node of a verb (V); together, they form a verb phrase (VP). VP → V NP is a “phrase structure rule.” The entry of a word in the lexicon also specifies syntactic information. For example, not all verbs take direct objects: those that do are called transitive verbs, those that don’t are intransitive. This distinction is captured in a verb’s “subcategorization frame.” Within the grammatical category of verbs, subcategories of verbs take different syntactic complementation options: the lexical entry of a transitive verb specifies that it takes an NP complement, while that of an intransitive verb specifies that it takes no complement at all. “Thematic relations” are also lexically specified, and they determine the types of semantic roles that a verb co-occurs with. Thus a transitive verb like *make* takes both an agent and a patient/undergoer, while an intransitive verb takes either an agent (as in *run*) or a patient/undergoer (as in *die*), but not both.

Psychophysiological techniques have been used to study language representations and processes at nearly all levels of analysis; the relevant methods, measures, and inferences will be reviewed briefly in the remainder of this chapter.

4. INFERENTIAL CONTEXT

4.1. What’s the word?

From the brain’s perspective, language is a mapping between physical inputs/outputs, in the form of written, spoken, or signed signals, and experiences, memories, and knowledge stored in long-term memory. One of the critical units for such mapping is the word. Psychophysiological methods have been aimed at better specifying the features of a word, the organization of different kinds of information associated with a word, and the various influences on word processing. One proposal is that information about words is represented in a mental “lexicon” containing both lower-level phonological and orthographic information, as well as higher-level information about a word’s meaning and its various syntactic properties (when applicable), such as grammatical gender and subcategorization (though see Elman, 2004). On the standard model, recognizing a word activates this information in the lexicon, in a process known as “lexical access.” This information, in turn, is used to combine the meanings of words

into phrases and the meanings of phrases into sentences and discourses.

In this section we consider how, where, and when the brain is able to distinguish between sensory input that is treated as language and other sorts of perceptual information, ERP effects of local and global frequency, and the sensitivity of ERPs to lexical word class and word meaning.

4.1.1. Lexical versus perceptual processing of word forms

Initially, a linguistic stimulus is just another sensory signal – a pattern of light hitting the retina or a constellation of sound pressure waves reaching the cochlea. It is not surprising, therefore, that the earliest brain responses to language are indistinguishable from those to other types of visual and auditory inputs. Eventually, however, the brain begins to categorize (and thus respond differentially to) the input, for example, as a visual string rather than a single object, as a familiar event rather than a novel one, as belonging to the class of stimuli that may be associated with meaning, and so forth. When and how these classifications unfold are critical questions that have been partially answered by psychophysiological studies.

Schendan, Ganis, and Kutas (1998) examined the time course of visual classification by comparing the ERP responses to object-like, word-like, and intermediate stimuli. Regardless of task, around 95 ms a negativity over midline occipital sites distinguished the response to single object-like stimuli from those to strings, followed 10 ms later by a further distinction between strings composed of real letters and non-letters. Thus in the scalp-recorded ERP the first sign of specialized processing of “linguistic” stimuli appears around 105 ms. Results from intracranial recording and fMRI studies suggest that such differentiations may be occurring in the posterior fusiform gyrus (Allison et al., 1994) and the occipitotemporal and inferior occipital sulci (Puce et al., 1996). Finally, random letter strings are differentiated from pronounceable letter strings and words beginning approximately 200 ms post-stimulus-onset in the ERP. Spatial imaging studies have revealed activations that differentiate words and pronounceable pseudowords from non-words and false fonts in left medial extrastriate regions (Petersen & Fiez, 1993). Magnetoencephalographic responses likewise point to an important role for occipito-temporal cortex in reading within 200 ms, delineating a systematic sequence of activations from basic visual feature processing to object-level analysis (Tarkiainen, Cornelissen, & Salmelin, 2002; Cornelissen et al., 2003). Overall, these results intimate a hierarchy in which visual responses become increasingly selective for classes of visual stimuli over time.

A similar time-course of categorizations seems to hold for auditory inputs as well, with the first distinction between meaningful and nonsense words in the ERP around 200 ms (Novick, Lovrich, & Vaughan, 1985). PET findings suggest that activity early in primary auditory cortex and posterior temporal areas is unlikely to be language

specific. In contrast, responses in and around Wernicke's area seem to be more specific for words, as well as for tasks exacting phonological processing such as judging whether two words rhyme (Liotti, Gay, & Fox, 1994). Across modalities and methods, therefore, observations support the idea that the processing of words diverges from that of other types of stimuli within about 200 milliseconds, and that this differentiation occurs in secondary perceptual processing areas of the brain.

4.1.2. Repetition, frequency, and neighborhood effects

Once words have been categorized as such by the perceptual system, other factors – such as a word's frequency in the language as well as within an experimental setting (repetition) – begin to affect their neural analysis (see Van Petten et al., 1991). The brain is sensitive to event repetition at many levels, reflecting its recent experience with a particular physical form as well as its recent activation of a particular feature, concept or meaning. For proper names, Pickering and Schweinberger (2003) observed font-sensitive repetition effects between 180–220 ms, font-insensitive repetition effects between 220–300 ms, and later same "person" repetition effects, whether accessed via the name or the face. Repetition reliably decreases N400 amplitude (a negativity between 300–500 ms) to words both within and between modalities, as well as to orthographically legal, pronounceable pseudowords, whether these are derived from (and thus closely resemble) real words or not. Thus, although the N400 is often associated with semantic processing (section 4.2.2), its amplitude can be modulated even when there is no specific meaning to be retrieved (Deacon et al., 2004). N400 repetition effects are largest for immediate repetitions and can be seen even in amnestic patients (Olichney et al., 2000). Finally, the N400 is often followed by a late positivity (LPC) that is also sensitive to repetition (Rugg, 1990).

The first reported effects of word frequency – that is, of the system's global experience with a particular linguistic stimulus – manifest around the time (~150 ms or so) that letter strings begin to be differentiated from words and pronounceable pseudowords. This stage of visual processing seems to be sensitive to orthographic regularity (larger P150 to words and pseudowords than to letter strings) and, more generally, to the amount of experience accrued for a given perceptual form (larger P150 to high than to low frequency words; Proverbio, Vecchi, & Zani, 2004). Then, between 200 and 400 ms, the latency of a left anterior negativity ("frequency sensitive negativity" or FSN), subsuming the N280, is sensitive to the eliciting word's frequency of occurrence in the language (King & Kutas, 1998; Osterhout, Bersick, & McKinnon, 1997; Münte et al., 2001). For words in list format, N400 amplitude is also an inverse function of a word's eliciting frequency with all other factors held constant (see Figure 24.1).

The processing of a particular word or word-like stimulus not only depends on how recently and how often it was experienced, but also on the system's experience with

other, sufficiently similar, stimuli. "Lexical neighborhood density," which refers to the number of known words that differ from a given target by only a single letter (*N*-metric; Coltheart et al., 1977), also modulates N400 amplitudes: words and pseudowords with many lexical neighbors elicit larger amplitude N400s than those with fewer neighbors (Holcomb, Grainger, & O'Rourke, 2002).

4.1.3. Other lexical variables

During the 200–400 ms time range in which the ERP becomes sensitive to word frequency, effects of lexical class also appear – open class or content words, such as nouns, verbs, adjectives, and adverbs with significant semantic content, versus closed class or function words, such as articles, determiners, prepositions, and conjunctions with more relational content. FSN latency is sensitive to word frequency, irrespective of word class, though other negative components in this latency seem to be sensitive to lexical class *per se* (Brown, Hagoort, & ter Keurs, 1999; Münte et al., 2001). Content words elicit much larger N400s than function words, except when the latter is less expected than usual (King & Kutas, 1995); among function words, those with richer lexical semantic content elicit larger N400s than those with less (Kluender & Kutas, 1993a; McKinnon & Osterhout, 1996).

The ERP is also sensitive to further lexical subdivisions, such as that between nouns and verbs, showing both early and late differences in laterality, distribution, and sensitivity to potential and actual functional roles (Koenig & Lehmann, 1996; Khader et al., 2003; Federmeier et al., 2000). Within the category of nouns, those depicting a tangible, often pictureable, entity (concrete nouns) elicit larger N400s over frontal sites than do abstract nouns (Kounios & Holcomb, 1994), although less so within a supportive sentence context (Holcomb et al., 1999). The specific brain areas activated and reflected at the scalp seem to be influenced by the semantic content of words as well, differing for action versus perception related words, and within action verbs as a function of the body part involved (Pulvermüller, 2001).

4.2. Two of a kind: processing of word pairs

As previously noted, much language research has been aimed at determining the internal organization of the mental lexicon. To this end, a large number of studies have contrasted the responses to pairs of words (or other meaningful stimuli) that systematically vary along some dimension (orthography, phonology, morphology, semantics) as people make some decision about them. The pattern of sensitivity to types and degrees of similarity between the two stimuli – as well as interactions with task – have been used to address questions such as (among others): (1) what features constitute a lexical entry, (2) what resources and/or stages of processing are involved in the access and manipulation of various kinds of linguistic information, and (3) whether or not it makes sense to talk about an "amodal"

representation of a concept that can be accessed via written, spoken, and signed words as well as via non-linguistic stimuli.

4.2.1. Orthographic, phonological and morphological relationships

As interfaces between the perceptual form of a word and its lexical and semantic properties, orthographic and phonological information are important components of most models of the lexicon. Several ERP studies have shown that the influences of these cues can be observed in the N400 time window and beyond. For example, in rhyme-judgment tasks, rhyming word pairs elicit a smaller negativity between 250–550 ms than do non-rhyming word pairs (Sanquist et al., 1980). When the rhyming pairs are orthographically dissimilar (*moose-juice*), reduced N400 amplitudes can be attributed to the phonemic similarity. However, when phonemic and orthographic similarity are crossed, Polich and colleagues (1983) found that both influence the amplitude of the N400, consistent with behavioral reports that orthography cannot be ignored during rhyme judgment. Rugg and Barrett (1987) further demonstrated that orthographic, and not just visual, similarity modulates N400 amplitude. However, the nature of the task seems to affect the expression of these effects: whereas semantic similarity effects obtain even under passive viewing conditions (more below), Perrin and Garcia-Larrea (2003) found that phonological similarity affected the N400 only when participants were making active judgments about the stimuli (though phonological effects on the N400 can be observed when the judgment itself is not about phonology; Liu, Perfetti, & Hart, 2003).

Morphological influences on word processing also have been observed in the ERP by around 250 ms. Morphological processing involves both the derivation of new words (“derivational morphology”) and the marking of case, number, tense, and other word features (“inflectional morphology”). Several studies suggest that language users rapidly decompose words into their morphological constituents. McKinnon, Mark, & Osterhout (2003) observed larger N400s for pseudowords without morphemes (*flermuf*) compared to both real words and pseudowords with morphemes, suggesting that word-like stimuli are morphologically decomposed (even, in this case, for only partially productive morpheme stems, e.g., *inceive*). Dominguez, de Vega, and Barber (2004) compared morphological priming between pairs of Spanish words with a shared stem (*hijo/hija* [*son/daughter*]) to words that were not morphologically or semantically related, but shared a superficially similar stem (*foco/foca* [*flood-light/seal*]), and to those that were merely orthographically similar (*rasa/rana* [*flat/frog*]). They found that the brain rapidly distinguished between the morphologically- and superficially-related pairs; both elicited an initial amplitude reduction in the N400 time window, but this effect was sustained only for the morphologically (and thus semantically) similar pairs.

For many subsystems of inflectional morphology, regular patterns (e.g., in English past tense: *stretch/stretched*; in English plurals: *friend/friends*) can be contrasted with irregular ones (e.g., *catch/caught*; *woman/women*). Because electrophysiological measures reflect subtle processing differences between different classes of stimuli, they are well suited for determining the extent to which regular and irregular word forms are differentially processed. In three experiments, Penke et al. (1997) found that irregular past participle stems with the regular (i.e., incorrect) suffix *-t* elicited a left anterior negativity, whereas regular past participle stems with the irregular suffix *-en* did not. Weyerts et al. (1995) observed a similar-sized positivity from ~250 ms for both identity and morphological (infinitive) priming of past participles of regular verbs but a smaller and delayed morphological repetition effect relative to identity repetition for irregular verbs. In short, various ERP analyses do point to processing differences between regular and irregular morphological forms in adults, although it remains an open question exactly how distinct the neural representations of the two are.

4.2.2. Semantic relations between words

Reaction time and psychophysiological measures indicate that the processing of a single word (*cat*) is facilitated by the prior occurrence of a semantically related word (*dog*). This facilitation, known as semantic priming, is taken to reflect the way in which word representations are organized in our mental lexicon. Electrophysiological signs of semantic relations between words have been investigated primarily using the lexical decision task (Bentin, McCarthy, & Wood, 1985) and the category membership verification task (Boddy & Weinberg, 1981). In both tasks, ERPs to semantically primed words are more positive between 200 and 500 ms than are those to unprimed words, with the difference presumed to be a member of the N400 family. While the N400 effects in different modalities as well as cross-modally (Holcomb & Anderson, 1993) are similar in comprising a monophasic negative wave between 200 and 600 ms, they differ in amplitude, onset latency, and/or scalp distribution (Holcomb & Neville, 1990). Distributional differences notwithstanding, the reliability with which N400 amplitude is modulated by semantic relations has made it a useful metric for testing various hypotheses about language processing.

Among the more controversial issues in the semantic priming literature has been the relative contribution of “automatic” and “attentional” processes to the observed response facilitation (Den Heyer, Briand, & Dannenbring, 1983). This controversy grows out of the larger debate over the modularity of language abilities, with the assumption that modular processes are automatic. To determine whether the N400 indexes automatic lexical (modular) processes, or non-modular, controlled effects, researchers have examined the modulation of the N400 priming effect by factors such as the proportion of related and unrelated words (Holcomb, 1988; Chwilla, Brown, & Hagoort, 1995),

the temporal interval between prime and target (Anderson & Holcomb, 1995), and subjects' attentional focus (McCarthy & Nobre, 1993). Overall, it seems that the N400 priming effect persists under conditions typically more associated with automatic processing, though it is often altered quantitatively.

Studies addressing the issue of automaticity via forward and/or backward masking likewise have found N400 priming effects either unchanged or present, albeit smaller (Brown & Hagoort, 1993; Deacon et al., 2000; Kiefer & Spitzer, 2000). Masked and unmasked words also appear to similarly *interfere* with N400 priming (Deacon et al., 2004), although some have reported the eradication of N400 effects with masking (Ruz et al., 2003). Whereas N400 priming effects generally persist under masking and in the attentional blink paradigm, in which streams of rapid input must be attended and processed for response, causing some stimuli to be behaviorally missed ("blinked"; Vogel, Luck & Shapiro, 1998), LPC priming effects (linked to explicit, as opposed to implicit, memory; Olichney et al., 2000) do not (Misra & Holcomb, 2003; Rolke et al., 2001). Taken together, the results suggest that the N400 indexes processing that is neither completely automatic, because it changes in size and timecourse with reduced attention, nor completely controlled, because it persists at least partially when conscious attentional resources are severely limited, as in stage 2 and REM sleep (Bastuji, Perrin, & Garcia-Larrea, 2002).

4.2.3. Other semantic relations

N400 responses are not limited to words. A negativity between 300 and 500 ms with a wide-spread, generally centrally-maximal distribution, which is reduced in amplitude in the presence of supportive context information, makes up part of the brain's response to *any* potentially meaningful stimulus, including line drawings and pictures (Ganis, Kutas, & Sereno, 1996), faces (Bobes, Valdes-Sosa, & Olivares, 1994), meaningful environmental sounds (Van Petten & Rheinfelder, 1995; Chao, Nielson-Bohlman, & Knight, 1995), and gestures (Kelly, Kravitz, & Hopkins, 2004). These types of stimuli, as well as odors (Castle, Van Toller, & Milligan, 2000), also serve as effective context for the N400 response to words, causing amplitude reductions when they are predictive. However, linguistic content does not seem to be necessary for eliciting an N400, which has been observed for anomalies within scenes (Ganis & Kutas, 2003), picture stories (West & Holcomb, 2002), and short video clips (Sitnikova, Kuperberg, & Holcomb, 2003).

The N400 seems to reflect access to stored information at a number of levels: certain aspects of orthography, phonology, and morphology, as well as physical featural similarity between referents of words (e.g., shared shape or size characteristics of named objects; Kellenbach, Wijers, & Mulder, 2000), and a variety of types of meaning relationships (e.g., categorical, associative, schematic), including spatial reference frames (Taylor et al., 2001). This, coupled with the fact that the N400 is sensitive to factors related

to the ease with which information can be accessed from memory, has led to the suggestion that it indexes search through long-term, semantic memory. Indeed, N400-like potentials have also been observed in other domains in which memory search would seem to play a role, such as the processing of mathematical relationships among numbers (Galfano et al., 2004; Jost et al., 2003), though not all types of well-learned information elicit or influence N400s. For example, N400s are not observed to grammatical violations if these do not impact meaning, violations of melody (Besson & Macar, 1987) or prosody (Astesano, Besson, & Alter, 2004), or social expectancy (Bartholow et al., 2001) or to mismatches between faces and (recently learned) names (Huddy et al., 2003).

The N400 thus seems to index processing important for, but not limited to, language, which involves the access of relatively well-established, complex, and multidimensional representations from stimuli known from experience to be potentially meaningful. Potentials at the same latency, and sensitive to the same kind of semantic variables, are observed in the fusiform gyrus of patients with implanted electrodes (e.g., Nobre & McCarthy, 1995), although the inferotemporal cortex and superior temporal sulcus (which perform higher-order, modality-specific perceptual processing), as well as the medial temporal lobe, hippocampus, and ventrolateral prefrontal cortex (which process input from multiple modalities) are also active within this time window (Halgren et al., 1994a,b). The scalp-recorded N400 thus may reflect a set of temporally-restricted neural processes that are common to the analysis of all sensory inputs, allowing cross-modal interaction for the purposes of meaning construction (for MEG-based analysis, see Halgren et al., 2002).

4.3. Sentence comprehension

While the psychology of words is a rich field, analyses at the word level alone will not suffice to explain how meaning is derived from language, as even many aspects of words are difficult to understand without appealing to the sentence level or beyond.

4.3.1. Semantic context in sentences

The processing of words in sentences and how they are influenced by semantic and syntactic constraints have been extensively studied with ERPs. Kutas and Hillyard (1980) observed a large negativity peaking around 400 ms (N400) to a lexically semantically anomalous word at the end of a sentence; this has been replicated for written, spoken, and signed languages (see Figure 24.1). N400 elicitation, however, is not specific to semantic anomalies, and its amplitude reflects finer gradations of the contextual constraints placed on the eliciting word (Kutas & Federmeier, 2001). In fact, N400 amplitude and the cloze probability of a word (e.g., what proportion of subjects will fill in a particular word as being the most likely completion of a sentence fragment; Taylor, 1953) are inversely correlated at a level

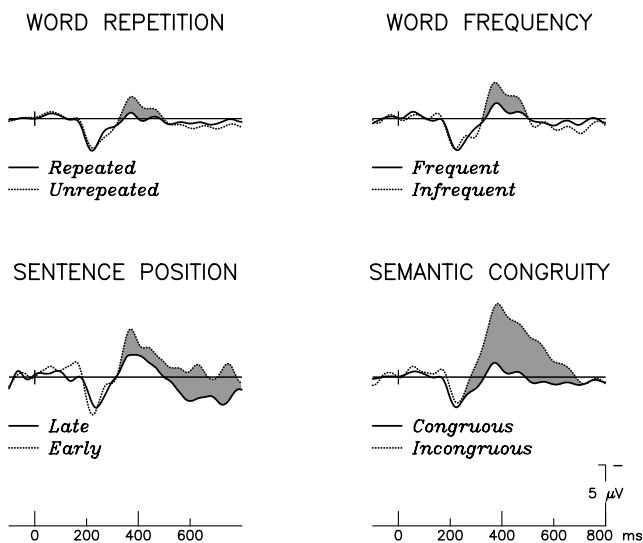

Figure 24.1. Sample N400 effects at a midline parietal site.

above 90%. Moreover, the finding that N400 amplitude to a low cloze word is the same regardless of the degree of prior contextual constraint was critical in establishing that the N400 does not index the violation of previously established expectancies for a particular word that was not presented, but rather the degree to which the sentence fragment prepares the way for the word that actually followed (Kutas & Hillyard, 1984). This effect of contextual constraint is also seen in the monotonic decrease in N400 amplitude to open class words with their ordinal position in congruent sentences, but not in random word strings of equal length. The semantic aspect of sentential context is also capable of eliminating the N400 frequency effect (Van Petten, 1995).

Contrasts of lexical/associative semantic relationships and sentence-level semantic relationships indicate that both independently influence N400 amplitude (Van Petten, 1995; see also Swaab et al., 2003, for a similar conclusion) and interact with comprehension skill (Van Petten et al., 1997). The N400 is sensitive to the relationships between a word and other words in the lexicon, its immediate sentential context, and discourse-level information, in both the auditory and visual modalities, as well as in nonverbal stories (West & Holcomb, 2002). van Berkum and colleagues (1999, 2003), for example, found that equivalent-sized N400s to the final words of isolated sentences like "Jane told her brother that he was exceptionally *quick/slow*" differed in amplitude when embedded in a discourse context like "That morning, Jane's brother finished his shower in only 5 minutes." It is important to note, however, that despite the exquisite sensitivity of the N400 to semantic relationships even outside of a sentence context and contextual expectancy (operationalized by cloze probability), it is not a good index of either sentential plausibility or meaning in terms of truth value: N400s to *white* are only marginally smaller than those to *sour* when completing sentence fragments such as "Dutch trains are —" (when they in fact yellow), are hardly present to *eat* in "For break-

fast the eggs would only *eat . . .*", and are equally small to *bird* in "A robin is/is not a *bird*" (Fischler et al., 1983; Kuperberg et al., 2003; Hagoort et al., 2004).

The N400 also has been used to examine when and how context exerts its influence on word processing. Van Petten and colleagues (1999) found that auditory ERPs to congruent and incongruent sentence completions differ within 200 ms after word onset, before the auditory signal was sufficient to uniquely identify the words (according to a gating study). Furthermore, the N400 to incongruent words (*captain*) that shared initial phonemes with the expected completions (*captain*) deviated from that to the expected item significantly later than did the N400 to incongruent words that did not share initial phonemes. Inconsistent with a bottom-up integration account, listeners do begin semantic analysis with incomplete acoustic information from contextually-derived expectations (semantic and perhaps phonological), prior to word identification and semantic access.

Such results suggest that language comprehenders may use context not only to guide the integration of the bottom-up information gleaned from a word in that context, but to actively prepare for the processing of likely upcoming – but not yet presented – words. Indeed, a number of recent studies have provided evidence that normal language comprehension involves semantic (and perhaps lexical) prediction. For example, Federmeier and Kutas (1999a) asked participants to read pairs of sentences leading to an expectation for a particular item in a particular semantic category; e.g.:

Ann wanted to treat her foreign guests to an all-American dessert. So she went out in the back yard and picked some apples.

which terminated with the expected item (*apples*), an unexpected item from the expected category (*oranges*), or an unexpected item from a different semantic category (*carrots*). Though both unexpected endings – of equal cloze probability and plausibility – elicited a large N400 relative to the expected one, those from the expected category elicited smaller N400s, even more so in high than low constraining contexts. As this pattern goes in the opposite direction from the rated plausibility of these items, N400 amplitudes to the within category items seem to be largely a function, not of the plausibility of the word itself, but of the expected (but not presented) exemplars. This constitutes clear evidence for prediction given that the featural overlap between the within category violation (*oranges*) and the contextually expected item (*apples*) could affect processing only if the features of the expected item were already activated in the comprehender's mind.

Further evidence for prediction in sentence processing has come from a series of studies in which readers' or listeners' ERPs to articles or adjectives differ according to whether they matched or mismatched the gender of an *upcoming* noun (written, spoken or in picture form) – a difference that indicates contextually-based expectation for a noun of a particular gender, or prescience

(Wicha, Moreno, & Kutas, 2004; van Berkum et al., 2005).

Alongside this evidence for predictive processing mechanisms in whole brain language comprehension is a growing realization that the brain may employ *multiple* processing strategies. Federmeier and Kutas (1999b) examined hemispheric differences in sentence comprehension by lateralizing the sentence-final words of three category types as described above. Since stimuli presented in one half of visual space are processed preferentially by the contralateral hemisphere, this procedure reveals hemispheric processing biases. Federmeier and Kutas replicated the pattern observed for normal reading when target words were preferentially processed by the left hemisphere (right visual field), but observed only a difference between expected and unexpected endings (of both types, consistent with plausibility ratings) for left visual field/right hemisphere processing. Thus, whereas left hemisphere comprehension strategies involve prediction, right hemisphere processing appears more bottom-up, focused on the *integration* of the current word with context information.

4.3.2. Syntactic investigations

Two of the most important and hotly contested debates within linguistics and psycholinguistics, namely, (1) the competence versus performance distinction (section 4.3.2.1) and (2) the modularity of language representation and language processing (section 4.3.2.2) have played out most energetically with regard to the syntactic (phrasal and sentential) levels of linguistic analysis, as detailed below.

4.3.2.1. The role of working memory, a performance construct, in syntactic processing. The main focus of psychophysiological investigations of working memory (WM) in syntactic processing has been structures in which one sentence element must be associated with another at a distance (often across a clause boundary) in order for both to be interpreted correctly. In English, this is true of so-called “wh-questions”, formed from “wh-words” like *who*, *what*, *which*, *where*, etc., and relative clauses. Any sentence constituent – subject, object, object of a preposition, even an entire prepositional phrase – can be displaced as a question word or relative pronoun from the position it would occupy in a corresponding declarative sentence (indicated in the examples by underlining) to the left periphery of a clause, as shown here for subjects and direct objects:

- Declarative sentence: She said [the reporter
 criticized the senator].
- Subject wh-question: **Who** [did she say
 [—criticized the senator]]?
- Subject relative clause: The reporter [**who** [she said
 [— criticized the senator]]]…
- Object wh-question: **Who** [did she say
 [the reporter criticized —]]?]
- Object relative clause: The senator [**who** [she said
 [the reporter criticized —]]]…

The displaced element is referred to as a “filler,” and the corresponding underlined position is referred to as a “gap” (Fodor, 1978), reflecting the fact that the gapped position must be “filled” with some such displaced constituent for sentence interpretation to succeed, and that the two are interdependent: fillers without gaps are illicit (*Who did she say the reporter criticized the senator?), and gaps without licensing fillers are equally ill-formed (*Did she say — criticized the senator?). For this reason, structures of this nature are generally referred to as dependencies. Just exactly how the association of gaps with their fillers is effected in linguistic representation and processing is a long-standing unresolved issue.

Gaze duration (Holmes & O'Regan, 1981), word-by-word reading times (King and Just, 1991), and pupillary diameter measures (Just & Carpenter, 1993) have established that, in English, object relative clauses are more difficult to process than are subject relative clauses, due in part to the added load they place on working memory. Information provided earlier in the sentence (the filler) must be maintained over time in order to determine the correct identity of the corresponding gap, and in object dependencies this information must be maintained over a longer distance while the processing of additional material continues (Kluender, 1998; Gibson, 2000).

In an ERP study of English *wh*-questions, Kluender and Kutas (1993a,b) showed in word-by-word comparisons of sentence positions between filler and gap that, relative to control sentences, object questions reliably elicited greater negativity over left anterior regions of scalp between 300 and 500 ms post-word onset (left anterior negativity, or LAN), while subject questions did not, presumably due to the increased working memory load of object dependencies. Direct comparisons of subject versus object relative clauses in the visual (King & Kutas, 1995) and auditory (Müller, King, & Kutas, 1997) modalities in English over longer time windows revealed that these phasic effects were most likely time slices of slow anterior negative potentials (left-lateralized with visual but not auditory presentation; see Figure 24.2). In a related paradigm comparing biclausal structures that differed only in the first word (“After/Before the scientist submitted the paper, the journal changed its policy”), Münte, Schiltz, and Kutas (1998) showed that “before” sentences with reversed chronological order similarly elicited slow negative potentials over left anterior sites, which were directly modulated by working memory capacity. Studies of *wh*-questions in German (Kluender & Münte, 1998; Fiebach, Schlesewsky, & Friederici, 2001; Felser, Clahsen, & Münte, 2003) and objects displaced leftwards (“scrambled” in linguistic terminology) in Japanese (Ueno & Kluender, 2003) essentially replicated the English results.

Other studies have added to this overall picture. Because of the idiosyncrasies of German word order, the use of German nouns ambiguously marked for nominative (subject) versus accusative (object) case can postpone the disambiguation of subject from object relative clauses and questions until the final word of the clause. When this is the

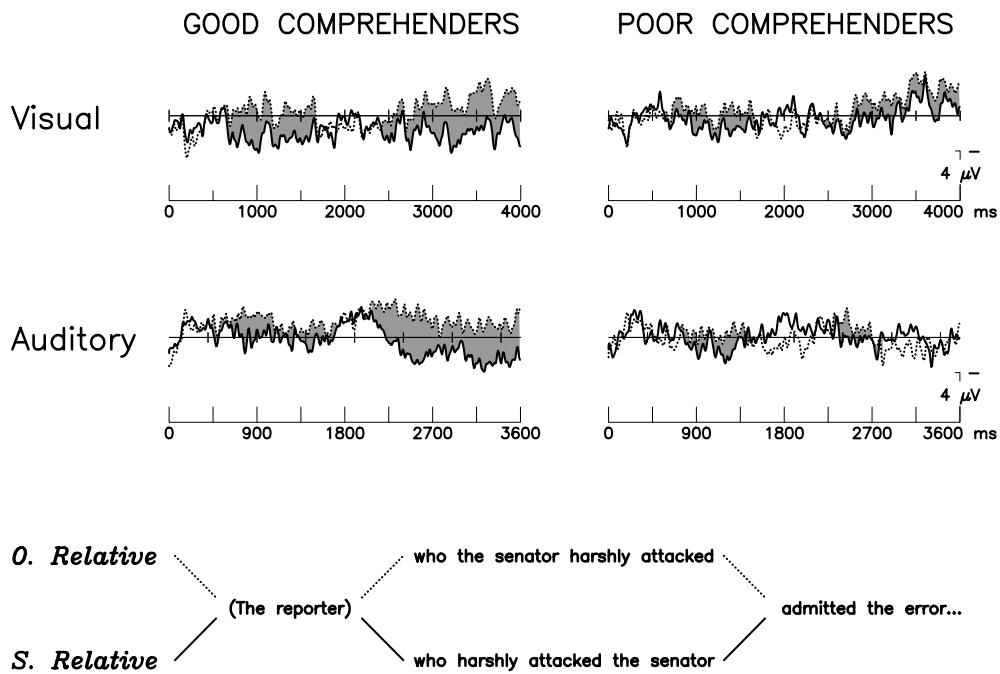

Figure 24.2. Comparison of grand average ERPs to subject relative (solid line) and object relative (dotted line) sentences from a left anterior site in good and poor comprehenders for word by word (500 ms/word) reading and natural speech. The visual data are taken from King and Kutas (1995) and the auditory data are taken from Mueller, King and Kutas (1997). Reprinted by permission of the authors.

case, readers appear to prefer and expect subject dependencies, as evidenced by the fact that the final word of object dependencies elicits a late positivity similar to that seen in response to dispreferred parses and ungrammatical stimuli – the P600 (Mecklinger et al., 1995) – though primarily in participants with high verbal working memory spans (Bornkessel et al., 2004).

Kaan et al. (2000) found that the association of a filler with its gap in English object questions similarly elicits a late positivity, which they interpreted as associated with integration rather than with storage costs of syntactic working memory (Gibson, 2000). This effect of gap-filling also has been replicated in verb-final languages like German (Fiebach, Schlesewsky, & Friederici, 2001; Felser, Clahsen, & Münte, 2003) and Japanese (Ueno & Kluender, 2003).

Overall, these studies conform to the generally accepted linguistic analysis of long-distance dependencies and point to its psychological reality with regard to the processing mechanisms involved. A related line of inquiry in the neural imaging literature has focused on the localization of such mechanisms by studying differences in activation of cortical areas in response to subject versus object dependencies. In an fMRI study, Just, Carpenter, and Keller, (1996) compared subject and object relative clauses with control sentences containing conjoined clauses, and found left-lateralized activation in both Broca's and Wernicke's areas in response to both relative clause conditions, with object relative clauses showing the greatest levels of activation. They interpreted these findings as reflecting gen-

eral working memory demands distributed across multiple cortical areas, directly or indirectly subserving lexical and syntactic processes (Keller, Carpenter, & Just 2001).

A series of PET studies by Caplan and colleagues comparing subject and object dependencies produced differing but mostly consistent results (Stromswold et al., 1996; Caplan, Alpert, & Waters, 1998, 1999; Caplan et al., 2000). Overall, this series of studies consistently elicited activation in the inferior frontal gyrus (BA 44 or 45) – and less consistently in the anterior cingulate, medial frontal gyri, and the superior parietal lobe – in response to object dependencies. These were interpreted as a measure of syntactic complexity related to syntactic integration processes. Subsequent studies, however, failed to confirm this precise picture. Caplan et al. (2001), for example, in an attempted replication of Just, Carpenter, and Keller, (1996), found that object versus subject relative clauses yielded activation of the left angular gyrus (BA 39), and marginal activation in the adjacent portion of the left superior temporal gyrus (BA 22) – essentially Wernicke's area. Ben-Shachar and colleagues (2003; 2004) reported greater activation of left inferior frontal cortex, but also of the posterior superior temporal gyrus bilaterally, when various types of object dependencies in Hebrew were compared with conditions lacking long-distance dependencies; no such effects were seen in direct comparisons with subject dependencies.

Cooke et al. (2001) manipulated the linear distance between filler and gap as well as clause type, and found

that all long (relative to short) filler-gap conditions consistently elicited activation in the right posterior superior temporal gyrus. Holding filler-gap length constant, comparisons of object relative clauses with subject relative clauses produced activations in the left posterior temporal-occipital area and the right lingual and fusiform gyri, but not in inferior frontal regions. Only when object relative clauses with long filler-gap distances were compared to either subject or object relative clauses with short filler-gap distances was there activation in left inferior frontal cortex, albeit BA 47. In a similar study of German *wh*-questions, Fiebach, Schlesewsky, and Friederici (2001) likewise failed to find activation in left inferior frontal regions except when object questions with long filler-gap distances were compared to subject questions with short filler-gap distances; they linked Broca's area to syntactic working memory resources, rather than to syntactic integration costs related to syntactic complexity.

Caplan, Waters, and Alpert (2003) and Waters et al. (2003) used the Stromswold et al. (1996) stimuli to examine individual differences in the processing of relative clauses. Both studies reported correlations with processing speed rather than working memory capacity; inferior frontal areas (left-lateralized in the first study, bilaterally in the second) were activated in response to object relatives only in subjects with fast reaction times, while slow-responding subjects showed activation only in left parietal (first study) or superior temporal areas (second study).

In short, there seems to be some relation between the processing of object dependencies, particularly those with long distances between filler and gap, and the activation of left inferior frontal regions. Though consistent with the left lateralization of slow anterior negative potentials to object dependencies in ERP studies, this is unlikely a direct one-to-one mapping, but rather part of a more complex neural network, as suggested by the additional, disparate areas activated by object dependencies in most neural imaging studies (cf. Keller, Carpenter, & Just 2001).

The status of working memory processes in the processing of object dependencies remains similarly unclear at this point. While all the ERP studies cited are consistent with the hypothesis that left anterior negativity (LAN) is an index of working memory resources engaged in the processing of more difficult object dependencies, the exact correlation has not yet been conclusively established. King and Kutas (1995) showed that better relative clause comprehenders had larger LAN responses, but this can at best be taken as an indirect measure of working memory capacity. Münte, Schiltz, and Kutas (1998) showed a direct correlation between working memory capacity as measured by reading span and LAN amplitude, but not in a study of long-distance dependencies. Finally, the direct correlation in the Fiebach, Schlesewsky, and Friederici (2001) study of German *wh*-questions was not in the expected direction.

Discrepancies between ERP studies and neural imaging studies further complicate the picture. The Cooke et al.

(2001) and Fiebach, Schlesewsky, and Friederici (2001, 2002) studies both suggest that activation of left inferior frontal areas of cortex is tied to the processing of long-distance object dependencies that especially tax working memory, not object dependencies *per se*. If so, then the role of working memory in long-distance dependencies may indeed be more of a performance than competence factor. On the other hand, the corresponding Fiebach, Schlesewsky, and Friederici (2001) ERP study reported a shorter but reliable anterior negativity in object versus subject questions with short filler-gap distances, perhaps indicating a greater sensitivity of ERP measures to such transient responses. Finally, the finding of Waters et al. (2003) that working memory capacity does not differentiate localization of cortical response to object dependencies (i.e., both high- and low-capacity subjects show bilateral activation in the inferior frontal lobe), while speed of sentence processing does (i.e., only high-proficiency subjects show bilateral inferior frontal activation) points to the fact that other individual differences contributing to overall proficiency need to be taken more seriously in future investigations as well. The bilingual neural imaging literature serves as a useful reference point in this regard, as it has convincingly shown that proficiency level is also a better predictor of second-language cortical representation than age of acquisition (Perani et al., 1998). Given what we now know about the plasticity of cortical representation (Merzenich et al., 2001), this should come as no surprise.

4.3.2.2. The role of modularity in syntactic processing.

Within sentence processing, there are two separate but related areas of investigation with regard to modularity. One has to do with the dissociation of syntactic from semantic aspects of processing (section 4.3.2.2.2); the other has to do with the dissociation of automatic from controlled aspects of syntactic processing itself (section 4.3.2.2.1). In both cases, the intended contrast is between the automatic processes inherent in a phrase structural parsing module, and more controlled processes like semantic interpretation, which are considered to be the purview of a central processor. Since specialized modules by hypothesis feed into the central processor, which takes their output as its own input, controlled processes within the central executive are presumed to occur later within the overall processing stream than automatic, modularized processes, and to be associated with a different underlying neural system.

The fine-grained temporal resolution of ERPs together with the possibility of, at least inferentially, dissociating the neural processes associated with different types of cognitive events by examining their various parameters (polarity, latency, overall morphology, and scalp distribution) have fueled a large body of research aimed at teasing apart automatic from controlled processes, at the same time that PET and fMRI have been used to look for localization differences, as reviewed below.

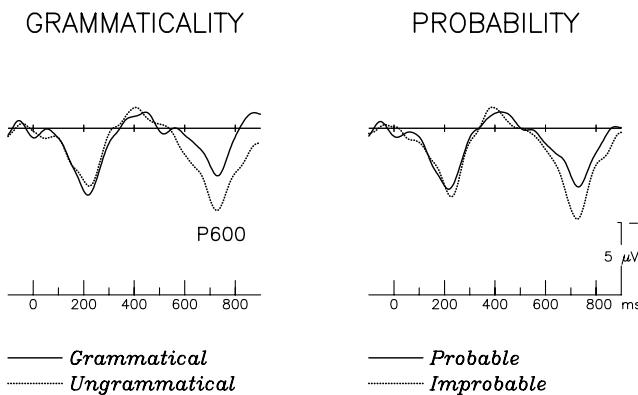

Figure 24.3. Grand average ERPs to mid-sentence words at a right parietal site: ungrammatical versus grammatical continuations (left), and improbable (20%) versus probable continuations, regardless of grammaticality (right). Data from Coulson, King, and Kutas (1997).

First, it may be useful to briefly give an overview of the three main ERP components that figure in these debates: the N400, the LAN, and the P600. The N400 component is discussed at length in sections 4.1.2, 4.2.2, and 4.3.1. Kutas and Hillyard (1983) attempted a dissociation of the N400 to violations of semantic well-formedness from potentially different ERP responses to violations of grammatical (morphosyntactic) well-formedness, including violations of number agreement between subjects and verbs ("she dig") and within noun phrases ("a balloons"), as well as the use of finite and non-finite verb forms in inappropriate sentence contexts ("to stayed", "are consider"). Significant early negative differences (300–400 ms) were found in all three conditions over anterior sites, together with marginally significant late positive differences over parietal sites 300 ms post-onset of words immediately following grammatical violations (Kutas and Hillyard, 1983: p. 544, Figure 4). Kutas and Hillyard thus noted that the association of the N400 with semantic but not grammatical anomalies pointed to non-identical processing systems.

It was not until a decade later, however, that the significance of these other components became apparent when a spate of exploratory ERP studies of syntactic processing (Neville et al., 1991; Osterhout & Holcomb, 1992; Hagoort, Brown, & Groothusen, 1993; Kluender & Kutas, 1993a) confirmed the existence of both a left-lateralized anterior negativity (LAN) between 300 and 500 ms post-stimulus onset, and a later broad positive shift (500–800 ms) with a more central distribution (P600; see Figure 24.3). These ERP components were elicited in response to various manipulations of sentence structure, and contrasted with the N400s to semantic manipulations within the same experimental designs. While the polarity and latency of the LAN (or family of such negative potentials) are essentially the same as that of the N400, they differ in their eliciting conditions, scalp distribution and morphology. Both the distribution and the latency of the P600 vary

more widely: while it typically exhibits a posterior distribution, it sometimes appears over anterior regions of scalp (Osterhout & Holcomb, 1992), and it can onset as early as 200 ms (i.e., overlapping the P200 component).

After these early studies, much effort went into characterizing exactly which cognitive processes each potential might be indexing. With regard to the P600, the main debate centers on whether or not it is specific to syntactic processing (Osterhout & Hagoort, 1999), or reflects instead the engagement of a more general purpose process, reflected by a family of positive potentials known as the P3, especially the P3b (cf. Donchin & Coles, 1988), to unexpected but task-relevant anomalies of various types (Gunter, Stowe, & Mulder, 1997; Coulson et al., 1998a,b). In line with the latter view, a number of studies have demonstrated similar late positivities in response to various violations of semantics or pragmatics – either following the N400 response (Munte et al., 1998) or replacing it altogether (Shao, 1995; Kolk, Chwilla, van Herten, & Oor, 2003; Stowe, Kuperberg, Sitnikova, Caplan, & Holcomb, 2003; Hoeks, Stowe, and Doedens, 2004; van Herten, Kolk, & Chwilla, 2005) – and in response to orthographic violations that leave correct pronunciation intact (Munte et al. 1998), harmonic violations in music (Patel et al., 1998), and violations of arithmetic rules (Nunez-Pena & Honrubia-Serrano, 2004). In line with the former view, it has been reported that the P600 elicited by syntactic anomalies is absent in patients with lesions of the basal ganglia (Frisch et al., 2003; Kotz et al., 2003; however, not in Friederici, von Cramon, & Kotz, 1999) and reduced in patients with Parkinson's disease (Friederici et al., 2003), though patients with basal ganglia lesions produce normal P300 responses in an auditory oddball paradigm. There is a related debate regarding the functional significance of the P600 within language contexts: should it be considered an index of syntactic processes *per se* (Hagoort, Brown, & Groothusen 1993), of late, controlled processes of reanalysis and repair once a syntactic parsing error has been detected in a multi-stage parsing model (Friederici, Hahne, & Mecklinger, 1996), of syntactic integration processes in general (Kaan et al., 2000), of the reanalysis necessitated by any kind of linguistic parsing difficulty (semantic, morphosyntactic, or orthographic; Munte et al., 1998), or of structural integration processes generally construed (Patel et al. 1998)?

With regard to the LAN, the first challenge was to tease apart the influence of (morpho)syntactic violations versus that of working memory in syntactic processing. Early studies reported LANs both to violations of syntactic well-formedness (Neville et al., 1991; Friederici, Pfeifer, & Hahne, 1993) as well as to manipulations of syntactic working memory (Kluender & Kutas, 1993a,b; King & Kutas, 1995). Kluender and Munte (1998) showed anterior negativities to manipulations of both working memory load and grammaticality within the same experimental design: the negativity elicited by WM manipulations consisted of slow frontal potentials (as in King &

Kutas, 1995), which could also be seen in individual word responses, while the negativity to syntactic violations consisted of more reliably left-lateralized phasic responses. At times, these phasic responses can be bilaterally distributed as well, under auditory (Hahne & Friederici, 2002) and visual (Hagoort, Wassenaar, & Brown, 2003) stimulus presentation.

Much discussion has also focused on the existence of a left anterior negativity that starts 150–200 ms earlier than the LAN, but usually persists into the same 300–500 ms latency window, and exhibits the same scalp distribution. This early left anterior negativity or ELAN (Neville et al., 1991; Friederici, Pfeifer, & Hahne 1993) is sometimes but not always elicited by word category violations, which occur when the parser's expectation that the next incoming word will be of a particular grammatical category (e.g., a noun following an article and adjective, such as "the red...") is violated. What remains unclear is whether the ELAN, which has been elicited only in manipulations of this kind, is a response to the presence of the unexpected word category (a verb following "the red...") or the absence of the expected category (e.g., a noun).

4.3.2.2.1. The relationship of automatic and controlled syntactic processes. Frazier and Fodor (1978), among others, proposed that parsing consists of at least two stages, an initial structure-building process based on hierarchical phrase structure and independent of meaning, and a later phase of syntactic reanalysis that comes into play when the initial parse fails and requires revision. Part of the motivation for such a model came from so-called "garden path" sentences (e.g., "The horse raced past the barn fell"), in which the parser is essentially led "down the [wrong] garden path." In this classic example, the parser initially attempts to analyze this sentence as containing an intransitive verb, but is stymied by the sentence-final verb "fell," which forces a reanalysis of "raced" as a passive participle within a reduced relative clause ("The horse [that was raced {by some unspecified rider} past the barn] fell"). The claim has been that the first (-pass parsing) process is automatic, not under conscious control, and impervious to non-syntactic influences, whereas the second process of revision or reanalysis is instead a conscious, controlled process that interacts with other types of information, such as that provided by semantic and/or pragmatic context.

An obvious factor contributing to the garden path phenomenon during silent reading is the lack of prosodic information or intonational contours that are superimposed on the words "raced" and "barn" to mark the (prosodic) boundaries of the reduced relative clause. Such prosodic boundaries help to avoid the garden path effect, and are reflected in the brain's responses to spoken sentences as a positive deflection in the ERP, known as the closure positive shift (Steinhauer et al., 1999); they are also elicited to a lesser degree for subvocal prosodic phrasing in written texts that include punctuation such as commas (Steinhauer, 2003).

Since the earliest studies of syntactic parsing reported both LAN and P600s to grammatically ill-formed stimuli, and since the two components have essentially complementary latency windows (300–500 ms and 500–800 ms, respectively), there has been an understandable attempt to map these components onto different stages of syntactic parsing (Friederici, Pfeifer, & Hahne, 1993; Osterhout et al., 1994). Most researchers now agree that the P600 most likely reflects either revision or integration – under either interpretation, a controlled process – despite the lack of consensus on whether the P600 is specific to syntactic processing, much less to language (see 4.3.2.2).

The existence of ERP markers of earlier, automatic stages of syntactic processing is similarly controversial. In particular, the exact relationship of the ELAN (100–300 ms), and the LAN (300–500 ms), has not been conclusively established, as in most paradigms that elicit an ELAN there is also a LAN present. In any case, the LAN is taken to precede semantic processes indexed by the N400, and dissociations of the two by factors that suppress the N400 but not the LAN have been demonstrated in normal populations (Friederici et al., 2004; Friederici, Steinhauer, & Frisch, 1999; Hahne & Friederici, 2002; Hahne & Jescheniak, 2001). Dissociations of the (E)LAN from the P600 have similarly been demonstrated in normal populations (Hahne & Friederici, 1999) and in patients with left frontal cortical lesions (Friederici, von Cramon, & Kotz, 1999).

While the imperviousness of the ELAN to experimental manipulations of this type and its suppression under degraded visual presentation suggest that it may index automatic processes, the component has to date been reliably elicited using only one general stimulus paradigm. The validity of claims made from the ELAN thus must await further research.

4.3.2.2.2. The relationship of syntactic and semantic processes. Although there is general agreement that comprehension requires reconciliation of semantic information about what the words in a sentence might mean and structural information about how they relate to each other, a heated debate rages as to whether or not initial syntactic analyses are modular (informationally encapsulated) and, at least initially, operate automatically, isolated from more controlled semantic/conceptual/pragmatic processes. There are fMRI data consistent with both theoretical perspectives. On the one hand, some brain areas appear to be selectively activated during semantic (e.g., BA 47 in the anterior LIFG) or syntactic processing (BA 44 in the posterior LIFG for word order processing, (Dapretto & Bookheimer, 1999; Indefrey et al., 2001), consistent with the possibility that these two levels of analysis can proceed independently. On the other hand, neuroimaging investigations offer no shortage of substrates for semantic-syntactic interactions – many brain areas that are reliably activated during both semantic and syntactic tasks (Kaan & Swaab, 2002), with activation patterns that differ only in degree (Kang et al., 1998; Kuperberg et al., 2003; Ni

et al., 2000). Moreover, to the extent that researchers have explicitly sought semantic-syntax interactions, such patterns have been found in Broca's area (Röder et al., 2002), the frontal operculum in the LIFG, and the left anterior STG (Friederici, Meyer, & von Cramon, 2000).

ERP data are equally equivocal on this issue. When researchers have combined semantic violations and syntactic violations and compared the brain's response to such double violations with that for each of the simple violations alone, they have consistently found that the LAN – viewed by some as an early sign of syntactic parsing operations – is insensitive to semantic manipulations (Gunter, Friederici, & Schriefers, 2000; Gunter, Stowe, & Mulder, 1997). Based on such evidence, Friederici and her colleagues argue that the earliest parsing operations proceed impervious to semantic information (see section 4.3.2.2). The results for the processes reflected in the N400 and P600, however, are less straightforward.

Several laboratories have demonstrated that N400 effects triggered by semantic manipulations are modulated by a number of different morphosyntactic factors. For example, the N400 to a semantically anomalous (versus congruent) noun in a sentence is larger when the semantic violation co-occurs with a mismatch between either the gender or the number of the noun and that of an associated article (Hagoort, Wassenaar, & Brown, 2003; Wicha, Moreno, & Kutas, 2004). Though this apparent "syntactic boost" in N400 amplitude could be a spurious consequence of overlap between an N400 and a LAN elicited by the syntactic violation (Gunter, Friederici, & Schriefers, 2000), its posterior scalp distribution favors the view that it is an increase in N400 amplitude per se. This could be an increase engendered by the additional load placed on semantic integration processes by the concomitant need to deal with the syntactic inconsistency (Hagoort, 2003). An increase in N400 amplitude triggered by verb inflection violations even in the absence of a semantic violation likewise attests to N400 sensitivity to morphosyntactic variables (Gunter & Friederici, 1999). These sorts of data thus seem to indicate an interaction of certain semantic and syntactic variables between 200 and 500 ms after word onset. However, word-category violations seem to suppress the significant N400 increase that would otherwise have been elicited by a semantically anomalous word (Friederici et al., 2004; Friederici, Steinhauer, & Frisch, 1999; Hahne & Friederici, 2002; Hahne & Jescheniak, 2001), in line with a more modular syntax-first view of sentence processing, with the breakdown in phrase-structure building due to a syntactic violation effectively shutting down any subsequent semantic analysis (Friederici et al., 2004).

Assessing semantic effects on the P600 component, typically linked to moments of syntactic ambiguity or outright violation (but see section 4.3.2.2), is complicated by the fact that it often follows close on the heels of an N400, as in double violations, leading to at least partial overlap of the two. Smaller positivity in the P600 time window to

double violations might thus reflect less P600 activity per se or partial overlap with a larger preceding N400. In fact, the inference with regard to the independence versus interaction of semantic and syntactic processes hinges on how P600 amplitude is measured. Measured with respect to a pre-stimulus baseline, semantic fit and grammatical factors (gender agreement or verb inflection) seem to interact, with the P600 to double violations smaller than to pure grammatical violations (Wicha, Moreno, & Kutas, 2004), perhaps because less effort is devoted to syntactic re-analysis (smaller P600) when finding meaning is difficult (Gunter, Friederici, & Schriefers, 2000). In contrast, when P600 amplitudes are measured with reference to the immediately preceding N400 peak, the interaction between semantic and morphosyntactic factors does not reach statistical significance, perhaps reflecting independence (Hagoort, Wassenaar, & Brown, 2003; though see Wicha, Moreno, & Kutas, 2004).

Though N400s are especially sensitive to semantic manipulations, P600s fairly reliably modulated by parsing difficulties, and LANs often elicited by morphosyntactic violations, the jury is still out on whether these brain potentials reflect psychophysiological primitives that readily map onto individual linguistic processes or representations. Indeed, it may be a mistake to attempt functional brain surgery (or phrenology) according to predetermined linguistic categories. Since neither psychophysiological measures nor linguistic analyses are completely above reproach, it may ultimately prove more rewarding to investigate what functions brain circuits actually compute, and how these could yield the types of regularities that linguists and psycholinguists have uncovered over the years. It may also be useful to bear in mind that the language comprehender's main goal is not to identify or categorize linguistic errors, but to make sense – whenever possible – of the available linguistic input.

4.4. Language production

While language production has been less thoroughly investigated with neuroimaging (especially electrophysiological) techniques than language comprehension, this gap has been narrowed in the past six or so years with the development of the lateralized readiness potential (LRP) and the no go N200 effect. Both have been used to delineate the relative time course of information transmission (encoding and/or retrieval) within a two choice go/no go paradigm, typically involving tacit picture naming.

The LRP is derived from a negative-going readiness brain potential (RP) that develops around 800 or so ms prior to a voluntary movement (Kornhuber & Deecke, 1965); a few hundred ms before the actual movement, the RP becomes larger over the central scalp contralateral to the moving hand. Single cell recordings from monkey cortex indicate that the lateralized portion of the RP is generated, at least in part, in the primary motor cortex (Miller, Riehle, & Requin, 1992).

The LRP is a derived measure computed in the stimulus-locked average with respect to the correct hand (Coles, 1989). On each trial, potentials from left (C3') and right hand (C4') areas are subtracted from one another (equivalent to a bipolar C3'-C4' recording), yielding the lateralized portion of the RP. These difference RPs are then averaged separately for trials where each hand was the correct response and subtracted from each other, canceling lateralized potentials unrelated to response preparation and leaving the average lateralization associated with response preparation – the LRP. Response preparation thus can be monitored a few hundred ms prior to an overt response and even when no response is given: its polarity indicates which response hand is being prepared and its amplitude indicates the degree of preparation, with overt response initiation triggered when LRP amplitude exceeds a certain threshold. The LRP is thus taken as a real-time measure of selective response preparation.

Also appearing in stimulus-locked averages within a dual choice go/no go task, when the motor response is withheld as per the cued instructions, is a fronto-central negativity (1–4 uV) with a latency that varies with task demands. This no go N200 is presumed to reflect response inhibition processes within the frontal cortex, based on single unit activity patterns in monkey frontal cortex during go/no go tasks, and suppression of the monkey's overt response on go trials by stimulation of prefrontal cortex at the time a no go N200 would have occurred if the response were withheld (Sasaki, Gemba, & Tsujimoto, 1989; see also Casey et al., 1998 for supporting fMRI evidence). The peak latency of the N200 effect (go minus no go ERPs) is typically taken as an upper estimate of the time by which the information needed for the go/no go decision must have been encoded. Overall, the N200 is larger, more robust, and more reliably elicited across individuals than is the LRP.

Essentially the same experimental paradigm (two choice go/no go paradigm) has been employed to delineate the relative time course of availability of different types of linguistic information (conceptual, semantic, word form or lemma, syntactic, phonological) during tacit picture naming. Participants view line drawings and are asked to make two decisions on the basis of the depicted item's characteristics (semantic versus phonological decisions as in van Turennout, Hagoort, & Brown, 1998; Schmitt, Münte, & Kutas, 2000; semantic versus syntactic decisions as in van Turennout, Hagoort, & Brown, 1998; Schmitt et al., 2001). Within an experimental setting, one decision maps onto the responding hand (which hand executes the response if there is one) and the other onto the go/no go choice (whether or not any overt response is given) and vice versa.

Though tacit naming in such a design is not actual language production, it is assumed that decisions (necessary for implicit as well as overt naming) made during a trial render the semantic, conceptual, syntactic and phonological properties of the depicted item available, with a time course measurable with psychophysiological measures and without the accompanying artifacts of overt

speech. Moreover, it is assumed that (in many cases, even partial) information is transmitted to the response system as it becomes available. Accordingly, if the responding hand is mapped onto information that is available faster than the information that determines whether or not any response is given, then there will be some response preparation (LRP activity) on no go trials, at least until the information needed for the go/no go decision is available to halt response preparation. LRP presence on no go trials with this mapping but not the reverse thus reflects the temporal availability advantage of one information type over another. This temporal advantage is also presumably reflected in the onset and peak latencies of the N200 no go effect (no go minus go difference), as the N200 for no go trials can occur only after enough relevant information that the response is to be withheld has accrued.

Overall, the results of these electrophysiological studies of language production have been remarkably consistent. On average, following a pictured item, conceptual/semantic information is available by ~150 to 225 ms, syntactic (gender) information is available by ~225 to 275 ms, and phonological information is available by ~275 to 400 ms. These results then indicate that semantic processing precedes syntactic processing, which in turn precedes phonological processing. These results, however, cannot be used to distinguish between models of language production that argue for or against strict seriality wherein phonological processing is temporally contingent upon a full syntactic analysis and/or syntactic processing is contingent on a complete semantic analysis (Rahman, van Turennout, & Levelt, 2003).

5. CONCLUSIONS AND FUTURE DIRECTIONS

Psychophysiological data have thus converged with behavioral data to fashion a set of viable hypotheses about *when* and *where* language processes occupy the brain – data that in some cases also constrain accounts of *how* language processing (reading, listening, preparing to speak) must be transpiring in real time. The past few decades or so of research attest to the multifaceted nature of language. Indeed, language processing involves an astonishing array of computational and neurobiological processes that operate on a large number of representation types at a number of different time scales in much of the brain's expanse. Much research effort has gone into cataloging and understanding these differences, such that we now know something about the different information types that are typically activated, their relative order of availability, their relative importance, and their relative independence, as well as something about the brain areas involved. Even routine language processing seems to engage considerable amounts of the brain, including not only cortical but also subcortical regions, and, within the cortex, areas in every lobe and in both hemispheres, although typically not to the same extents.

Recent work has highlighted the right hemisphere's role in language comprehension, revealing that it performs functions that are arguably as critical for real understanding as those under the purview of the left hemisphere. More neuroimaging studies of nonliteral language processing in the coming years will be a welcome addition to the existing handful on metaphor, jokes, indirect speech acts, and the like, in our aim of understanding not only the right hemisphere's capacity for and involvement in language but also the nature of the differences, if any, between literal and nonliteral language processing. A relatively new approach to these issues combines neuroimaging techniques with the visual half field paradigm – an excellent way to get a sense of how each hemisphere in the intact brain reacts to input when it receives a slight processing headstart. However, ultimately, we need to face the challenge of explaining how the two hemispheres work in unison during language while making use of the different processes and representations that previous research has defined. Understanding language as an integrated, goal-directed process will moreover require elucidation of the relationships holding among language subcomponents, and between language and other cognitive abilities.

There is as of yet surprisingly little consensus on precisely which brain areas are essential for – as opposed to merely involved in – language processing, their exact computational function(s), and therefore on their specificity for language. Likewise, there is still remarkably little accord among researchers about the degree to which language representations and/or processes (if such a sharp distinction is ultimately viable) are functionally isolable from non-linguistic representations and/or processes, or, within the domain of language, whether or not any subprocesses are isolated from each other. Moreover, whatever one's stance with respect to these issues, we are all comparatively illiterate with respect to how, if at all, the answers to these questions are tempered by individual differences of any kind (age, personality, mood), the particular language or type of languages under investigation (different languages or modalities of linguistic input), and/or the specifics of the dependent measures and/or experimental paradigms with which the questions are probed.

Even experiments that go beyond the single word to include whole sentence processing, discourse, text, and nonliteral language are a far cry from the types of communicative interactions that we encounter daily outside the laboratory. And, indeed, a few researchers are breaking new ground in their inquiry into more natural language processing, so-called "language in the wild," which arrives in fits and starts with pauses, false starts, repetitions, and without a complete sentential structure. Neuroimaging researchers also have begun to explore the communicative role of gestures. Yet another direction of current research pays homage to the crucial social aspect of language acts by recording brain activity from two participants in parallel or from only one participant in the conversational presence of another. In addition, even within the sterile

context of the laboratory, increasingly more neuroimaging researchers are beginning to appreciate that individual and group differences in age, working memory capacity, physical and intellectual experiences and general knowledge, psychological and emotional traits and states, as well as biological gender, all may impact the pattern of behavioral and neuroimaging results obtained, and thereby the inferences that we are likely to draw from them. One consequence of this is that researchers are sorting experimental participants into group types as a function of other criteria or subjecting the data to correlational analyses. Such an approach may help to explain the substantial variance in the neuroimaging data that seems to characterize even the best experimental designs.

Much of this variance comes from differences in what we know. And, what we know not only influences what we ultimately understand from language input but also the very processes by which we make sense of that input – determining what information is activated and in what order and with what strength, and how quickly an utterance or text is functionally stored for subsequent retrieval. Very little is known, however, about the relative importance of immediate context and longer-term background knowledge for meaning construction, and future research will need to address their interaction. It will also be important to understand just how critical it is for what is comprehended and/or how comprehension proceeds that people's experiences take place within human bodies with sensory receptors, motor effectors, and the brain betwixt. More research will be devoted to delineating how language representations are built out of both abstract, linguistic features and concrete, perceptual features.

There is also a continued need to explore connections between language processing and other cognitive feats, such as visual scene analysis, the understanding of diagrams, and the perception of music, as these activities likewise require that meaning be obtained over time from a well-structured source of information. By understanding the similarities (and differences) between these types of cognitive processes, we gain insight into the general principles underlying all of cognition, as well as an increased understanding of the defining properties of language.

In large part, psychophysiological data tend to be used either atheoretically, as findings to add to some database of what we know about when, or where any particular factor may have its influence on some brain (and/or behavioral) measure, or theoretically, as empirical evidence for (or in a few cases against) some particular point of view or hypothesis. Misguidedly, however, many instances of this latter use tend to be offered as empirical support for some position when they are just not inconsistent with it. In some cases, the authors seem to believe in their theory so strongly that almost any significant effect within the neuroimaging data constitutes support for the biological plausibility and validity of the original theory. Tempting as this may be, it is not a particularly productive approach

to scientific inquiry. Nor is intentionally or unintentionally ignoring relevant data from another imaging modality. Indeed, one of the biggest challenges facing us in the next few decades will be how to make sense not only of discrepant results, but of the data from different imaging modalities, as we still know so little about the fundamental relationships among them. It should go without saying that the more we continue to learn about the physiological and physical basis of our measures and their sensitivities to external and internal energies, the better. However, even with what we know now, we can begin to use psychophysiological data not only to give body to our favorite linguistic theories, but to develop theories of brain functioning which can account for our brain's ability to understand and to produce language, the types of miscommunications and breakdowns that routinely do or could never occur, the nature and time course of language development and usage across the lifespan for a first language, a second language, or more, as well as language processing in individuals experiencing abnormal language experiences due to innate or experiential factors.

In the future, then, using the various and sundry psychophysiological tools at our disposal, we may yet come to understand how Dickinson used her brain to generate poems – which we use our brains to decipher and appreciate.

25 Emotion and Motivation

MARGARET M. BRADLEY AND PETER J. LANG¹

PROLOGUE

Part of the complexity in studying emotion is defining it: There are almost as many definitions as there are investigators (see Panksepp, 1982, for a representative list). An aspect of emotion upon which most agree, however, is that in emotional situations, the body acts. The heart pounds, flutters, stops and drops; palms sweat; muscles tense and relax; blood boils; faces blush, flush, frown, and smile. We note these reactions in ourselves, and make inferences about the emotional life of others based on visible bodily responses. These changes are clear and strong in what William James (1890) called the “coarser emotions: fear, rage, grief, love, in which everyone recognizes a strong organic reverberation.” James, however, also thought that body was involved in subtle emotions, even though the “organic reverberation is less obvious and strong.” Lange (1882), joined with James in their eponymous theory, was even more grounded in biology, defining emotion explicitly as a cardiovascular response: “We owe...the emotional side of our mental life, our joys and sorrows, our happy and unhappy hours, to our vasomotor system.” (p. 80)

In the late 19th and early 20th centuries when James and Lange were speculating about the basis of affective life, emotion’s “organic reverberation” was not easy to assess in a precise, quantitative way. With the advent of elec-

tronic amplifiers, however, it has become possible to measure a broad range of physiological reactions to emotional challenges in the laboratory. In 1958, John Lacey could confidently state: “Such measures as skin resistance, heart rate, blood pressure, blood flow, skin temperature, blood-oxygen saturation, gastric motility, pupillary diameter, muscle tension, and other variables have been shown to be remarkably sensitive and responsive measures in a variety of “emotional” states. Conflict, threat and frustration; anxiety, anger, and fear; startle and pain; embarrassment; pleasant and unpleasant stimuli; – all these produce autonomic changes.” (p. 160).

In the late 19th and early 20th centuries when James and Lange were speculating about the basis of affective life, emotion’s “organic reverberation” was not easy to assess in a precise, quantitative way. With the advent of electronic amplifiers, however, it has become possible to measure a broad range of physiological reactions to emotional challenges in the laboratory. In 1958, John Lacey could confidently state: “Such measures as skin resistance, heart rate, blood pressure, blood flow, skin temperature, blood-oxygen saturation, gastric motility, pupillary diameter, muscle tension, and other variables have been shown to be remarkably sensitive and responsive measures in a variety of “emotional” states. Conflict, threat and frustration; anxiety, anger, and fear; startle and pain; embarrassment; pleasant and unpleasant stimuli; – all these produce autonomic changes.” (p. 160).

Despite this clear relation to bodily physiology, emotion is often considered synonymous with mental “feelings” in the popular culture, but its etymological roots are consistent with the biological imperative: the word emotion stems from the Latin *moveare*, meaning to move. When emotions are intense, people move: they act, they react, sometimes dramatically, as in crimes of passion. It is instructive that the word ‘motivation’ stems from the same verb; a motive is, literally, ‘something that moves one’. Whereas the term ‘emotion’ is usually reserved for describing stimuli that are felt to be moving, prompting an affective experience in humans, ‘motivation’ is the word more often used in interpreting the actions of animals.

¹ The International Affective Picture System (IAPS, Lang, Bradley, & Cuthbert, 2004), International Affective Digitized Sounds (IADS, Bradley & Lang, 1999a) and Affective Norms for English Words (ANEW, Bradley & Lang, 1999b) are available on CD-ROM. These stimulus sets and technical manuals can be obtained on request from the authors at the NIMH Center for the Study of Emotion and Attention, Box 100165 HSC, University of Florida, Gainesville, FL 32610-0165, USA.

Bradley at NIMH Center for the Study of Emotion and Attention (CSEA), Box 100165 hsc, University of Florida, Gainesville, FL 32610-0165.

Not surprisingly, William James noted the conjunction of these two descriptors, and, influenced by Darwin, emphasized a close relationship between emotion and motivation. In James's view, the basic motives (which he called "instincts") of both humans and animals are obligatory actions that are elicited by specific stimuli in the environment. The organism automatically freezes, flees, or fights at the sight of a predator, depending on the environmental context. Instincts, for James, were very like what we would now call motivational systems, defined by limbic circuits, and now a major focus of neuroscience research. James further noted that any object that elicited an instinct elicited an emotion as well, and that instincts and emotions "*shade imperceptibly into each other*". Even so, instinctive (motivated) behavior differs from the emotions: "Emotions... fall short of instincts, in that [whereas] the emotional reaction usually terminates in the subject's own body, the instinctive reaction is apt to go farther and enter into practical relations with the exciting object." That is, emotions are action dispositions, mobilizing the body for behavior, but in which the overt action itself is often delayed or totally inhibited.

CONCEPTUALIZING MOTIVATIONAL ORGANIZATION

Those studying motivated behavior in animal subjects have consistently agreed that two basic parameters of *direction* and *intensity* control action (e.g., Schneirla, 1959; Hebb, 1949). That is, in the simplest organism, stimuli that promote survival (e.g., food, nurturance) elicit behaviors towards the eliciting stimulus, whereas those that threaten the organism prompt withdrawal, escape, or avoidance. Both approach and avoidance behaviors can occur with varying strength, speed and vigor. In humans, although the specific direction of behavior (i.e., approach, avoid) is no longer completely dictated by the eliciting stimulus, the basic motivational parameters of direction (towards, away) and intensity can still be considered fundamental in organizing emotional behavior.

Biphasic motivation

For instance, most theorists agree that the primary distinction among emotional events is whether they are good or bad (Arnold, 1960), appetitive or aversive (Dickinson & Dearing, 1979) agreeable or disagreeable (MacLean, 1993), positive or negative (Cacioppo & Berntson, 1994), pleasant or unpleasant (Lang, Bradley, & Cuthbert, 1990), hospitable or inhospitable (Cacioppo, Berntson, & Crittes, 1996) which clearly relates to the motivational parameter of direction in animal behavior. Moreover, all agree that hedonically valenced events differ in the degree to which they arouse or engage action – a link to motivation's intensity parameter. Based on these observations, a number of theorists have advocated a biphasic approach to emotion, which posits that emotion fundamentally stems from varying activation in centrally organized appetitive and defensive motivational systems that have evolved to mediate the

wide range of adaptive behaviors necessary for an organism struggling to survive in the physical world (Konorski, 1967; Davidson et al., 1990; Lang, Bradley, & Cuthbert, 1990; Cacioppo & Berntson, 1994).

Dickinson and Dearing (1979) further proposed that these two motivational systems, (*aversive* and *attractive*) were activated by a wide range of different unconditioned stimuli, and additionally that they had *reciprocal inhibitory connections* (p. 5) which modulated learned behavior and responses to new unconditioned input. However, Miller (1959) proposed that motivation to approach and avoid could be simultaneously engaged (e.g., a stimulus could be both aversive and attractive) resulting in an inhibition of action with an intermediate state of arousal. More recently, Cacioppo and Berntson (1994) suggested a flexible conceptualization of biphasic activation, in which appetitive and defensive activation varies from being mutually reciprocal (Dickinson & Dearing, 1979), to being simultaneously active, to being separably active. Different points in bivariate space, defined by the intensity of biphasic motivational activation, identify instances when defensive and appetitive activation are highly co-active to when they reciprocally related, with the entire space representing all possible scenarios.

Discrete states

Another way to conceptualize emotion is in terms of a set of diverse, discrete emotions, such as fear, anger, sadness, happiness, and so on. Lists of basic emotions have typically varied from theorist to theorist. Descartes (discussed in Panksepp, 1982) listed wonder, love, joy, desire, hate, and sadness as fundamental; this is the last time that positive emotions outrepresented negative, and that love was included on the list. Watson (1924), observing allegiance to definitions based on observable behavior, had a short list of fear, rage, and sexual activity. More contemporary lists include surprise, enjoyment, interest, disgust, shame, distress, fear, contempt, and anger (Izard, 1972); surprise, acceptance, desire, fear, rage, panic, and disgust (Plutchik, 1980), and others.

Lists of discrete states have traditionally been the products of introspective analyses. James famously conjectured that our feelings, consciously apprehended, were in fact percepts of the bodily changes induced directly by a compelling stimulus; and furthermore, that (at least for the stronger, *coarse* emotions of anger, fear, etc.), specific emotions would have a specific physiology. This hypothesis prompted intense psychophysiological research over the last century. However, as John Lacey noted already in 1958: "The search for differential patterns of bodily response in differently named affective states was abandoned early in the history of psychophysiology, with results generally conceded to be disappointing." That is, while there were some provocative findings (e.g., Ax, 1953; Ekman, 1971; see Cacioppo et al., 1993, for a review), the stimulus contexts were generally idiosyncratic to the laboratory, participant response variability was high, and results

failed to replicate. More recently, Cacioppo et al. (1993) noted additional problems including inadequate experimental designs, inappropriate comparisons, use of different dependent measures, and, importantly, comparisons across very different induction contexts. Nonetheless, Cacioppo et al. (1993) selected studies that met a number of important criteria for determining emotional specificity, and still, the data were quite disappointing, with "... little evidence for replicable autonomic differences..." (p. 125).

Physiology and action

In addition to a lack of empirical confirmation, the question of whether specific emotional states are related to specific physiological patterns neglects the important facts that physiology will vary with action, and that actions associated with the same emotional state will also often vary. That is, most, if not all, peripheral (and to some degree, central) indices of physiological activity will vary as a function of the amount and type of somatic involvement and the accompanying demand for metabolic support. Put bluntly, running (or preparing to run) will produce a very different configuration of physiological activity than sitting and observing, with activity in one system (e.g., cardiovascular) dependent, to some degree, on activity in another system (e.g., somatic). Moreover, both animal and human research indicate that a cue signaling threat, for example, can lead to fight, flight, or freezing, as well as a variety of specific idiosyncratic behaviors ("displacement" behaviors as described by Tinbergen, 1969, and other ethologists; also see Mackintosh, 1983), depending upon available contextual support and the organism's learning history. The physiology of fear in the context of headlong flight will necessarily be different from the physiology of fear in the context of freezing. From a psychophysiological standpoint, it will at least be necessary to specify whether a commonly proposed discrete emotion (e.g., "fear") occurs in a context which prompts fleeing fear or freezing fear or fighting fear.

STUDYING EMOTION IN THE PSYCHOPHYSIOLOGICAL LABORATORY: INDUCTION CONTEXT, AFFECT VARIATION & THREE SYSTEMS MEASUREMENT

Lacey (1958) noted the great variety of contexts in which emotion can be induced in the laboratory: "The threat to the organism can be real or imagined, present or recalled or anticipated, social or physical, verbalizable or totally inaccessible to verbalization at the time. In all these situations many physiological changes occur.... Indeed, in predisposed individuals, painful and even dangerous somatic changes – such as headache, backache... production of blood, bile and excessive hydrochloric acid in the stomach... can be precipitated by the [mere] discussion of conflictual and psychologically threatening material." (p. 160). Lacey was also cognizant of what he called "situational stereotypy" – the idea that the nature and direction of phys-

Broad Domains of Emotion Induction in the Psychophysiological Laboratory

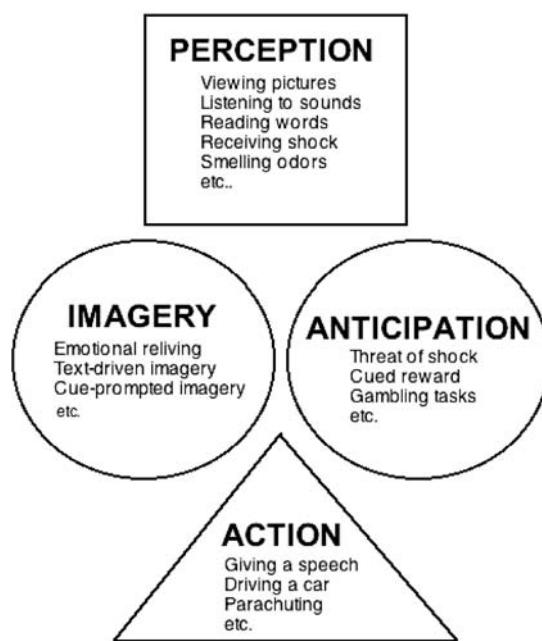

Figure 25.1. The most common induction paradigms in the psychophysiological study of emotion can be roughly classified as involving perception, imagination, anticipation, or action.

iological change is dependent, to a great extent, on the experimental context.

In the emotion literature, on the other hand, inferences regarding the physiology of fear, for example, are often made by comparing data from contexts as diverse as hearing loud noises, anticipating shock, imagining an intruder in the house, looking at a picture of an amputated leg, viewing a scary film, giving a speech, putting one's hand in cold water, or hearing an anguished scream. Conversely, responses to stimuli such as receiving money, listening to joyful music, looking at a picture of puppies, viewing an erotic film, imagining a day on the beach, receiving a good grade, thinking about winning the lottery, or anticipating a vacation are compared on the basis that they prompt a happy emotional state. The diverse sensory, cognitive, and motor processes elicited by these induction procedures may prompt quite different physiological profiles, irrespective of modulation by emotion. Moreover, the nature and direction of affect's modulatory influence can also depend on the specific induction context. Taken together, understanding the psychophysiology of emotion will depend on clearly specifying the context of the emotional induction in the laboratory.

Induction context

In the laboratory, contexts routinely used to induce affective reactions can be roughly organized into those that primarily target perception, anticipation, imagination, or action (see Figure 25.1). While clearly not mutually

exclusive (e.g., most anticipatory or imagery tasks include some perceptual input), these induction domains represent broadly similar contexts with respect to psychophysiological responses that may be task, but not emotion, related. For instance, physiological reactions in perception differ both quantitatively and qualitatively from those in imagination, due to the requisite physiology of these different tasks. Moreover, both within and between broad induction contexts, specific parameters can have strong effects on the degree and nature of emotional engagement – i.e., the ease with which neural systems mediating emotional responses are activated – and the resulting pattern of physiological change that can be associated with affective engagement.

Perception. Tasks that primarily target *emotional perception* focus on measuring affective responses to sensory information that is presented in visual (e.g., pictures, words, films, etc.), acoustic (e.g., sounds, music, etc.), tactile (e.g., shock, cold pressor, etc.), olfactory, or gustatory modalities. Perceptual cues can vary in a number of ways that may influence the magnitude and likelihood of emotional engagement, including their modality (e.g., visual, acoustic, tactile, etc.) and duration, the degree to which they are unconditioned (e.g., an electric shock) or conditioned stimuli (e.g., picture of bomb exploding) and the extent to which they involve static (e.g., picture) or dynamic cues (e.g., film). For instance, it is likely that cues in different modalities have differential access to motivational circuits. In non-human primates, visual input to the amygdaloid complex, a neural structure implicated in affective reactivity, is more extensive than auditory input (Amaral et al., 1992), suggesting that modality may be important in engaging affective responses. Similarly, whereas intense physical stimuli (e.g., painful shocks, loud noises) reflexively (and unconditionally) prompt defensive reactions, symbolic (conditioned) stimuli such as the pictures, films, and language cues often used in emotion research rely on learning and association formation for motivational activation, with ramifications for the strength of emotional response.

Imagery. Many psychophysiological studies of emotion measure responses in the context of mentally created or “relived” emotional events. In the *emotional imagery* context, participants are prompted to mentally engage in imagining events that represent a wide range of emotional experiences in the world. Parameters potentially affecting the extent and strength of emotional and physiological engagement in this context include the information in the eliciting cue, and whether the events imagined are non-fictional (i.e., personally experienced) or fictional (i.e., non-experienced). For instance, Jones and Johnson (1978) demonstrated that imagery cues describing action produced more cardiac reactivity during imagery than cues describing passive scenes, and Lang and his colleagues (Miller et al., 1987; Lang et al., 1980) further

demonstrated that when information describing appropriate responses (e.g., your palms are sweaty) is included, emotional responding during imagery is enhanced. Moreover, when subjects imagine emotional events that have been personally experienced, larger skin conductance and heart rate changes occur than when events are imagined that are not personally relevant (Miller et al., 1987), suggesting that motivational and physiological activation is more successful when a specific event is episodically represented in memory. Importantly, in the experiments described above, specific texts were used to prompt imaginal experience. Because the degree of psychophysiological responding during imagery relies intimately on information in the prompting cue, those which specify *only* the image’s affective quality (e.g., “imagine a happy event in your life”) may fail to clearly define or control important features of the imagined event.

Anticipation. In this affective context, emotional reactions are assessed during a period in which a subject awaits the presentation of an affective stimulus. Threat of shock studies (e.g., Grillon et al., 1991), and classical conditioning paradigms (see Ohman, this volume) fall into this class. Anticipating rewards or payoffs in gambling tasks represent an appetitive anticipatory context (Skolnick & Davidson, 2002). Numerous temporal and associative parameters have been noted as critical in modulating conditioning effects (e.g., MacIntosh, 1983; Stern, 1972), and are potentially relevant when assessing emotional reactions during anticipation (see Putnam, 1990). Among these are the duration of the cuing stimulus, and the nature of the cue (i.e., a light or a picture, for example), both of which can affect the amount of orienting activity (e.g., perceptual intake) that is occurring during the anticipatory interval. The specificity of the warning cue can also affect anticipatory reactions, in terms of whether the cue provides specific (e.g., snake) or non-specific (e.g., something bad) information regarding the upcoming affective event.

Action. Emotional actions, such as giving a speech, driving a car (for a phobic), or parachuting from an airplane represent active induction contexts in which psychophysiological reactions can be measured. Contexts involving overt action are employed less often in psychophysiological investigations of emotion, and for good reason. Gross motor activity can saturate amplifiers, produce artifact in cardiovascular and electrodermal records, and generally interfere with recording the often smaller physiological effects related to emotional parameters. The main variable in an action context is the required activity: Giving a speech will obviously be more physiologically demanding than a simple button press. Ambulatory monitoring studies, which attempt to study emotional reactions (e.g., panic) as they occur in the natural environment, fall within this class, and these investigators are coping with the issues involved in trying to separate the physiology of emotion

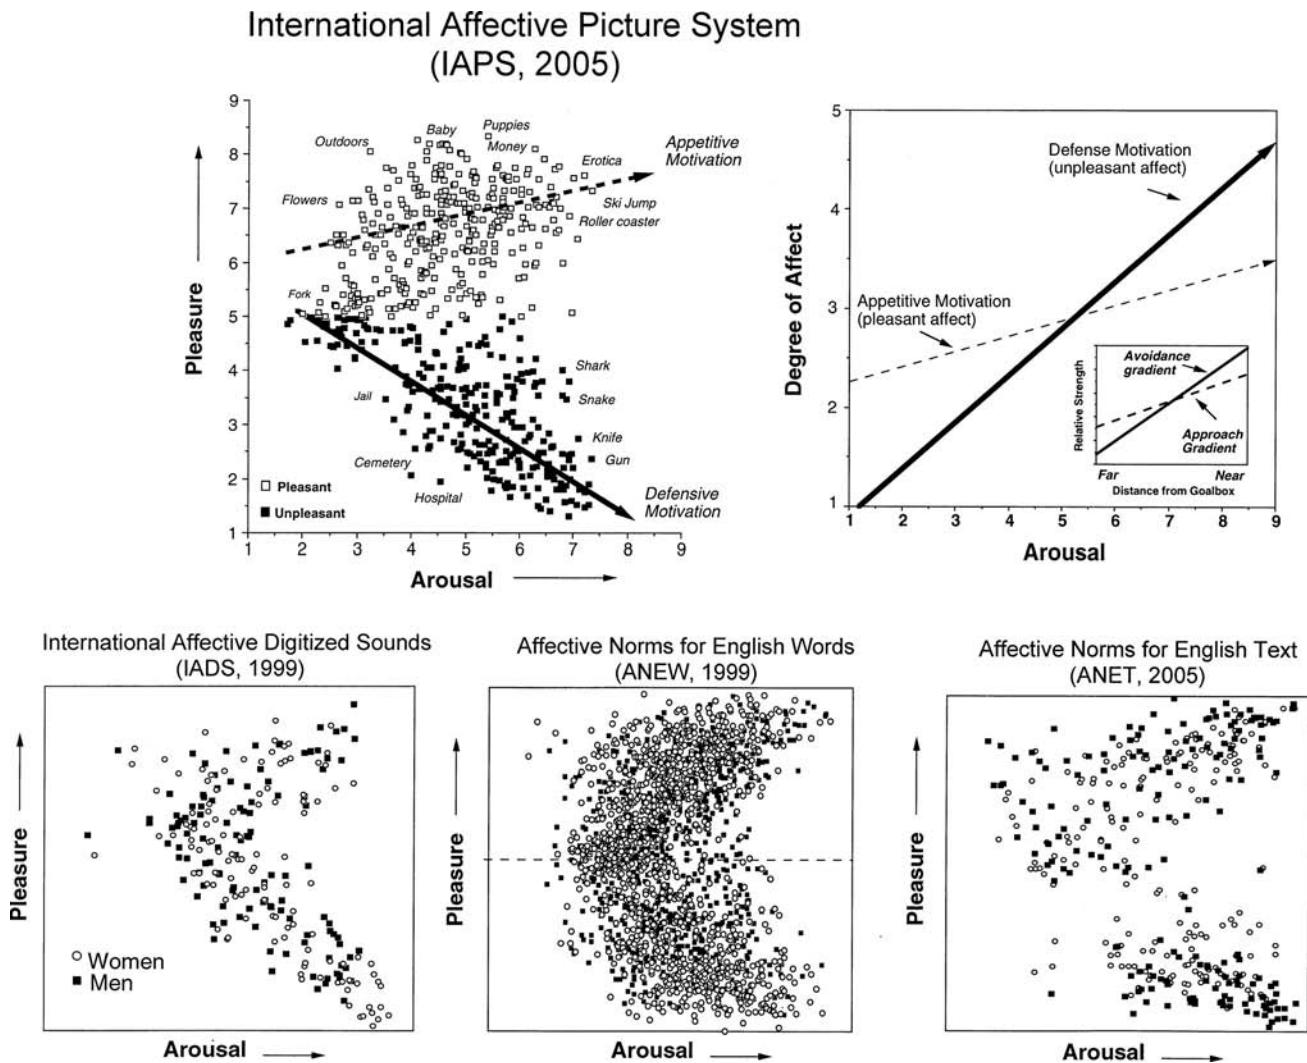

Figure 25.2. Emotional stimuli (pictures, sounds, words, text) are each plotted in the 2-dimensional space defined by the mean ratings of judged pleasure and arousal for each stimulus by a large group of participants. Regression lines drawn through the pleasant and unpleasant stimuli for affective picture ratings are similar to the approach and avoidance gradients first found by Miller (1959) when studying motivated behavior in rats. From Lang et al. (2005), Bradley & Lang (1999a), and Bradley and Lang (1999b).

from the physiology of ongoing action (e.g., see Wilhelm & Roth, 1996; Turpin, 1990; Alpers, Wilhelm, & Roth, 2005).

Affect variation

Following selection of a specific induction procedure, the emotion researcher will need to systematically vary affective features of the stimulus or task, and investigators working from a biphasic motivational perspective will be concerned with varying the degree to which the stimulus activates the defensive and/or appetitive systems. Beginning with Wundt's (1896) early studies of feeling states, it has been recognized that emotional differences among stimuli – words, objects, events – can succinctly be described by a few affective dimensions. In more current factor analyses of evaluative reports (e.g., Osgood, Suci, & Tannenbaum, 1957; see also Mehrabian & Russell, 1974;

Russell, 1980), two dimensions of *pleasure* and *arousal* control the majority of the variance. In the biphasic view, evaluative reports of *pleasure* roughly index which motivational system is activated by the stimulus or task (i.e., appetitive “pleasant,” or defensive “unpleasant”), whereas judgments of *arousal* index (again, roughly) the degree of activation in each motivation system.

Using ratings of *pleasure* and *arousal* gathered from large standardization samples, Lang, Bradley, and their colleagues have developed several sets of affective stimuli defined by these evaluative reports for use in emotion research. The stimulus sets include extensive samples of pictures (Lang, Bradley, & Cuthbert, 2004), sounds (Bradley & Lang, 1999a), words (Bradley & Lang, 1999b) and texts. The distribution of these stimuli in Cartesian space defined by their mean pleasure and arousal rating are quite similar across stimulus sets (see Figure 25.2).

Furthermore, it is noteworthy that the separate regression lines for pleasant and unpleasant pictures (Figure 25.2, top right) are consistent with the hypothesis of varying activation in two underlying appetitive or defensive motivational systems. When activation in both systems is minimal (neither pleasant nor unpleasant), emotional arousal is low and events are usually labelled Unemotional or Neutral. From a motivational perspective, this suggests only a weak tendency to approach or withdraw from the stimulus, and little energy mobilization required for what is, essentially, an absence of response. As defensive or appetitive motivation increases, arousal increases as well, presumably indexing the metabolic requirements of increased attention and anticipated actual action (e.g., approach or avoidance; appetitive incentive or defense).

The slopes and intercepts of the separate regression lines for pleasant and unpleasant pictures (Figure 25.2, top right) also recall the motivational gradients of approach and avoidance that Neal Miller described (1959) based on the strength of behavior in rodents, moving in a runway either towards a food reward or away from a punishing shock (Figure 25.2, top right, inset). Like Miller's data, the slope of the regression line for appetitive motivation is less steeply inclined than the slope for defense-activating, unpleasant stimuli, and the intercept for appetitive materials has a larger offset than does aversive material. Miller noted that the activation of approach behavior (towards food) began when the animal was relatively distant from the goal (hence the larger offset); in contrast, avoidance behavior (i.e., away from shock) began at a point more proximal to the site of the shock and showed a more rapid increase in intensity.

Broadening Miller's analysis, Cacioppo and his colleagues (Berntson, Boysen, & Cacioppo, 1993; Cacioppo, Gardner, & Berntson, 1997) suggest that weak appetitive activation is the base motivational disposition of organisms. They propose, furthermore, that this *positivity offset* of the appetitive gradient – the tendency to approach at low levels of motivation – is the foundation of orienting and exploratory reactions that mediate necessary, quotidian interactions with environmental stimuli. On the other hand, when unpleasant stimuli are proximal, the defense system is abruptly engaged, and rapidly dominates the organism's behavior. The point at which defensive motivation overcomes appetitive motivation is a function of the strength of aversive stimulation and individual differences in temperament and learning history. Survival, however, is always the bottom line and *negativity bias* and the ascendancy of defense when aversive stimuli are near is a fundamental disposition in a world full of diverse threats and dangers.

Discrete emotional states. Researchers proceeding from a discrete emotion view, on the other hand, will seek stimuli or tasks that are held to induce specific emotional states such as fear, anger, sadness, etc. Many recent efforts to study discrete emotions have used facial expressions

to define discrete emotions in experimental stimuli, and Ekman and colleagues (Ekman & Friesen, 1979) have developed a coding system (Facial Action Coding System: FACS; Ekman, Friesen, & Hager, 2002) that has been widely used in the observational analysis of the human face, reacting to emotional stimuli. Based on the facial data, Ekman defined a set of primary affects (fear, anger, disgust, joy, sad, surprise), proposing that they were programmed centrally and accompanied by specific patterns of bodily reactions.

A number of facial stimulus sets that reliably vary in the discrete emotion labels people apply to them are now available to researchers that consist of photographs of models posing the basic affective expressions (Pictures of Facial Affect, Ekman & Friesen, 1979; the Karolinska Directed Emotional Face System (KDEF), Lundqvist, Flykt, & Öhman, 1998). The latter collection includes color photographs of several different male and female actors posing facial expressions in a naturalistic manner. In general, posed facial expressions communicate the intended specific emotions, as evidenced by the reliability of emotion labeling by naive observers. Furthermore, research (Ekman, 1971) suggests that at least a subset of facial expressions communicates similar emotions that are reliably labelled across different races and cultures (an issue that intrigued even Darwin, 1873).

3-system measurement

The indices that can be measured and quantified across emotional induction contexts include three systems of (1) evaluative reports, (2) physiological responses, and (3) overt actions (e.g., Lang, 1968). In much of psychological research, emotion measurement relies mainly on evaluative reports, including verbal descriptions (e.g., "I'm afraid"), ratings (e.g., ratings of fear on a scale of 1 to 10), reports of associated responses (e.g., circling or listing bodily reactions), and a variety of other methods that elicit judgments from subjects regarding their affective reactions. On the other hand, overt actions, such as running, jumping, fighting, freezing, and so on, which are used extensively in studies of motivated behavior in laboratory animals, are somewhat less commonly measured in human studies, but have included observable behaviors such as overt facial expressions. Physiological responses are those bodily events that can be assessed using psychophysiological instrumentation and methods, and are not necessarily observable. In emotion research to date, these have included responses in cardiovascular, electrodermal, somatic, reflex, gastric, respiratory, central, and neuroendocrine systems.

There are a number of possible relationships between three-system measures of emotion. Affective reactions can be assessed by measuring only overt behavior (e.g., freezing) or physiology (e.g., cardiovascular), in the absence of verbal reports, as studies of motivated behavior in animals demonstrates. Motivational systems operate

independently of a link to a developed language system. In addition, when behavior is observable, changes in associated physiological measures will also tend to occur. Most obviously, if a person is overtly smiling, changes will be detected in EMG activity measured over the appropriate muscles. Because of their inter-dependence, behavioral and physiological measures will not be 'discordant' in the same sense that reports of affective experience and physiology may be.

THE PSYCHOPHYSIOLOGY OF EMOTION: AUTONOMIC AND SOMATIC MEASURES

The autonomic and somatic responses – heart, skin, and muscles – that are hallmarks of affective response are proximally controlled by the peripheral nervous system (see Guyton & Hall, 1996, for an overview), and the anatomical and functional distinctions between its parasympathetic ("homeostatic") and sympathetic ("fight or flight") branches have been important in the study of emotion. The sympathetic nervous system is characterized by post-ganglionic fibers that are quite lengthy, and which branch and divide as they make their way to specific target organs. Functionally, this means that a single sympathetic fiber activates a number of different effectors, providing an anatomical substrate for Cannon's emergency reaction, which proposed a volley of responses – heart rate and blood pressure increases, electrodermal reactions, increase in respiration rate and depth – on the basis of sympathetic activation. Conversely, the post-ganglionic fibers in the parasympathetic branch are short, and therefore more likely to quickly target a specific effector.

Most organs are innervated by nerves from both the parasympathetic and sympathetic divisions, which tend to exert opposite effects. The reciprocal effects of these two systems on different organs are mediated by the release of different neurotransmitters at the neuro-effector junction, with acetylcholine released by parasympathetic fibers (cholinergic) and noradrenaline released by sympathetic fibers (adrenergic). Their subsequent action (e.g., increase or decrease in heart rate) is also temporally differentiated by the fact that noradrenaline dissipates slowly, whereas acetylcholine dissipates more rapidly. Thus, parasympathetic control will tend to activate specific organs with rapid, phasic effects, whereas sympathetic control is not only more diffuse, but also somewhat longer lasting.

Cardiovascular reactions and emotion

Early investigations exploring emotion in perception assessed cardiovascular activity such as vascular changes and heart rate (e.g., Roessler, Burch, & Childers, 1966; Epstein, 1971; Turpin & Siddle, 1983) as a function of differences in stimulus intensity, as this variable was considered critical in eliciting orienting or defense responses. Low-intensity sensory stimuli were held to prompt orienting activity, mediated by parasympathetic dominance and

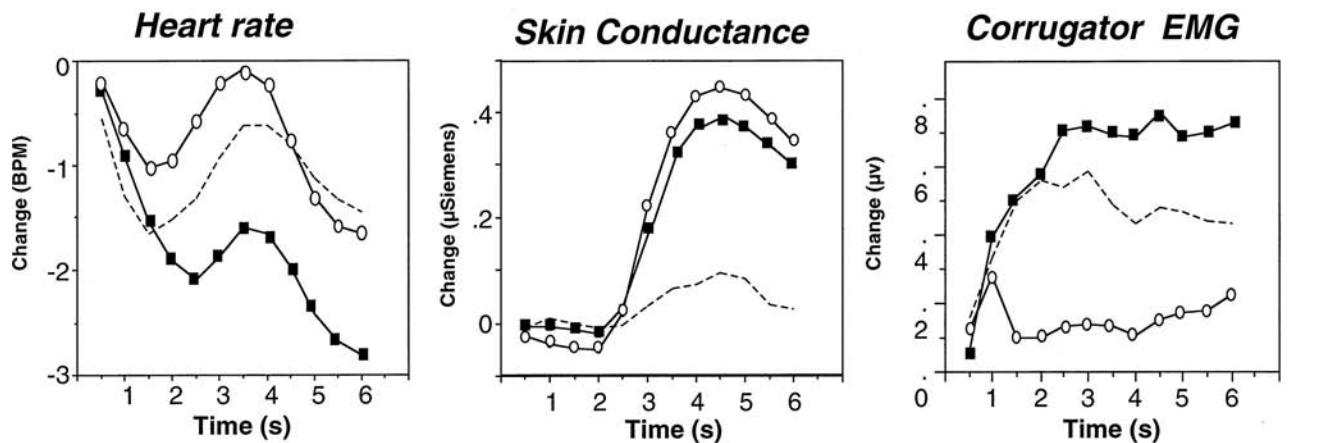

associated with a pattern of peripheral and cephalic vasoconstriction and heart rate deceleration, whereas intense stimuli were hypothesized to prompt defense responses, mediated by sympathetic reactivity, and associated with peripheral vasoconstriction, cephalic vasodilation, and heart rate acceleration (see Sokolov, 1963; Graham 1979; Turpin, 1986).

In this conception, sympathetic activity was associated with mobilization to respond to aversive events, whereas pleasant affect was associated with parasympathetic dominance (Arnold, 1960; Gellhorn & Loofbourrow, 1963; Schneirla, 1959). This notion suggests a mode of consistent reciprocal activation between the sympathetic and parasympathetic branches that is no longer tenable. Rather, Berntson, Cacioppo, and Quigley (1991; see also Berntson et al., 1994) have proposed a theory of autonomic control in which physiological measures of a dually-innervated end-organ (e.g., the heart) may differ as a function of the weighting of activation in the parasympathetic and sympathetic systems: systems can be independently active, reciprocally controlled, or co-active.

For instance, Quigley and Berntson (1990) demonstrated that heart rate acceleration to an aversive stimulus (in the rat) is larger than to a low-intensity stimulus not because of differential sympathetic activity, but because parasympathetic activity decreases with high-intensity stimulation. Similarly, in humans, an aversive loud noise prompts a cardiac defense response that consists of an initial acceleration (4–6 s), followed by a decelerative component (17–23 s), and a later secondary accelerative component (31–76 s). Similar to Quigley and Berntson (1990), Reyes del Paso, Godoy, and Vila (1993) concluded that the initial acceleratory component is mediated by the parasympathetic system (vagal release), as this component was not blocked by the administration of a sympathetic beta-adrenergic blockade. On the other hand, the delayed secondary acceleration was blocked by the drug (as was stroke volume), suggesting that the slower cardiac component was at least in part sympathetically mediated.

In a picture perception context, stimulus "intensity" has generally been implemented by varying hedonic valence, and work by the Laceys (e.g., Libby, Lacey, & Lacey, 1973), Klorman (e.g., Klorman, Weissberg, & Austin, 1975; Klorman, Weissbert, & Wiessenfeld, 1977), and Hare (e.g., Hare, 1973; Hare, Wood, Britain, & Shadman, 1971; Hare, Wood, Britain, & Frazelle, 1971) consistently found that the heart decelerated, rather than accelerated, when people viewed pictures of unpleasant emotional events, contrary to the notion that these aversive stimuli might prompt defensive heart rate acceleration. Based on these kinds of data, Lacey (1967) originally proposed the notion of *stimulus specificity* (i.e., that specific stimuli or tasks are associated with specific patterns of physiological response). Based on these data, Lacey hypothesized that cardiac deceleration was an index of perceptual processing, reflecting sensory intake, whereas cardiac acceleration was an index of mental processing, reflecting sensory rejection.

Looking at PICTURES

Listening to SOUNDS

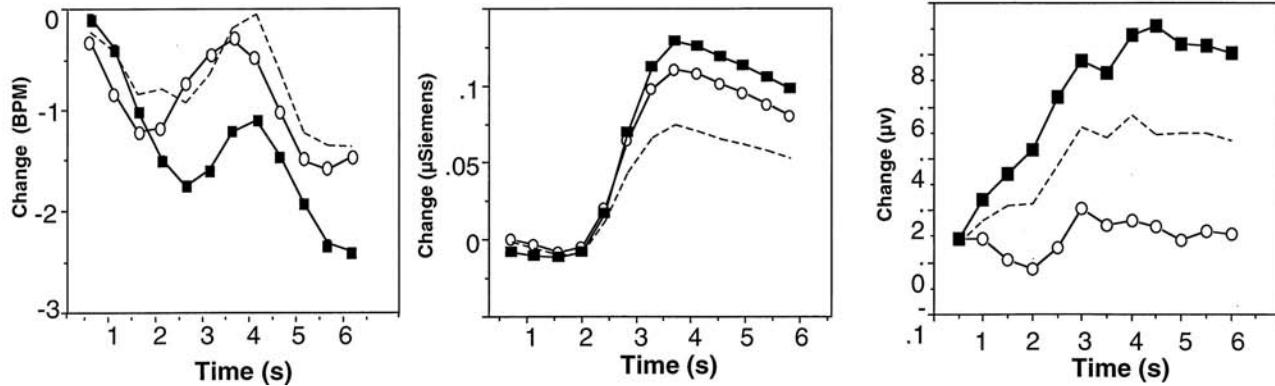

Figure 25.3. Cardiac, electrodermal, and facial EMG (corrugator supercilii) activity during perception of 6 s presentations of pleasant, neutral, or unpleasant pictures (top) and sounds (bottom) show similar affective modulation. Based on data reported in Bradley et al. (2005) and Bradley and Lang (2001).

In the aversive picture perception context, Lacey assumed people were perceptually rejecting the aversive content and turning inward, or away from the sensory display.

Many recent studies have confirmed that the cardiac response during aversive picture viewing involves significant initial deceleration. When viewing pictures, those that are rated as unpleasant typically prompt more initial deceleration than do pleasant or neutral pictures (Lang et al., 1993; see Figure 25.3, top left). When specific picture contents are explored, significant cardiac deceleration is obtained for all unpleasant contents, including highly arousing pictures of threat and mutilation, as well as relatively low arousal contents such as pollution and loss (Bradley et al., 2001a). An initial deceleratory response when viewing unpleasant pictures is reminiscent of the fear bradycardia elicited in animals to threatening stimuli. In animals, this decelerative response is vagally mediated, as atropine (a parasympathetic blockade) completely eliminates it, indicating release of parasympathetic control, and has been interpreted as reflecting heightened sensory intake and orienting (see Campbell, Wood, & McBride, 1996). Consistent with a hypothesis of increased sensory intake, highly arousing appetitive pictures, particularly those involving erotica, prompt significantly more initial cardiac deceleration than pleasant pictures rated as lower in arousal (Bradley et al., 2001a), suggesting that pleasant, arousing contents can also attract increased perceptual processing and sensory intake.

If cardiac deceleration during picture perception reflects sensory processing, cardiac responses in other perceptual contexts should also show decelerative differences that reflect hedonic valence. Consistent with this, heart rate also reliably decelerates when viewing films (rather than pictures) that depict bloody surgical interventions (Palomba et al., 2000), suggesting a stance of heightened attention and intake. Moreover, listening to highly

If cardiac deceleration during picture perception reflects sensory processing, cardiac responses in other perceptual contexts should also show decelerative differences that reflect hedonic valence. Consistent with this, heart rate also reliably decelerates when viewing films (rather than pictures) that depict bloody surgical interventions (Palomba et al., 2000), suggesting a stance of heightened attention and intake. Moreover, listening to highly

arousing unpleasant sounds (e.g., bombs exploding, etc.) also prompts greater initial deceleration than listening to neutral sounds (Bradley & Lang, 2000; Figure 25.3, bottom left). On the other hand, reading sentences that describe emotional or neutral events prompts significant cardiac deceleration, but does not vary with emotion: In this perceptual context, the sensory cues (words) require equivalent processing and the cardiac response reflects sensory intake that does not differ in terms of the affective meaning of the words. Associative processes following encoding (i.e. imagery) do reflect differences in emotional arousal that are not decelerative, but accelerative, in direction (Vrana et al., 1986).

Imagery. Lacey originally proposed that heart rate acceleration indicated “sensory rejection,” and was an index of internal processing on the basis of data indicating clear accelerative responses during tasks involving mentation, such as silent arithmetic calculations. Consistent with these findings, the general heart rate response during mental imagery is an acceleratory response that is often enhanced by affective features of the imagined stimulus, with a number of studies finding greater heart rate increases during text-prompted fearful, compared to neutral imagery (Bauer & Craighead, 1979; Cook et al., 1988; Grayson, 1982; Grossberg & Wilson, 1968; Haney & Euse, 1976; Lang et al., 1983; May, 1977b; Van Egeren, Feather, & Hein, 1971).

Heart rate similarly accelerates when imagining pleasant, compared to neutral, scenes (Vrana & Rollock, 2002), and the increase is even more pronounced when participants imagine emotional scenes based on their actual life experiences (Miller, Patrick, & Levenston, 2002). In general, heart rate acceleration during imagery varies most consistently with stimulus arousal – increasing for emotionally arousing (either pleasant or unpleasant) images (Cook et al., 1991; van Oyen Witvliet & Vrana, 1995; Fiorito & Simons, 1994), and these effects are more pronounced when the imagined scenes are personally relevant (Miller, Patrick, & Levenston, 2002).

In an effort to separate cardiac concomitants of mental imagery from heart rate variance associated with simply processing text, Schwartz (1971) developed a paradigm in which subjects first memorized emotionally arousing texts, then imagined the events described by these texts in a fixed sequence. Simply imagining arousing stimuli (i.e., without prior processing of the text prompt) resulted in greater heart rate acceleration than when imagining a neutral sequence (e.g., the letters ABCD). May and Johnson (1973) required subjects to memorize neutral or arousing words, and Vrana, Cuthbert, and Lang (1986) had subjects memorize sentences describing neutral and unpleasant events and then used tones to cue imagery. In all cases, heart rate acceleration was increased when imagining emotional, compared to neutral, events. A second study by May (1977b) found that actively imagining a fear-

ful sentence produced more heart rate acceleration than either hearing the sentence, or seeing a slide depicting the same material as the sentence.

Lang (1987) has interpreted heart rate acceleration during emotional imagery as indicating that in imagery, as in an actual situation, heart rate changes reflect activation of information associated with appropriate actions. Consistent with this, Jones and Johnson (1978, 1980) obtained faster heart rate during imagery of high activity sentences (e.g., “I feel happy, and I’m jumping for joy.”) than imagery of low activity relaxing sentences (e.g., “I feel happy, and I just want to relax.”), and Miller et al. (1987) demonstrated that, like imagery of fear or anger scenes, imagery of active (neutral) scenes produced greater heart rate acceleration and electrodermal reactivity than neutral scenes involving low activity.

Taken together, the heart rate patterns obtained during picture perception and imagination are consistent with Lacey’s (1967) early observation that deceleration is associated with sensory intake (perception), whereas acceleration is associated with mentation. On the other hand, Lacey’s interpretation of heart rate acceleration during imagery as reflecting sensory rejection, has been refined: Rather than focusing on sensory processing (e.g., rejection of perceptual information), a number of theories (see Cuthbert, Vrana, & Bradley, 1991, for a review) hypothesize that cardiac acceleration during imagery reflects action engagement prompted by the imagery scene.

According to Lang’s (1979) bioinformational theory of emotional imagery, affective events are represented in memory by an associative network that includes coded sensory, conceptual, and action information. Stimulus units in the associative network code information regarding specific sensory and perceptual features of the event (e.g., visual, acoustic, and tactile features of a snake and the current context), whereas meaning units code conceptual information previously learned about the stimulus (i.e., snakes are dangerous). An important feature of bio-informational theory are units that code appropriate actions in the representation of emotional events. Although many cognitive models primarily focus on stimulus and semantic information, bio-informational theory emphasizes the importance of action units, which code associated behaviors (e.g., running) and relevant autonomic support (e.g., heart rate acceleration) that are part of the associative structure of an emotional event. During mental imagery, activation of relevant action units in affective networks prompts heightened physiological engagement during emotional, compared to neutral, events, because emotion is, inherently, a disposition to act.

Electrodermal reactivity and emotion

Whereas the heart is dually innervated, and subject to modulation by either parasympathetic or sympathetic activity (or both), the electrodermal system is innervated solely by the sympathetic system, although the mechanism of its

action is cholinergic, rather than adrenergic. In a variety of induction contexts, electrodermal reactivity consistently varies with emotional intensity, with larger responses elicited in either unpleasant and pleasant contexts and that are most pronounced in those that rated highly arousing.

During picture perception, for example, many studies have found increased skin conductance when people view pictures rated as emotional, compared to neutral, regardless of whether they are rated pleasant or unpleasant in hedonic valence (e.g., Lang et al., 1993; Winton, Putnam, & Krause, 1984; see Figure 25.3, top middle). Moreover, electrodermal reactions increase with increases in defensive or appetitive activation, with the most arousing pleasant and unpleasant contents (e.g., erotica, threat, and mutilation) prompting the largest responses (Bradley et al., 2001a). Similarly, when listening to affective sounds (Bradley & Lang, 2000; Verona et al., 2004) or music (Gomez & Danuser, 2004), skin conductance activity increases as the acoustic stimuli are rated higher in emotional arousal, regardless of hedonic valence (see Figure 25.3, bottom middle). Demonstrating consistent modulation by affective intensity across perceptual contexts, elevated electrodermal reactions are also clearly found when people view film clips that are either unpleasant (Kunzmann, Kupperbusch, & Levenson, 2005; Palomba et al., 2000) or pleasant (Christie & Friedman, 2004). When hedonic valence and emotional arousal of film stimuli were co-varied, skin conductance responses were largest for highly arousing films, irrespective of hedonic valence (Gomez et al., 2004), consistent with the notion that these reactions primarily reflect differences in emotional arousal, rather than hedonic valence.

Whereas the cardiac patterns seen in perception and imagery are quite different, skin conductance responses during imagery often show the same modulation by emotional arousal as perceptual contexts. For instance, Miller, Patrick, and Levenston (2002) found increased skin conductance responses when people imagined pleasant or unpleasant, compared to neutral, events, and these responses were accentuated when personally relevant scenes were imagined. Similarly, as Figure 25.4 (left panel) illustrates, anticipating the presentation of a threatening stimulus (e.g., shock; Bradley, Moulder, & Lang, 2005) or a pleasant stimulus (e.g., a picture of erotica; Sabatinelli, Bradley, & Lang, 2001) also prompts large skin conductance changes that reflect increased arousal during anticipation.

Taken together, rather than simply responding to aversive stimulation, the sympathetic nervous system, as indexed by the electrodermal reaction, is also engaged by appetitive activation, and, moreover, appears to be similarly activated in perception, imagery, and anticipation contexts. One interpretation is that this physiological measure reflects the primary nature of emotions as action dispositions that are mediated by sympathetic activity preparing the organism for fight, flight, and other appropriate appetitive and defensive behaviors. Regardless of whether

the affect cue involves perceptual, imaginal, or anticipatory processing, those that activate the fundamental appetitive or defensive motivation systems engage measurable sympathetic activity, as measured by the palmar skin conductance response. Thus, whereas the cardiac response differs in emotional perception and emotional imagery, presumably reflecting differences in sensory intake in the different induction contexts, the electrodermal response in both perception and imagination indexes the preparation for action that is the hallmark of both motivation and emotion.

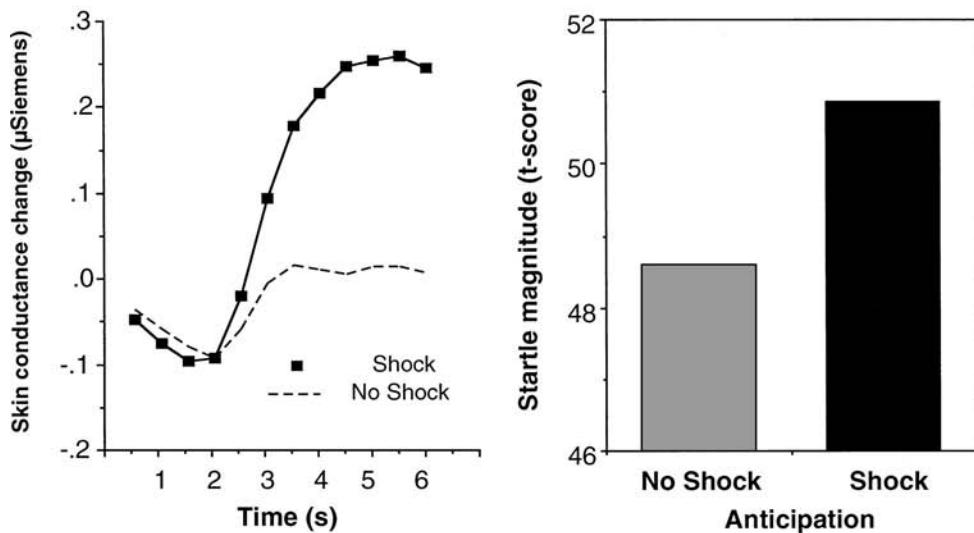

Facial EMG and emotion

Facial expressions of emotion, such as frowns, grimaces, smiles, and so on are often the most overt signs of emotional engagement, and are mediated by muscles that are attached to the skin of the face, all of which are innervated by the facial nerve (cranial nerve VII) via the facial motor nucleus located in the pons. The facial motor nucleus is organized into subdivisions (medial, lateral, dorsal, intermediate) that contain the motor neurons controlling different facial muscles, with the upper half of the nucleus containing neurons that generally control the lower part of the face, and neurons in the lower half innervating the upper facial muscles. Different branches of the facial nerve (temporal, zygomatic, buccal, cervical, and marginal mandibular) innervate different facial muscles, with combinations of activity in different muscles related to various facial expressions that are common in emotion.

In the Facial Action Coding System (FACS; Ekman & Friesen, 1986; Ekman, Friesen, & Hager, 2002), "action units" that correspond to observable activity in specific muscles and facial regions can be scored by an observer. In a recent study, Kohler et al. (2004) used FACS to code expressions in a set of 128 photographs that included posed and evoked faces displaying happy, sad, fearful, and angry expressions. Their primary goals were to identify the characteristic action units present in different expressions and to determine whether unique action units are related to correct recognition performance (in a sample of naive participants). For happy expressions, an action unit associated with a lip corner pull was present in all expressions, and appeared to be critical in both defining and recognizing a smile. On the other hand, expressions of sadness elicited characteristic features (e.g., furrowed eyebrows, opened mouth with raised upper lip) but no clear unique features, seeming instead to rely on a combination of features for successful recognition.

Identification of more subtle changes in facial muscle activity can be achieved by monitoring electromyographic (EMG) activity using electrodes placed over appropriate facial muscles. In fact, appropriate facial EMG activity accompanies changes in appetitive and defensive activation in a number of different induction contexts (e.g., Fridlund, Schwartz, & Fowler, 1984; Tassinary, Cacioppo, & Geen, 1989). Most commonly, measurement of activity

Anticipating Shock

Anticipating Erotica

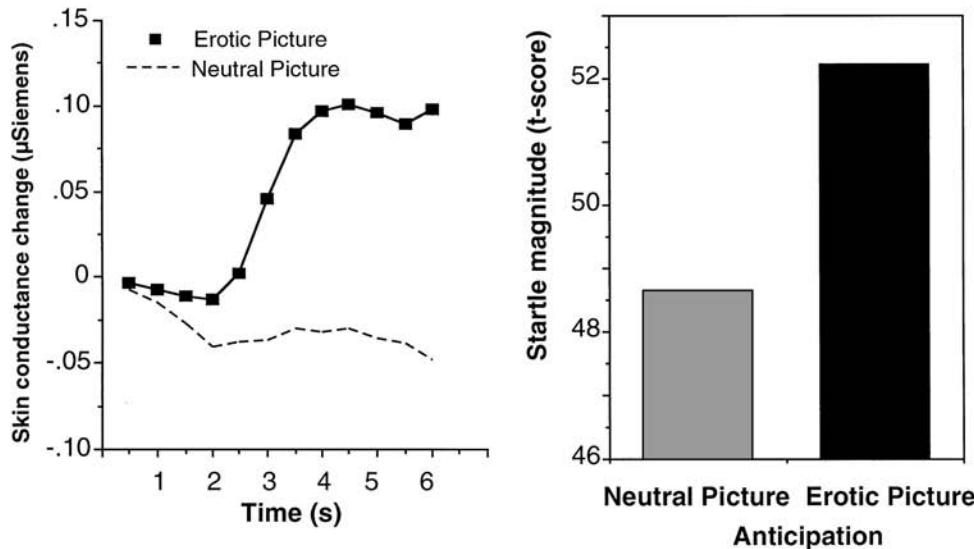

Figure 25.4. Electrodermal and startle reflex magnitude when anticipating an electric shock or anticipating the presentation of an erotic picture show similar modulation. Based on data reported by Bradley et al. (2005) and Sabatinelli et al. (2001).

over the muscles associated with frowning and smiling have been used as indices of affective engagement in perception, imagery, and anticipation.

The corrugator supercilii muscles, located above and between the eyes, are responsible for lowering and contraction of the brows. This facial action is held to be an index of distress (see Ekman, Levenson, & Freisen, 1983; Fridlund & Izard, 1983, for a review) and firing of motor units in this muscle region is obtained if a stimulus is judged to be unpleasant (even if the degree of unit activity is insufficient to produce visible

brow movement). Significant contraction of the corrugator muscle occurs when viewing pictures that are rated as unpleasant, compared to neutral pictures (Cacioppo et al., 1986; Lang et al., 1993), and shows similar modulation when people listen to unpleasant, compared to neutral, sounds, as Figure 25.3 (left panel) illustrates. Moreover, activity measured over this muscle often shows relaxation below baseline activity for materials rated high in pleasure.

Larsen, Norris, and Cacioppo (2003) measured facial EMG activity in a variety of different perceptual contexts,

including viewing affective pictures, listening to affective sounds, and reading affective words. In all contexts, a highly significant linear relationship was found relating corrugator supercilii EMG activity to hedonic valence, with greater corrugator supercilii activity elicited when viewing the most unpleasant stimuli. Moreover, the most highly pleasant materials prompted significant inhibition, consistent with the hypothesis that appetitive and defensive activation show reciprocal effects on this facial muscle.

When exploring specific picture contents, Bradley et al. (2001a) found that all unpleasant picture contents prompted significant increases (over neutral) in corrugator EMG activity, with pictures of mutilations and contamination (i.e., disgust) prompting slightly larger changes than other unpleasant stimuli. Although women responded with greater overall facial EMG activity than men, all participants showed significant increases in corrugator EMG reactivity when viewing unpleasant pictures (Bradley et al., 2001b), indicating that both men and women facially respond to aversive stimuli. The least corrugator EMG activity was obtained for pleasant pictures depicting babies and families, which are rated quite high in pleasure, but relatively low in arousal.

Activity measured over the *zygomaticus major* muscle occurs when the cheek is drawn back or tightened (Tassinary, Cacioppo, & Geen, 1989), and this muscle is involved in facial expressions of smiling. Because emotional expressions such as smiling have communicative function in human culture and can be initiated for instrumental effect, their connection to a reflexive psychophysiology of emotion cannot be automatically assumed. That is, a person may choose to look "happy," engaging in deceptive behavior to achieve some goal, in much the same way that individuals may, for similar reasons of social use, say that they are "happy"(or angry) in the absence of any confirming physiology. Ekman, Davidson, and Friesen (1980) have considered this issue, and noted an interesting observational difference between true and false smiles. Whereas an authentic "Duchenne" smile includes both action of the *zygomaticus major* and *orbicularis oculi* muscles, false "social" smiles involve only the *zygomaticus major* muscle.

Consistent with the hypothesis that facial EMG activity in picture perception reflects an authentic emotional reaction, Cacioppo et al. (1986) found co-activation of the *zygomaticus major* and *orbicularis oculi* muscles when participants viewed pleasant, compared to neutral, pictures. When specific picture contents were assessed (Bradley et al., 2001a), co-activation in these facial muscles was again apparent, and was most pronounced for pictures judged to be high in pleasure, but not highly arousing, including pictures of babies, families, and food. Facial EMG activity consistent with smiling at babies and families was only apparent for women (Bradley et al., 2001b), however, and neither men nor women showed any evidence that pictures of highly arousing erotica evoked facial expressions related to smiling.

Unpleasant materials that are highly arousing also prompt slight increases in activity measured over the *zygomaticus major* muscle. Lang et al. (1993) noted a significant quadratic trend for this zygomatic muscle in which highly unpleasant pictures prompted significant activity (although less than for highly pleasant stimuli). Larsen, Norris, and Cacioppo (2003) replicated this finding, and further found that this pattern was more representative of reactions to pictures and sounds; simply reading unpleasant words did not engage strong activity over this facial muscle. When exploring specific picture contents, Bradley et al. (2001a) found that increased zygomatic activity during unpleasant picture viewing tended to co-occur with significant changes in both the corrugator supercilii and the *orbicularis oculi* muscles. Co-activation in these three muscles was associated with a pattern of facial activity that was most pronounced for pictures rated as disgusting, including mutilated bodies and contamination (e.g., spoiled food, etc.) scenes. Thus, this muscle also appears to be active in a facial expression of disgust that involves both lowering of the brow and tightening of the cheek and eyes.

Studies investigating facial EMG activity during mental imagery have also consistently found that activity measured over the corrugator supercilii and *zygomaticus major* muscle regions index the hedonic valence of the imagined stimulus (e.g., van Oyen Witvliet & Vrana, 1995; Fiorito and Simons, 1994; Fridlund, Schwartz, & Fowler, 1984). Schwartz and his colleagues (e.g., Schwartz, Ahern, & Brown, 1979; Schwartz, Brown, & Ahern, 1980) conducted a series of studies which indicated that corrugator and zygomatic EMG activity primarily differentiated between imagery of negative (e.g., fear, sadness, anger) and positive (e.g., happy) emotions, whereas EMG activity over the masseter and lateral frontalis muscle regions did not differ. Importantly, Schwartz, Brown, and Ahern (1980) also found that women were more reactive than men, consistent with the sex differences obtained in picture perception.

Summarizing the imagery work, Cacioppo et al. (1993) conclude that covert measures of facial EMG activity in imagery may reflect "...a rudimentary bivalent evaluative disposition or *motivational tendency* rather than discrete emotions" (p. 136). Facial expressions of disgust may be an exception, however. In a recent study in our laboratory, imagining unpleasant events was, as usual, associated with increased corrugator EMG activity for scenes that people label as evoking fear, anger, and disgust. On the other hand, similar to picture perception, scenes involving disgust uniquely involved co-activation of corrugator supercilii and *orbicularis oculi* EMG activity, consistent with the idea that EMG activity reliably discriminates facial expressions of disgust in both perception and imagery.

Startle reflex modulation

In most mammals, an abrupt sensory event will prompt a startle response, a chained series of rapid extensor-flexor movements that cascade throughout the body (Landis &

Hunt, 1939). This reaction is a defensive reflex, facilitating escape in simpler organisms, and perhaps still serving a protective function in more complex animals (i.e., avoiding organ injury as in the eyeblink, or in retraction of the head to avoid attack from above, Yeomans, Steidl, & Li, 2000). When under threat (of pain or predation) animals show an exaggerated startle reflex. As first described by Brown, Kalish, and Farber (1951), the amplitude of the acoustically elicited startle reflex in rats is increased when elicited in the presence of a light previously paired with footshock. Humans similarly show larger startle blink reflexes when processing cues previously paired with exposure to aversive shock (Hamm et al., 1993).

Davis (1989; Davis, Hitchcock, & Rosen, 1987) and others (e.g., Koch & Schnitzler, 1997) have systematically investigated the neural circuitry underlying potentiation of the startle response during aversive learning in animals. When stimulated by an abrupt noise, the afferent path of the reflex proceeds from the cochlear nucleus to the pontine reticular formation; from there efferent connections pass through spinal neurons to the reflex effectors. This is the basic obligatory circuit, driven by the parameters of the input stimulus (e.g., stimulus intensity, frequency, steepness of the onset ramp). A secondary circuit, intersecting this primary reflex pathway, determines startle potentiation after fear conditioning. There is now overwhelming evidence that the amygdala is the critical structure mediating this effect: First, there are direct projections from the central nucleus of the amygdala to the reticular site which mediates potentiation (i.e., nucleus reticularis pontis caudalis); second, electrical stimulation of the amygdala's central nucleus enhances startle reflex amplitude; finally, and most important, lesions of the amygdala abolish fear conditioned startle potentiation (Davis, 1989).

In studies with human beings, rapid eye closure is one of the most reliable components of the behavioral sequence that constitutes the startle response, and the associated blink reflex can be measured electromyographically by placing sensors over the orbicularis oculi muscle beneath the eye (see Figure 25.5). When startle probes are administered in the context of picture perception, blink responses are reliably potentiated when viewing unpleasant pictures, and inhibited when viewing pleasant pictures, compared to neutral picture processing (see Figure 25.5; Vrana, Spence, & Lang, 1988; see Bradley, Cuthbert, & Lang, 1999 for an overview). These effects have proven highly replicable in the picture perception context (e.g., Bradley et al., 2001a; Buchanan, Tranel, & Adolphs, 2004; Cook et al., 1992; Dichter et al., 2004; Hamm et al., 1997; Vanman et al., 1996). Startle potentiation is largest for unpleasant pictures that are rated highly arousing (e.g., threat and mutilation), while the most arousing pleasant pictures evidence the largest startle inhibition (e.g., erotica and romance; Bradley et al., 2001a; Schupp et al., 2004).

The startle reflex is modulated by affective valence during picture viewing regardless of whether the startle probe

is visual, acoustic, or tactile (e.g., Bradley, Cuthbert, & Lang, 1991; Hawk & Cook, 1997), indicating that modality-specific processes are not central in these modulatory effects. Affective modulation of startle is also not confined to static visual percepts: The startle reflex is modulated by affective valence when dynamic visual stimuli (i.e., affective films) are presented (Jansen and Frijda, 1994; Koukounas & McCabe, 2001), or when the sensory modality involves odors (Erlichman et al., 1995). Furthermore, when the emotional stimuli consist of short, 6 s sound clips of various affective events (e.g., sounds of love-making; babies crying; bombs bursting), and the startle probe is a visual light flash, the same pattern of affective modulation is obtained, suggesting that its mediation in perception is broadly motivational and thus consistent across affective foregrounds of different stimulus modalities (Bradley & Lang, 1998).

In the picture viewing context, a search for differences in startle potentiation when viewing different categories of unpleasant pictures have produced mixed results. Balaban and Taussig (1994) first found evidence for greater reflex potentiation when viewing pictures depicting fearful scenes than other unpleasant contents, and more recently Stanley and Knight (2004) reported greater potentiation when viewing threat, compared to mutilation, pictures. On the other hand, Yartz and Hawk (2002) found that startle reflexes elicited when viewing disgusting pictures that either involved blood or other disgusting contents (e.g., bugs, toilets, etc.) showed potentiation similar to that elicited when viewing pictures of threat. Bradley et al. (2001a), in a similar design, also found equivalent potentiation for threatening scenes involving animals (presumably eliciting fear) and disgusting contents (e.g., mutilations or others), although fearful pictures of human attack (particularly toward the viewer) prompted slightly (and significantly) larger reflexes than pictures of mutilated humans. Taken together, although there is some evidence of slightly larger reflex potentiation when viewing scenes involving threat or imminent danger (fear?), the effect is somewhat variable, possibly reflecting differences in material or participant samples.

The defense cascade in picture perception. Like normal subjects, specific phobics show potentiated startles when viewing unpleasant pictures. However, startle reflexes are even more enhanced when these subjects view pictures of the objects they fear (Hamm et al., 1997). On the other hand, the typical bradycardia obtained during unpleasant picture viewing does not characterize the response of phobic subjects to pictures of objects they fear (e.g., Hamm et al., 1997; Klorman, Weissbert, & Wissenfeld, 1977): rather, when high fear subjects view pictures of the phobic object, the heart accelerates. Also unlike non-phobic subjects, they quickly terminate "looking" in a free-viewing situation. Thus, whereas reflex potentiation to aversive materials characterizes responses for highly arousing unpleasant pictures for both normal and phobic subjects, cardiac and other behavioral measures of attentive

Startle Reflex & Emotional Perception

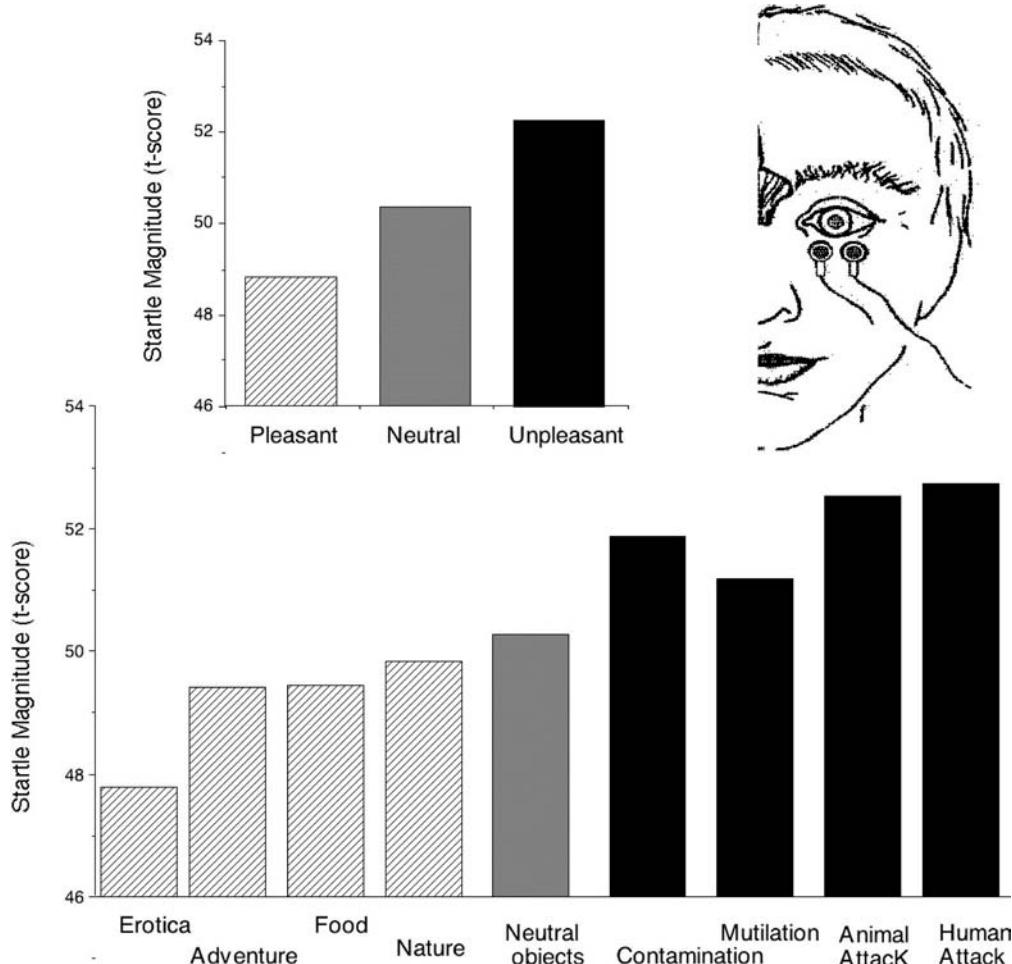

Figure 25.5. During picture perception, the startle blink reflex is modulated by hedonic valence, with potentiation during unpleasant picture viewing, and attenuation during appetitive picture viewing. Startle reflex modulation is greatest for pictures that are rated as highly arousing, including erotica, threat, and mutilation. Based on data from Bradley et al. (2001a).

orienting are absent when phobics process very highly fearful content.

These data suggest that, instead of a single response indicating activation of the defensive motivation system, one observes instead a cascade of physiological responses, changing in different ways as activation increases. The idea that defense involves stages of responding has been advocated by a number of theorists, including Tinbergen (1969), Blanchard and Blanchard (1989), and Fanselow (1994). Based on data obtained during picture perception, we have proposed a similar cascade of changing defensive reflexes, determined by increasing metabolic and neuromuscular mobilization that is paralleled by greater judged emotional arousal. Figure 25.6 illustrates the defense cascade model in picture perception.

Stimuli that moderately activate the defensive system prompt a pattern of responding that is suggestive of oriented attention, in which measurable conductance

changes are obtained, the heart decelerates under vagal control, and startle reflexes are not potentiated. In fact, at lower levels of rated arousal, the startle reflex is inhibited when viewing unpleasant, compared to neutral, pictures (Bradley et al., 2001a; Cuthbert, Bradley, & Lang, 1996). Thus, at this first stage of defensive activation, heightened attention and orienting are apparent, signaled by cardiac deceleration and dampened startle reflexes, both of which are consistent with the hypothesis of greater sensory intake and resource allocation to a meaningful foreground. (As Lacey [1958] recognized, unpleasant events are not automatically “rejected,” but instead evoke a physiology consistent with sustained attention.) This reflex pattern changes dramatically, however, when danger becomes more imminent, with mobilization and active defense reflexes occurring later in the sequence. Evidence of a change in defensive posture is first seen in the startle reflex: As the stimulus becomes more threatening/arousing

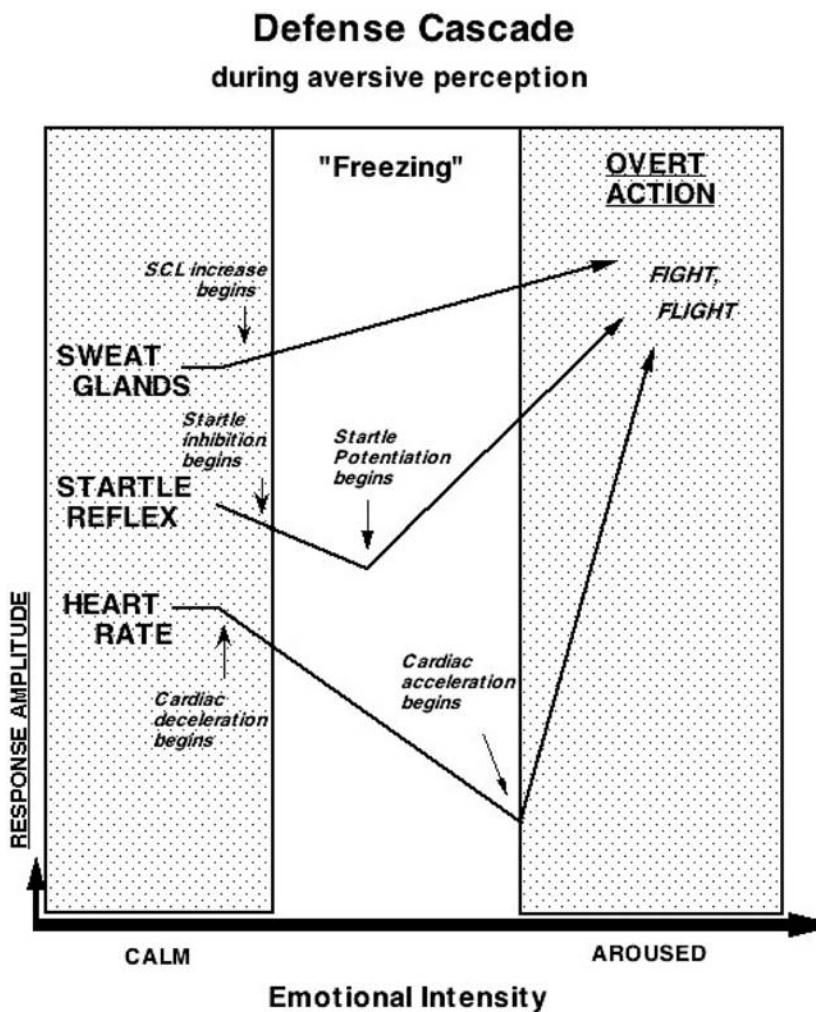

Figure 25.6. Stages of defensive responding are depicted, in which different physiological systems change at different rates, based on the intensity of activation in defensive motivation (see Lang, Bradley, & Cuthbert, 1997).

(a negative outcome is more imminent), startle amplitude increases and the reflex is potentiated rather than inhibited. As defensive activation increases, just prior to action, the heart rate response is also modulated: Vagal release is followed by a sympathetically driven acceleration that is the classic cardiac defense response. Thus, when processing pictures of their feared objects, phobic subjects do not show the initial decelerative stage of defense, but instead show an immediate cardiac acceleration, accompanied by dramatically large startle reflex potentiation. In effect, phobics are more aroused by these stimuli, and thus further along in the ‘defense cascade’ than normal subjects processing standard unpleasant pictures.

Reflex modulation in anticipation. The defense cascade model describes defensive reactions that occur specifically concurrent with *perception* of external stimuli, i.e., when sensory stimuli are processed that vary symbolically in degree of threat (probability of harm), and thus weakly or strongly activate the defense motivational system. In the

picture-viewing context, of course, pleasant stimuli (varying in arousal) do not prompt a similar change in startle probe modulation. Rather, there is a progressive augmentation of the cardiac decelerative/inhibitory startle attentive set that is maximal at the highest levels of picture arousal (most dramatically, for pleasant erotic images). Interestingly, however, and highlighting the importance of understanding the local effects of the emotion inducing context, these two physiological measures (heart rate and startle blink reflexes) show parallel responses to pleasant and unpleasant stimuli in the context of *anticipation* and *imagery*.

For instance, when men reporting high fear of snakes anticipated (during a 6 s interval) presentation of an erotic, snake or neutral picture, startle reflexes were significantly and similarly potentiated during anticipation of either type of arousing content – snakes or erotica – compared to neutral household objects (Sabatinelli, Bradley, & Lang, 2001). The same pattern of reflex potentiation was found when non-fearful participants anticipated viewing a selection of pleasant or unpleasant images, relative to anticipation of neutral pictures (Nitschke et al., 2002). Furthermore, numerous studies have demonstrated that the startle reflex is reliably enhanced during an interval when participants anticipate the possibility of

receiving electric shock, compared to a “safe” period (e.g., Grillon et al., 1991; Bradley, Moulder, & Lang, 2005). Recently, reflex potentiation was consistently observed in our laboratory during an interval in which participants anticipated the possibility of winning a substantial sum of money. Similarly, Skolnick and Davidson (2002) found reliable reflex potentiation when participants anticipated winning in a gambling game, as well during a period in which they anticipated the presentation of aversive noise.

Reflex modulation in imagery. Several studies (Witvliet & Vrana, 1995; Robinson & Vrana, 2000) have examined startle modulation during text-driven imagery, varying both the hedonic valence (pleasant, unpleasant) and judged arousal (low, high) of the imagery scripts. Although startle blinks were consistently larger when imagining unpleasant, compared to pleasant scenes; nevertheless, reflexes elicited when imaging pleasant, arousing scenes were potentiated relative to pleasant scenes rated lower in arousal. Bradley, Cuthbert, and Lang (1995) obtained similar results: Compared to imagining neutral scenes, the

startle reflex was significantly potentiated when imagining either unpleasant or pleasant events.

In a series of imagery studies conducted in our laboratory, the pattern of startle modulation that we obtained replicated Vrana and colleagues, with low arousal scenes again prompting significantly smaller blink reflexes than high arousal scenes during both pleasant and unpleasant imagery. No differences were found among unpleasant scenes rated as highly arousing (regardless of different emotion reports of eliciting fear, anger, or disgust). However, when the participants imagined pleasant, highly arousing scenes (e.g., winning the lottery), startle reflex magnitude was substantially greater than for less arousing pleasant contents, and equivalent to blinks elicited when imagining highly arousing unpleasant scenes. Miller et al. (2000) also found that blinks elicited during pleasant (arousing) imagery were equivalent to those elicited during unpleasant (arousing) imagery, noting this particularly for imagined scenes that were personally relevant.

Thus, different from the modulatory pattern found during *perception* and attentive intake (i.e., the reflex inhibition seen during picture perception), reflex modulation during mental *imagery* is more similar to that observed in *anticipation*, that is, the startle reflex is potentiated when imagining highly arousing events, regardless of their affective valence. Overall, the startle data suggest that reflex inhibition – both during appetitive perception and early defensive vigilance – accompanies sensory processing and heightened attention to external stimulation, with a resulting inhibition of reactions to other sensory input (as is also found for non-startling reaction time probes, Bradley, Cuthbert, & Lang, 1996). However, when the perceptual stimulus is sufficiently arousing (proximal, threatening, imminently aversive), active defense mobilization ensues, priming related defensive reflexes, such as the startle blink.

During the anticipation of a future event (or during mental imagery), however, there is generally no concurrent sensory intake that competes with startle probe processing. Moreover, during mental imagery, the dominant cardiac pattern is accelerative, rather than decelerative, consistent with the hypothesis that preparation for action, rather than sensory intake, characterizes imaginal processing. It is also instructive to consider the heart rate response that can occur in an anticipatory context: Chase, Graham, and Graham (1968) noted that if the anticipated event requires vigorous motor action, the anticipatory cardiac response is a marked acceleration. Assuming that affective anticipation involves active preparation, potentiation of both autonomic (heart rate acceleration) and somatic motor responses (startle reflex potentiation) might be an expected consequence. When comparing the responses of fearful subjects in anticipation and mental imagery, Lang et al. (1983) noted that, for snake phobics, increases in both skin conductance and heart rate were found both when imagining scenes involving snakes and when anticipating an actual confrontation with an alive snake. One is tempted to conclude that similar cognitive processes, and a physiology primed for action, may characterize both anticipation and

imagination of emotional events, prompting similar modulation by emotion for cardiac, electrodermal, and startle responses.

THE NEUROANATOMY OF EMOTION

Understanding the neural circuits mediating the psychophysiology of emotion will depend to some degree on determining which brain structures are important in controlling the peripheral autonomic and somatic responses that together define emotion. Not surprisingly, control systems occur at every level of the central nervous system: from the spinal cord to the brain stem to sub-cortical and cortical structures (for a more extensive discussion, see LeDoux, 1987; Gellhorn & Loofbourrow, 1963; Guyton & Hall, 1996). Thus, for instance, mechanisms in the spinal cord can affect the level of activity in sympathetic and parasympathetic fibers in the absence of supraspinal controls. Among the more important *brain stem* control structures is the medulla oblongata: Electrical stimulation of the rostral portion of this structure evokes sympathetic reactions throughout the body, including heart rate and blood pressure increases, dilation of pupil, inhibition of gastro-intestinal activity, secretion of sweat, etc. Conversely, activation of the vagal nucleus of the medulla oblongata causes a decrease in heart rate and blood pressure and an increase in gastrointestinal activity – reactions associated with parasympathetic activity. Because of its ability to control many elements of autonomic function, the medulla oblongata has been proposed as the final common pathway for autonomic responses associated with defense reactions (LeDoux, 1987).

Cannon originally advocated that key structures in the brain, particularly the hypothalamus and thalamus, were important in controlling peripheral emotional reactions, which was supported by a number of animal studies demonstrating that electrical stimulation of the hypothalamus produced physiological reactions associated with sympathetic activation, and even full motor sequences indicative of emotion, including freezing, piloerection, hissing, and attack (collectively termed the *defense reaction*, Hess & Burgger, 1943), as well as grooming, mating, and feeding/drinking. Lesions of the hypothalamus (Bard, 1934) effectively eliminated these reactions. Despite proposing a much more extensive neural circuit, Papez (1937) also focused on the hypothalamus as a central structure in mediating emotion, particularly bodily responses. Although Papez's circuit is generally considered incomplete today, mainly because it neglects to include structures currently thought important in emotion (e.g., amygdala) and includes structures that are now recognized as more important for memory (e.g., hippocampus; LeDoux, 1987) certain key structures in Papez' circuit, such as the thalamus and cingulate cortex have been implicated in recent neuroimaging explorations of emotional processing (e.g., Breiter et al., 1997; George et al., 1995; Lane, Reiman, Ahern et al., 1997; Lane, Reiman, Bradley et al., 1997).

Prior to the advent of neuroimaging techniques, information regarding the neural circuits mediating emotional experience and expression relied on data from animal studies and patients suffering different types of brain damage. New technologies for measuring brain activity during emotional processing (including PET, fMRI) now allow an investigation of cortical and subcortical activity during emotional processing in awake alert human participants. The explosion in neuroimaging studies over the past 10 years has produced a burgeoning data base in which new studies are added at an exponential rate, many of these focused on emotion and affect. Making sense of this large data base will rely, again, on careful attention to the specific context of emotional induction in the scanner.

For instance, in a recent meta-analysis of brain activation during emotional processing, data from over 100 PET and fMRI studies were aggregated across a number of different induction contexts (e.g., viewing facial expressions, listening to music, conditioned fear, anticipating pain, and so on (Murphy, Nimmo-Smith, & Lawrence, 2003). When the resulting activation clusters that reportedly varied with emotion were plotted in a 3-dimensional space defined by the Talairach-Tourneau coordinates, a figure eerily reminiscent of the entire brain emerges. Assuming that different perceptual, anticipatory, imaginal, and action contexts prompt activity in divergent and overlapping neural circuits, it may be difficult to understand the neural circuitry of emotion in the absence of making comparisons that control the specific context of emotion induction.

In another meta-analysis (Phan et al., 2004), an effort to control the specific context of the emotional induction was made by comparing neural activation in visual perception, auditory perception, or imagery contexts as they varied with fear, sadness, anger, etc. Across all studies, no specific brain region was reliably activated, suggesting that emotion is not mediated by a specific neural structure. The region most likely to be active across different induction contexts was the prefrontal cortex (medial), a structure highlighted as central in emotion by Davidson (2003), whose work on hemispheric asymmetry indicates tonic differences in resting EEG in frontal regions as a function of affect and temperament (Davidson, 2002).

Regions implicated as active in different affective induction contexts included a greater probability of anterior cingulate and insula activation during emotional imagery, with affective visual perception more likely to additionally include greater activation of occipital cortex and the amygdala. Animal and human patient studies had already noted the potential importance of the amygdala in emotional processing, based, to a large extent, on the same type of data originally invoked to support the hypothalamus as the center of the emotion system. Thus, both lesion and stimulation studies in animals indicate that specific nuclei in this structure mediate specific emotional phenomena, both appetitive and defensive (e.g., Amaral et al., 1992; Gaffen, 1992). Stimulation of the amygdala produces rage, attack and defense reactions similar to those earlier elicited by activation of the hypothalamus

and lesions of the amygdala eliminate the fear-potentiated startle response (Davis, 1986), and have been implicated in disrupting appetitive behaviors such as mating, food-getting, and reward learning (Gaffen, 1992).

The amygdala includes multiple afferent and efferent connections to cortical, subcortical, and brainstem structures that have been implicated in mediating the autonomic and somatic responses involved in emotional behaviors (see Davis & Lang, 2003). Inputs to the lateral nucleus of the amygdala include those from unimodal cortical sensory areas, including vision, audition and somatosensory (via the insula) information, as well as from polysensory association cortex. Olfactory input is relayed to the peri-amygdaloid nucleus (rather than lateral) and gustatory information may also be relayed to this nucleus via its thalamic input. Consistent with this, a number of neuroimaging studies have reported significant activation of the amygdala during perception of aversive visual, olfactory, auditory and gustatory stimuli (see Zald, 2003, for a review).

The outputs from the amygdala are extensive as well, and include almost all of the structures highlighted as important in emotional reactions, including direct connections to the hypothalamus, the central gray, the brain stem, the striatum, and cortical structures including the cingulate gyrus, frontal lobe, visual cortex, and more. The amygdala's central nucleus sends prominent projections to the lateral hypothalamus – a key center activating the sympathetic branch of the autonomic nervous system in emotion (LeDoux, 1987). In addition, direct projections from the lateral extended amygdala go to the dorsal motor nucleus of the vagus, the nucleus of the solitary tract, and the ventrolateral medulla. These brainstem nuclei are known to regulate heart rate and blood pressure (Schwaber et al., 1982), and may thus modulate cardiovascular responses in emotion.

Subcortical structures such as the amygdala and hypothalamus are clearly central in the expression of emotion, particularly in mediating the defensive and appetitive responses that even animal subjects clearly display when under threat or seeking sustenance. With increasing brain complexity, however, the neural circuitry of emotion increasingly includes activation in numerous cortical structures that can modulate subcortical activation, and vice versa. During picture perception, for instance, both unpleasant and pleasant pictures prompt significantly greater activation throughout the visual sensory regions, including middle occipital, inferior occipital, and fusiform cortex, as illustrated in Figure 25.7 (top left; see Lang et al., 1998; Bradley et al., 2003).

As noted by Amaral et al. (1992), the amygdala is extensively interconnected with the visual sensory system, in the primate with bidirectional connections that could promote both initial amygdaloid access as well as later perceptual modulation through its efferent connections. These projections could potentially “close the loop” with the visual system (Amaral et al., 1992), representing an amygdala feedback circuit that may be significant for the

fMRI activity during Affective Picture Perception

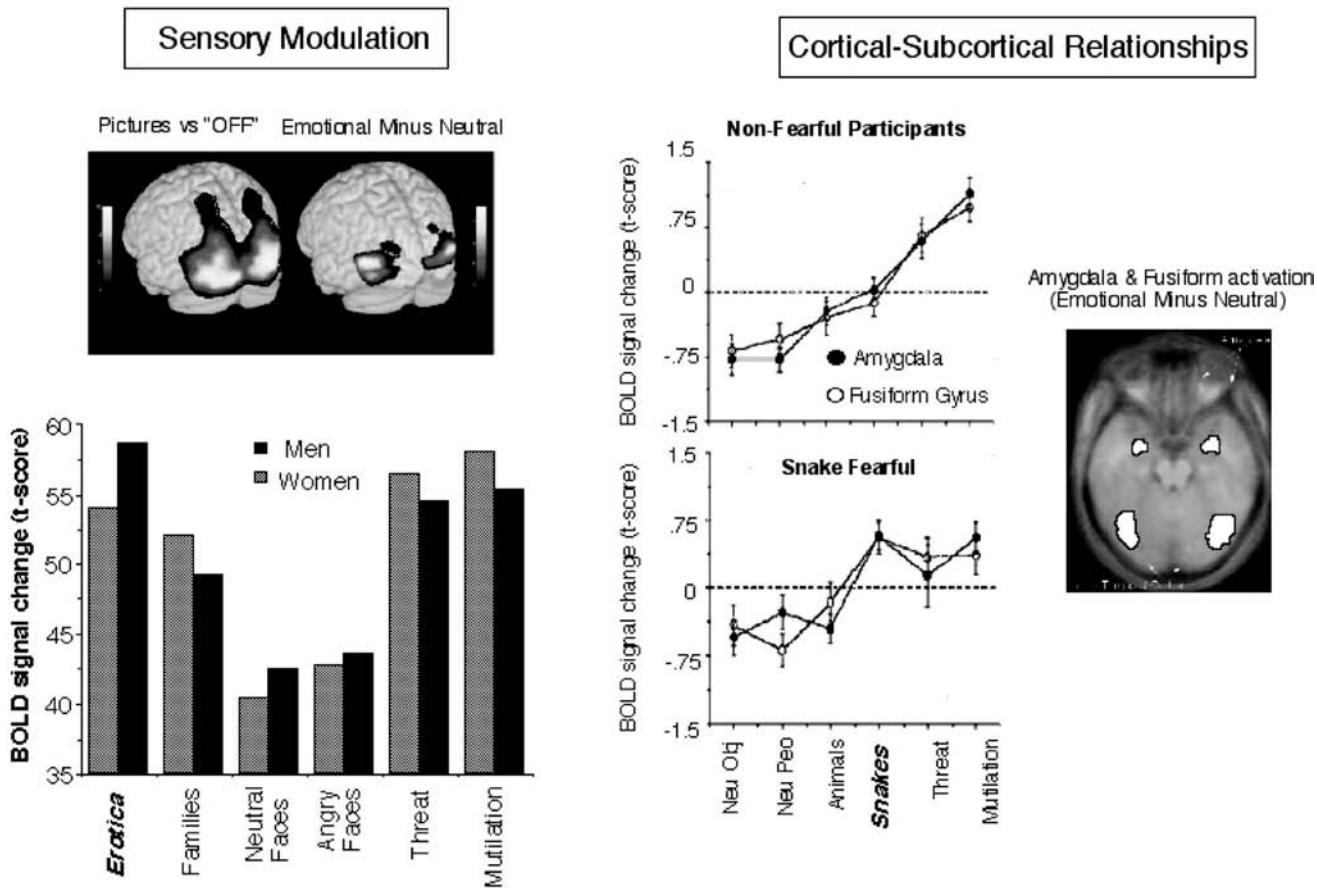

Figure 25.7. Neural activity measured during picture perception using functional magnetic resonance imaging shows greater activity in visual sensory cortex for emotional, compared to neutral, pictures, with men showing greater visual activation when viewing erotica than women. The co-variation in activation for sensory fusiform cortex and the amygdala is strikingly high, with snake phobics responding with greater activation in both structures when viewing snakes than non-fearful participants. Based on data from Sabatinelli et al. (2004, 2005).

sustained perceptual evaluation seen in the early stages of emotional processing. Consistent with this, as illustrated in Figure 25.7 (top right), activation in the amygdala consistently and significantly covaries with the magnitude of activation in the fusiform areas (Sabatinelli et al., 2005). Moreover, this effect is even more apparent when snake phobics view pictures of snakes: both the amygdala and the visual fusiform areas show significantly greater activation than for those reporting no fear of snakes (Figure 25.7). These data are consistent with previous PET studies showing greater activation in the occipital cortex when phobics view pictures of phobic objects (e.g., Fredrikson et al., 1993), and furthermore, indicate that increased activity in visual cortex is paralleled by heightened activation of the amygdala as well.

It is now also clear that not only aversive stimuli activate the amygdala: Numerous studies have found significantly elevated functional activity in this structure when people view highly arousing pleasant pictures (e.g., Lane, Chua, &

Dolan, 1999; Garavan et al., 2001; see Zald, 2003). In fact, the covariation between activity in the amygdala and in visual association areas such as the fusiform cortex when people view erotica is identical to that obtained for highly aversive stimuli (see Figure 7, bottom left; Sabatinelli et al., 2005). Hamann, Herman, Nolan, and Wallen (2004) recently reported larger increases in bilateral amygdala activation (and hypothalamus) when men viewed erotica, compared to women, in a study that included pictures of erotic couples, opposite sex erotica and non-erotic couples. Relatedly, men also show greater functional activity in visual cortical regions viewing erotica, compared to women (Sabatinelli et al., 2004; see Figure 25.7, bottom left). These data are consistent with evaluative and physiological data which find that men rate erotica as more arousing than do women, and also show heightened electrodermal reactions (Bradley et al., 2001b), suggesting that visual cues depicting erotica vary in the magnitude of appetitive activation in men and women. Moreover, taken together,

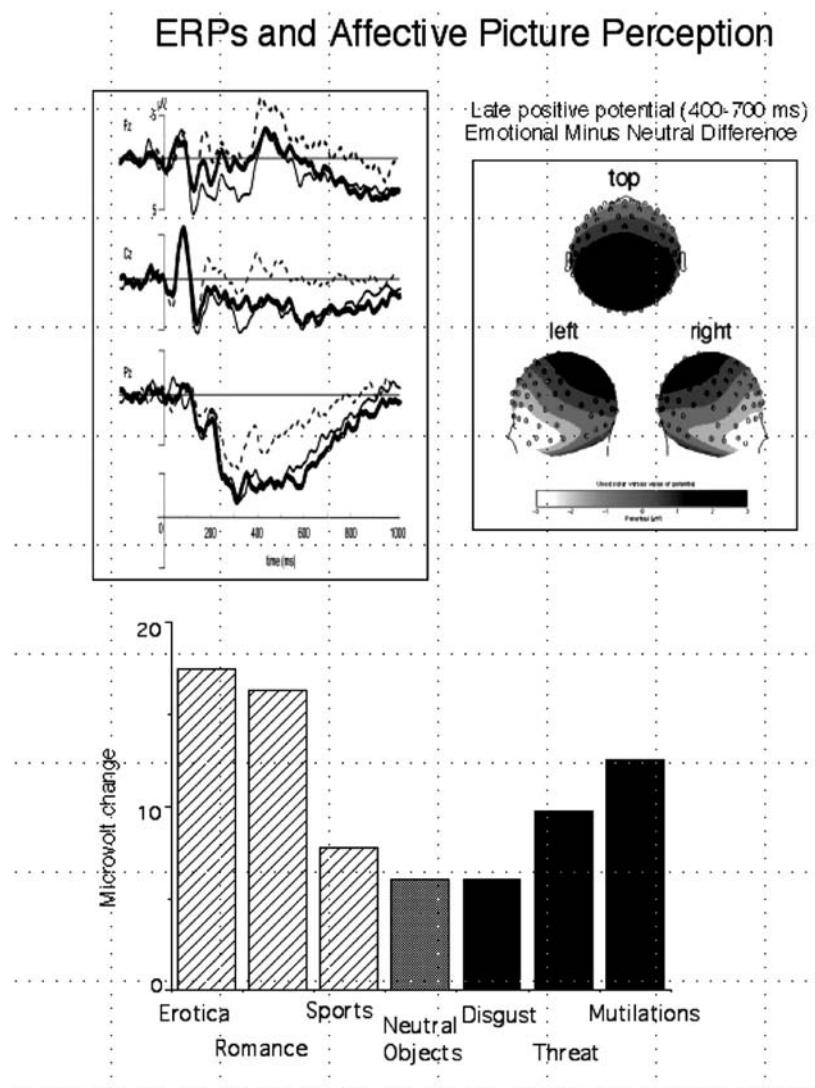

Figure 25.8. The late positive potential elicited 300–1000 ms after picture onset is larger when viewing emotional (pleasant or unpleasant), compared to neutral, pictures, and is maximal over centro-parietal sites (based on data from Keil et al., 2002). The magnitude of the late positive potential is largest for emotional pictures that are rated as highest in arousal (based on data from Schupp et al., 2005).

these data suggest a link between the magnitude of physiological reflexes, such as electrodermal reactivity, and the magnitude of cortical and subcortical activation such as the BOLD signal in the fusiform cortex and the amygdala.

In fact, as fMRI, PET and other imaging modalities are used to explore emotion in the brain, the classic psychophysiology of bodily reflexes has an increasingly important role to play. In order to confirm that regional changes in neural activity are in fact related to affect and motivation, we will need to measure the well-established reflex physiology of emotion by simultaneously recording these, if possible, or by measuring these affective reactions in the same participants and paradigm in a simulated imaging context. As emotion researchers well know, evaluative reports are only loosely related to emotion's physiology, varying greatly in their covariation with context as well as with the personality and temperament of the participants, and can not serve as the sole measure of emotional engagement in neuroimaging explorations. (see Figure 25.8). Rather, standard practice in neuroimaging studies should be to include a coincident sample of measures

that assess hedonic valence (e.g., facial EMG or cardiac response in perceptual contexts) and emotional arousal (e.g., skin conductance; event-related potentials).

The neurophysiology of emotion

A second source of information regarding the neural activity accompanying affective processing is measurement of electrophysiological signals on the scalp, which provide excellent information regarding the timecourse of neural processing. When measuring event-related potentials during affective picture viewing, the most common finding is of a larger late positive potential (Cacioppo et al., 1994) that is elicited 300–1000 ms after picture onset and is maximal over centro-parietal sites. The late positive potential is more pronounced when viewing emotional (pleasant or unpleasant), compared to neutral, pictures (Palomba et al., 2000; Cuthbert et al., 2000), and is largest for highly arousing pictures of erotica, mutilation, and attack (Schupp et al., 2004).

On the other hand, although several studies have reported modulation of earlier ERP components, the nature and direction of the difference are quite variable across studies. For instance, Cuthbert et al. (2000) found that pleasant pictures prompted greater positivity in a 200–300 ms time window following picture onset (at frontal, central, and parietal sites) and a similar pattern of greater positivity over parietal, central, and frontal sites for pleasant pictures in this time window was reported by Palomba, Angrilli, and Mini (1997).

Using a dense sensor array, a variety of effects that are maximal over occipital sensors have also been reported in early time windows. Using a relatively slow (1.5 s) presentation, emotional pictures (pleasant or unpleasant) have prompted less positivity over occipital sensors than neutral pictures in a 200–300 ms time window following picture onset (e.g., Schupp et al., 2003). On the other hand, when pictures are presented very rapidly (e.g., 3 per second), a somewhat different pattern is obtained, with emotional pictures prompting greater negativity than neutral pictures over occipital sensors which is again maximal 200–300 ms after picture onset (Jung-Hofer et al., 2001).

Even earlier effects, in the neighborhood of 100 ms following picture onset have also been reported. Larsen, Norris, and Cacioppo (2003) reported an occipital P1 (about 114 ms after picture processing) that was larger for unpleasant, compared to pleasant, pictures in a design which assessed ERPs to pictures presented in varying hedonic contexts. Keil et al. (2002), on the other hand, found a larger N1 occipitally specifically for pleasant, compared to unpleasant or neutral, pictures. Taken together, the variety of modulatory patterns by hedonic valence and/or emotional arousal very early in the viewing interval suggest that characteristics of specific stimulus sets, subject samples, or task parameters may contribute at least in part to early ERP differences during affective picture viewing, as the pattern of ERP modulation varies widely even in very similar picture perception contexts.

The larger late positive potential for emotional pictures (compared to neutral) is, however, a robust and well-replicated finding. It has also been reliably observed that the amplitude of the late potential increases systematically with the judged arousal of emotional pictures (Cuthbert et al., 2000). According to a biphasic view of emotion, motivationally relevant pictures activate reentrant projections from the anterior, basal brain, naturally engaging attentional resources and enhancing processing in the secondary and tertiary centers of the visual system (e.g., Amaral, 1992; Davis & Lang, 2003). Consistent with enhanced sensory processing, dipole source localization of the late positive potential highlights occipito-temporal and parietal sites. Using a dense sensor EEG array (129 electrodes), Keil et al. (2002) reported sources over both the occipito-temporal and posterior parietal areas that differed as a function of emotion, with greater source strength over these regions when viewing emotional, compared to neutral, pictures.

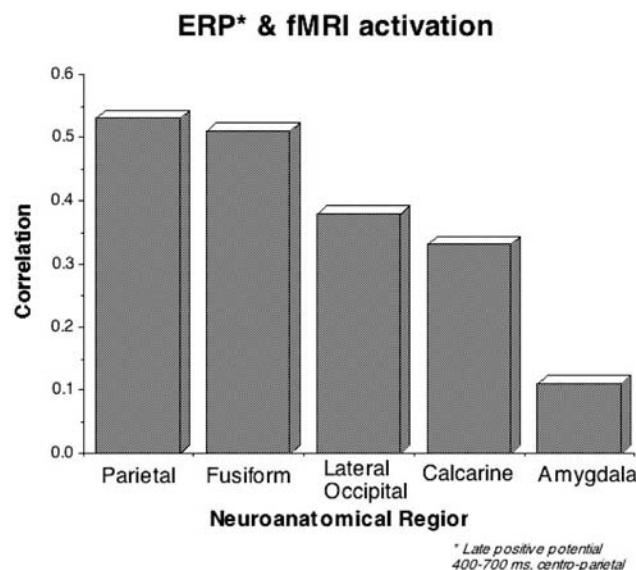

Figure 25.9. The correlation between the magnitude of the late positive potential scored in a window from 400–700 ms after picture onset over centro-parietal sites and the magnitude of BOLD activity in different brain regions, measured in the same participants viewing the same pictures in the scanner and in a simulated scanner using dense sensor (256 channels) EEG measurement.

In a recent study (Sabatinelli, Bradley, & Lang, 2005) ERPs and BOLD measures were monitored in the same experimental participants in the same picture perception paradigm, conducted once in the fMRI scanner and once in a MRI simulator (using dense sensor (256) EEG array). In the analysis of data from the fMRI session, greater BOLD activity for emotional, compared to neutral, picture viewing was found in regions that included the parietal, temporal (fusiform), lateral occipital, calcarine fissure, and amygdala. In the ERP session, the amplitude of the late positive potential recorded over centro-parietal sensors was (as seen previously) greater for emotional, compared to neutral, pictures. When correlations were performed that assessed covariation in the amplitude of the late positive potential and BOLD changes in each region (see Figure 25.9), the late positive potential correlated most strongly with activity in parietal and fusiform regions, and considerably less with either striate cortex or the deeper, more anterior amygdala. The data support the hypothesis that the emotion-related late positive potential is linked to enhanced processing in the dorsal (occipito-parietal) and ventral (occipito-temporal) processing visual streams.

EPILOGUE

Emotion and action

We have speculated that emotion and motivation are related processes, with both involving stimuli and events that move an organism towards action. Animal studies have clearly demonstrated that motivational circuits are initially activated by unconditioned stimuli – those that

reflexively active appetitive and defensive systems. New, 'conditioned' stimuli come to activate the same circuits, however, through association with these primary appetitive and aversive reinforcers (e.g., Halgren, 1981). Because humans, as well as animals, learn to respond in adaptive ways to a wide variety of different environmental stimuli and events through this basic learning process, stimuli that activate appetitive and defensive systems through association can be idiosyncratic, not so clearly valenced to bystanders, as well as not obviously related to basic survival mechanisms.

The close link between motivational engagement and overt action has been loosened in humans, presumably due to the evolution of cortical control of these fundamental behaviors (i.e., inhibition and delay), and development of the ability to mentally process, off-line, events that are not currently perceptually prompted. Thus, emotions are most often reported during inhibitory states, when the body is mobilized to respond but action is restrained. Nonetheless, when a provocation is intense (e.g., the attacker threatens), action (i.e., fleeing) is evident, even in humans. Weaker affective cues (e.g., a movie of the same scene), on the other hand, may elicit only small increases in muscle tension, a mere remnant of the original defensive activity. Thus, emotional reactions in humans often involve primarily a disposition towards, or preparation for, action (Frijda, 1986; Arnold, 1970; Lang, 1987), rather than clear overt expression.

Conscious experience of emotion

If emotion is defined in terms of subjective reports, overt behaviors, and bodily responses, one might wonder which measure, if any, taps conscious feelings. The issue of the conscious experience of emotion, and how to approach it scientifically, has posed a number of problems in emotion research. As LeDoux (1995) notes, "... it is understandable why the field of emotion has had so much trouble in solving the problem of emotion – it has set as its goal the task of understanding consciousness" (p. 1059). Animal theorists, in general, balk at using the term 'emotion' in describing motivated behavior in their subjects, mainly because of the added assumption of conscious awareness. The study of motivated behavior, however, does not necessitate taking on the Goliath issue of consciousness, which, in the end, may prove to be more amenable to philosophic, rather than scientific, inquiry.

From a measurement perspective, one solution is to operationally define conscious experience on the basis of evaluative reports: People's reports (verbal or non-verbal) about their emotional experience could be used to index the private, internal state that is usually meant when one speaks of feelings. Some might argue this is unsatisfactory, due to the dependence of personal reports on cultural norms and individual differences in disclosure. In addition, feelings are often held to include the bodily reactions involved in emotional response, such as a racing heart, sweaty palms, and so on. A second solution has

been to include 'conscious awareness' as a fourth type of response system in emotion. The difficulty here is that one needs a reliable operational measure of consciousness, and, other than the three-system measures of behavior, physiology, and reports, there are currently no additional methods for directly measuring an internal feeling state. Although clearly central to the personal experience of emotion, the concept of internal states raises more questions than it answers in the scientific study of emotion, as it can be simultaneously invoked as a cause (e.g., he ran because he felt afraid), an effect (e.g., he saw the bear and felt afraid) or, as James proposed, a consequence of the physiology (e.g., he saw the bear and ran so felt afraid).

Emotion and mood

In this chapter, the emphasis has been on discrete, phasic physiological responses to appetitive or defensive stimuli using cardiovascular, electrodermal, somatic, reflex, electrophysiological, and hemodynamic measures. Such phasic responding is representative of "emotional" reactions, whereas longer-lasting, more tonic changes in physiology are more representative of what is typically meant by "mood." In the laboratory, moods can be induced by sustained exposure to affective stimuli. Using sustained presentation of blocks of unpleasant, neutral, or pleasant pictures, for example, both corrugator EMG activity and the startle reflex increase in magnitude as the duration of aversive picture exposure increases (Bradley, Cuthbert, & Lang 1996; Smith, Bradley, & Lang 2005), indicative of a sustained and increasingly aversive mood state with the duration of exposure. Sustained exposure to pleasant stimuli, on the other hand, was less strongly associated with increasing appetitive activation in both studies.

Codispoti et al. (2003) recently explored neuroendocrine responses in the picture viewing context, using an intravenous catheter to draw blood samples during a 30-minute sustained exposure to mutilation, neutral, or erotic pictures presented in a blocked design on separate days. For unpleasant pictures, significant increases in norepinephrine, cortisol, and ACTH were found, compared to a baseline condition, consistent with previous data indicating that these neuroendocrine changes are associated with sympathetic activation mediated by sustained exposure to stress or aversive contexts (Lovallo & Thomas, 2000). For erotic pictures, these sympathetic changes were not obtained, with the main difference indicating an increase in prolactin from baseline to exposure. Taken together, whereas sustained exposure to aversive stimuli prompts tonic changes indicative of increasing defensive activation, sustained exposure to pleasant pictures is less strongly indicative of increasing appetitive activation.

Arousal and emotional intensity

The concept of arousal in the psychophysiological study of emotion has not fared well over the past thirty years, due in part to Lacey's (1967) observation that physiological

responses do not uniformly, and in parallel, increase with increasing arousal. This is supported by more recent data which find that different physiological systems change at different rates, with some (such as startle potentiation) modulated at relatively lower levels of arousal than others (see Lang, 1995). Thus, while not unidirectionally resulting in an increased response in all systems arousal, or intensity is a critical factor in organizing the *pattern* of physiological responses in emotional (i.e., hedonically valenced) reactions. Emotional intensity presumably reflects the strength of activation in motivational systems subserving appetitive and defensive behaviors, and, as such, has clear ramifications for the amount and type of physiological response.

Theorists reasoning from data on motivated behavior in animals have relied on a proximity dimension to operationalize intensity: Fanselow's (1994) model is based on 'predator imminence' (the distance of the threatening stimulus from the organism), and Miller (1959) also operationalized arousal in terms of distance from an aversive or appetitive goal. Drawing parallels between emotional intensity and imminence, arousal in humans appears to reflect the degree to which a stimulus elicits appropriate appetitive or defensive behaviors. The importance of variations in arousal within separable appetitive and defensive systems points to the necessity of controlling affective intensity when making psychophysiological comparisons between pleasant and unpleasant emotion.

Revisiting discrete states: The tactics of emotion

Biphasic and discrete state views of emotion are complementary, rather than mutually exclusive positions, as many theorists recognize (e.g., Mehrabian & Russell, 1974). Not only can a specific state such as fear be categorized along a dimension of aversiveness, but a particular aversive event can be described as involving fear. The issue of how to define discrete states of emotion is central in terms of distinguishing among specific emotions. Ortony, Clore, and Collins (1988) have provided a compelling cognitive analysis detailing the features of situations and stimuli that may differentiate among events people generally label with different emotional terms. Consistent with a biphasic view, the superordinate division in their scheme is one of hedonic valence, differentiating among desirable and undesirable events. Specific features of environmental events are then proposed to control how different hedonically valenced events are labelled. For instance, whereas "distress" labels the *actual* occurrence of an undesirable event, and "joy," the actual occurrence of a desirable event, "fear" and "hope" label undesirable and desirable events that are only *anticipated*.

Although conscious feeling states are often considered synonymous with a discrete emotion perspective, this is not necessarily the case. Panksepp (1982), for instance, advocates a discrete emotion view in the rat, based on his hypothesis that four separate neural systems of expectancy, rage, fear, and panic underlie motivated behavior. In his view, these emotions stem from systems that

have evolved to deal with specific classes of environmental stimuli (i.e., positive incentives, irritation, threat, and loss). The dependence of emotional behavior on specific stimulus contexts is also clearly an issue in the psychophysiological study of emotion, and one that has been emphasized throughout this chapter. Identifying the critical features of specific induction contexts and their implications for physiological and behavioral output (e.g., freeze, flee, or fight) in investigations of emotion may help us to understand whether and when there is consistent physiological patterning as a function of contextual similarity.

Conclusion

This chapter has explored the psychophysiological study of emotion primarily from a biphasic motivational view. This view posits that human emotions are organized by neural systems of appetitive and defensive motivation that mediate a range of attentional and action reflexes presumably evolved from primitive approach and withdrawal tendencies. Discrete states of emotion, such as fear, anger, sadness, and so on are considered to be based on tactical responses (e.g., freezing, fight, flight) that are deployed by the motive systems in specific environmental circumstances. Rather than physiology being emotion-specific, as James suggested, it was emphasized throughout this chapter that understanding the psychophysiology of emotion will depend on close attention to the context of its occurrence in the laboratory and in life. Common induction paradigms in the psychophysiological study of affect, including perception, imagination, anticipation, and action, generate overlapping and divergent physiological signatures that suggest common motivational determination but which elude easy folk description and instead, demand understanding of the specific sensory, attentional, and action requirements elicited in different emotional/motivational contexts.

Stress and Illness

BERT N. UCHINO, TIMOTHY W. SMITH, JULIANNE HOLT-LUNSTAD,
REBECCA CAMPO, AND MAIJA REBLIN

PROLOGUE

Life is largely a process of adaptation to the circumstances in which we exist. A perennial give-and-take has been going on between living matter and its inanimate surroundings, between one living being and another, ever since the dawn of life in the prehistoric oceans. The secret of health and happiness lies in successful adjustment to the ever-changing conditions on this globe; the penalties for failure in this great process of adaptation are disease and unhappiness. (Selye, 1956, p. vii)

Overview. It has been almost 50 years since the publication of the classic book by Hans Selye (1956) on stress, adaptation, and disease. In his formulation of the general adaptation syndrome, the role of the autonomic and endocrine systems on stress-related disease processes was highlighted. These two physiological systems continue to be the major focus of contemporary research aimed at understanding the health consequences of stress. The emergence of psychoneuroimmunology (PNI) as a discipline in the early 1970s has resulted in the immune system becoming a third major physiological perspective, which links stress to health outcomes. However, we now have a more detailed understanding of how these major stress systems are coordinated during threats and its implications for health. The major aim of this chapter is to provide a detailed overview of the links between stress and illness with an emphasis on underlying physiological and stress component processes (see Chrousos, 2006, this volume for an overview of stress physiology).

Historical background. The study of stress and disease has a rich history. The term “stress” originated from its physical analogy of strain present in materials. However, even before there was an understanding of the biological

stress process, researchers have been interested in how this “strain” might influence health. In one research program far ahead of its time, Ishigami (1918–1919) reported case studies suggesting that anxiety on the part of tuberculosis patients was associated with a poorer prognosis as a result of immune system changes. Ishigami (1918–1919) speculated that the higher tuberculosis mortality rates in Japan’s occupational class might be due, in part, to the increased stress and anxiety in such individuals.

A more systematic advance in our understanding of health relevant stress processes has its roots in the writing of French physiologist Claude Bernard (1878/1974). Bernard introduced the concept of dynamic equilibrium in order to understand disease. The dynamic equilibrium was conceptualized as a constant internal milieu that was critical because any factor that threatened this consistency could potentially adversely influence health. Although the main focus of Bernard’s work was on physical factors (e.g., temperature) in relation to dynamic equilibrium, this work set the stage for a generalization of this model to stress-related processes.

Perhaps the first researcher to make this leap was Walter Cannon (1929) who introduced the concept of homeostasis as an extension of Bernard’s work. Homeostasis was defined as the coordinated responses that maintain the steady state of the body. One of the factors that could threaten homeostasis according to Cannon was physical stress. However, Walter Cannon (1928) also suggested that emotional stress could be an important factor in this process. In his well-known work on the “fight or flight” response, he suggested that emotional stress can lead an organism to fight or flee, both factors that if successful can help protect homeostasis. These emotional responses were seen as driven by the catabolic effects of the sympathetic nervous system (SNS) that could energize the organism in times of need.

It was also the work by Walter Cannon that set the stage for viewing the SNS as one culprit for stress-induced health problems. Of course, Cannon viewed such responses as adaptive in the service of homeostasis and applicable primarily to short-term threats. A biological perspective that

directly addressed the longer-term effects of emotional distress can be traced to the classic work of Hans Selye (1956). In his model of the general adaptation syndrome (GAS), Selye found that animals exposed to more chronic stress seemed to go through a distinct sequence of behavioral and physiological changes. Initially, in what he termed the alarm stage, the SNS dominated. As more coping attempts were initiated (i.e., the resistance phase), the release of glucocorticoids (e.g., cortisol) from the hypothalamic-pituitary-adrenal (HPA) axis became important. The effects of glucocorticoids are broad and include increased glucose metabolism, increased lipolysis, and inhibition of immune processes (Munck, Guyre, & Holbrook, 1984). Although the immunosuppressive effects of cortisol was not anticipated by the GAS (Munck, Guyre, & Holbrook, 1984), the HPA axis was given special status by Selye as he suggested coping attempts that failed to terminate a stressor could result in exhaustion and compromise health.

Although more contemporary views of stress, physiological regulation, and disease (e.g., allostasis) have been proposed and are presently favored (see Berntson & Cacioppo, 2000; Sterling & Eyer, 1988), these prior perspectives provided important initial frameworks linking stress to physical health. The legacy of these perspectives is also evident in that a focus on the SNS and HPA axis continues to dominate contemporary research on stress and health. However, the emergence of PNI has resulted in the immune system as a third major physiological perspective for researchers interested in health and disease (see Solomon & Moos, 1964). More important is the fact that extensive interactions exist among the autonomic, neuroendocrine, and immune systems. Evidence for such interactions is starting to pave the way for a more integrated (but complex) view of how stress might influence health.

In the remainder of this chapter we provide a representative review of research linking stress to health outcomes. The major diseases considered here include cardiovascular disease, cancer, and infectious diseases. These diseases are perhaps the most studied in terms of links between stress and health, as well as being among the leading causes of mortality in the world. We will first cover briefly the basic epidemiology and pathophysiology of these diseases, and then review the evidence linking stress directly to these important health outcomes. Emerging evidence on the mechanisms by which stress is related to health will then be examined. We conclude by proposing a more integrative view of stress processes applied to health outcomes, as well as important future areas of research. To start, we provide a brief review of conceptual issues related to stress.

THE CONCEPTUALIZATION OF STRESS

The concept of stress is often used ubiquitously in the research literature to refer to either acute or chronic strains. The focus of researchers has historically emphasized stress as a stimulus (stressor), a response (biological

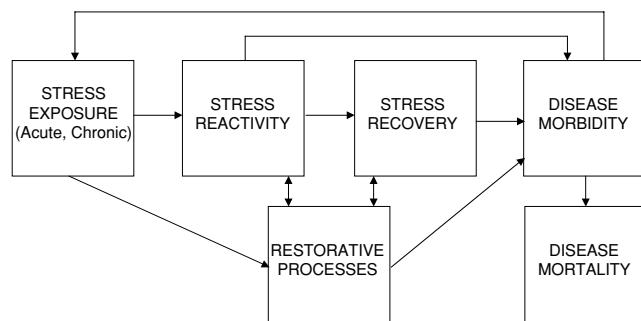

Figure 26.1. Stress-related component processes potentially related to health outcomes.

cal changes), or a transactional process in which perceptions of stress are emphasized (Lazarus & Folkman, 1984). A classic distinction is also usually drawn between more acute (or time-limited) versus chronic (long-term) stressors. Chronic stress is generally regarded as being more consequential for health and usually results from long-term exposure to stressors. However, chronic stress may also be a result of lasting perceptions of stress that are driven by ruminative thinking (Baum, O'Keefe, & Davidson, 1990). Thus, chronic stress may be defined as long-term exposure, lasting perceptions, or both (e.g., caregiving for a family member with Alzheimer's disease).

Although the time course and associated perception of stress have traditionally been emphasized in past research, more recent models are attempting to separate component processes associated with stress. This “new look” is important because a strict focus on general perceptions of stress does less to elucidate the precise mechanisms operating to influence health outcomes. Cacioppo & Berntson (in press) have argued that stress may have at least four health-related components: exposure, reactivity, recovery, and restoration. Exposure refers to the number of stressors that an individual experiences; reactivity refers to the strength of an individual’s physiological reaction to any given event; and recovery refers to how long it takes an individual to return to “baseline” following stressful events. A unique aspect of this perspective is on restoration, which focuses on anabolic processes that refresh or repair the organism, because stress may directly impede our ability to perform these functions (e.g., disturbed sleep and impaired wound healing).

A simplified conceptual model based on the framework of Cacioppo & Berntson ([in press](#)) is presented in Figure 26.1. Accordingly, stress exposure may be either acute or chronic and influence reactivity. Stress reactivity may then lead to differential stress recovery, and some evidence suggests these processes are separable (Linden, StosseI, & Maurice, [1996](#)). Stress reactivity, recovery, and exposure may also have effects on restorative processes such as sleep and wound healing. It is also predicted that these restorative processes may in turn influence stress reactivity and recovery, especially over time as insufficient restoration may be associated with changes in the set-point

and response characteristics of physiological systems (Sterling & Eyer, 1988; Epel, McEwen, & Ickovics, 1998). These stress components may ultimately influence health depending on the disease context (i.e., development or exacerbation of disease). Of course, disease morbidity also entails significant psychological, behavioral, and social adjustments that can in turn be associated with greater stress exposure (Nicassio & Smith, 1995). Although there are conceptual issues related to these stress components that will be discussed later (e.g., independence of components and time course), it provides a broad and potentially unique means for evaluating and organizing current research linking stress to health outcomes.

STRESS AND CARDIOVASCULAR DISEASE

Background information. Cardiovascular disease is a broad term used to cover several diseases of the cardiovascular system, including coronary artery disease (CAD) and hypertension. It is by far the leading cause of death in the United States and most industrialized countries (American Heart Association, 2004). In fact, it accounts for about as many deaths as the next six leading causes of death combined. It is estimated that if all major forms of cardiovascular disease were eliminated, life expectancy would be raised by about seven years. This stands in comparison to a life expectancy gain of three years if all forms of cancers were eliminated (American Heart Association, 2004).

CAD is a condition in which the coronary arteries become narrowed, and ultimately results in decreased blood flow to the heart. The pathological change in the coronary arteries is due to a process called atherosclerosis, which is a progressive buildup of fatty deposits within the arterial walls. This buildup is not a passive process that simply occurs with the passage of time. Recent research suggests that inflammation (e.g., macrophage activity or cytokine release) may play a key role in the progression of CAD (Libby, 2002; Ross, 1999). The end result of this process is the formation of arterial lesions and narrowing of the arteries. These processes increase the chance that a blood clot will form thereby increasing the risk of blocking the arterial passage. Although most people think of CAD as occurring in older adults, it is important to note that this atherogenic process starts very early. For instance, the beginnings of arterial plaque can be found in children, while some young adults already show evidence of advanced lesions. Of course, only when the disease is in its later stages (as is often the case with older adults) does it result in clinical symptoms. Thus, CAD is generally considered a disease with a long-term developmental history.

Hypertension is another leading cardiovascular disorder and is a condition of elevated blood pressure ($SBP \geq 140$ mmHg or $DBP \geq 90$ mmHg). However, there is also increasing appreciation of the health relevance of blood pressure previously labeled as "normal." Recent guidelines suggest that both SBP between 120–139 mmHg or DBP

between 80–89 mmHg be considered "prehypertension" (American Heart Association, 2004). In about 5% to 10% of cases, the cause of high blood pressure can be determined and is labeled secondary hypertension (e.g., kidney problems). However, in the vast majority of cases the cause of elevated blood pressure is unknown and is labeled essential or primary hypertension. Because of the heightened workload within the cardiovascular system, as well as the increased pressure in various organ systems, the consequences of hypertension can be kidney damage and increased risk of MI, stroke, and heart failure.

Evidence linking stress to cardiovascular disease. The overall evidence linking stress to cardiovascular disease appears strong (Krantz et al., 2000; Linden, Stossel, & Maurice, 1996; Rozanski, Blumenthal & Kaplan, 1999; Schneiderman et al., 2001; Smith & Ruiz, 2002). In a comprehensive review, Rozanski and colleagues (1999) found that exposure to both acute and chronic stress (especially work stress) was associated with an increased risk for morbidity and mortality from cardiovascular disease. Moreover, interventions explicitly aimed at decreasing stress appear to be effective in reducing cardiovascular mortality (Dusseldorp et al., 1999; Krantz et al., 2000; Linden, Stossel, & Maurice, 1996).

Because of the pathophysiology of CAD, there are at least two ways that stress may influence cardiovascular outcomes. The influence of stress on health may be due to effects on either the development or the exacerbation of CAD in clinical patients. Importantly, research suggests that stress may play a role in both processes, although the putative physiological mechanisms appear to differ. Animal studies clearly suggest a role for stress in the development of cardiovascular disease (Manuck, Kaplan, & Clarkson, 1983). In one study from an important program of research, Manuck, Kaplan, & Clarkson (1983) examined monkeys that were high or low in heart rate reactivity to stress. The monkeys were then placed in unstable, stressful environments in which they had to reestablish their dominance. Results revealed that monkeys who were high in heart rate reactivity had greater coronary atherosclerosis upon necropsy. These results have been replicated, are eliminated by β -adrenergic blockade, and exacerbated by other risk factors such as an atherogenic diet (Kaplan et al., 1987). These data are consistent with other animal models such as the borderline hypertensive rat that develops elevated blood pressure following exposure to chronic stress (Sanders & Lawler, 1992).

Another line of evidence for the role of stress in the development of disease comes from studies utilizing non-invasive imaging of carotid arteries (Kamarck et al., 2004; Troxel et al., 2003). Measures such as carotid ultrasounds and computed tomography (CT) scans of coronary arteries assess the extent of preclinical disease and are robust predictors of future cardiovascular risk (Rumberger et al., 1999). One study found that even when statistically controlling for various risk factors (e.g., lipid profiles and

resting blood pressure), a composite measure of stress was associated with higher carotid intima-media thickness in African American women (Troxel et al., 2003).

Epidemiological studies on CAD incidence in humans provide further evidence for an influence of stress on the development of cardiovascular problems. INTERHEART is a large, global case-control study aimed at understanding the risk factors for a first heart attack (Rosengren et al., 2004). Results from this huge undertaking in 52 countries showed that stress from both home and work was associated with an increased risk for a first heart attack after adjustments for age, gender, geographic region, and smoking habits (odds ratios of 1.38–2.14). These results are consistent with a recent large prospective study conducted in Japan that also found general perceptions of stress in initially healthy individuals to predict subsequent cardiovascular mortality over a seven to nine year followup in women (Iso et al., 2002). Although these two studies statistically controlled for known risk factors such as smoking, exercise, and body mass index, they may provide only a conservative estimate of the stress-disease link given it may be mediated, in part, by such health behaviors (Stetson et al., 1997). Nevertheless, these data are consistent with other prospective studies that found stress to predict the incidence of CAD in middle-aged to older adult samples (Ming et al., 2004; Rosengren, Tibblin, & Wilhelmsen, 1991).

Prospective studies further suggest a role for stress in the clinical course of diagnosed cardiovascular disease. A recent study by Sheps and colleagues (2002) examined stress-induced ischemia in the laboratory by having 196 cardiac patients perform a speech task. They found that wall motion abnormalities during the speech were predictors of mortality over the five-year followup (also see Manuck et al., 1992). These studies are consistent with work in the laboratory or daily life linking the experience of acute stress to arrhythmia/ischemia in cardiac patients (Carels et al., 1988).

It is important to note that interventions designed to decrease stress in cardiac patients also show some promise in reducing disease reoccurrence and mortality (Dusseldorp et al., 1999; Krantz et al., 2000; Linden, Stossl, & Maurice, 1996). Dusseldorp and colleagues (1999) reviewed 37 interventions consisting of health education, stress management programs, or both with cardiac patients. Results revealed that myocardial infarction reoccurrence was 20% to 29% lower in the intervention groups. Moreover, survival during the study period was about 34% greater in patients provided with such psycho-educational interventions.

Potential mechanisms linking stress to cardiovascular disease. Overall, strong evidence is available linking stress to the development and course of cardiovascular disease. One limitation, however, is that less direct evidence is available in these studies on the mechanisms responsible for such links. Furthermore, stress in these studies has usu-

ally been operationalized in its aggregate or as general perceptions. As a result, the more precise stress-related components that might be operating are unclear. There is, however, a relatively large literature linking stress to more “intermediate” cardiovascular endpoints such as reactivity, ambulatory blood pressure (ABP), or noninvasive imaging of carotid/coronary arteries. Such research can help clarify the conceptual role of stress in the development and exacerbation of cardiovascular disease.

One model linking stress to cardiovascular disease is represented by the reactivity hypothesis (Krantz & Manuck, 1984). According to this perspective, individuals or situations characterized by high levels of cardiovascular reactivity (usually indexed by blood pressure or heart rate) may be related to higher risk for the development and exacerbation of cardiovascular disease. Research linking reactivity to cardiovascular disease is still ongoing, but current evidence is consistent with this hypothesis. For instance, relatively high levels of reactivity prospectively predict increased blood pressure in adolescents (Matthews, Woodall, & Allen, 1993) and middle-aged adults (Light et al., 1992; Matthews, Woodall, & Allen, 1993). A recent review of this literature found evidence consistent with the reactivity hypothesis, although exceptions were evident (Treiber et al., 2003).

The more precise stress components responsible for these findings are unclear as the reactivity hypothesis assumes that both exposure and reactivity are important to influence disease. This assumption is important to emphasize as several studies suggest that modeling the effects of stressful environments strengthen the association between cardiovascular reactivity assessed in the lab and disease outcomes. For instance, Everson and colleagues (1997) found that workplace demands and cardiovascular reactivity assessed in the lab interacted to predict changes in carotid atherosclerosis four years later. More specifically, individuals more reactive (as indexed by anticipation of an exercise test) and with more demanding jobs had up to 40% greater progression of intima-medial-thickness and plaque height (also see Lynch et al., 1998). These results echo the comments by Light (2001) who noted that prior animal models in which the reactivity hypothesis was based (e.g., borderline hypertensive rat) show that the combination of social environment and genes are critically important to model.

The mechanisms responsible for reactivity effects on CAD, however, may differ depending on the stage of disease. The role of stress reactivity in the development of disease highlights the role of endothelial injury because mechanical (e.g., shear force) or chemical (e.g., catecholamines) factors are important precipitating events (Krantz & Manuck, 1984). More recent research focuses on the possibility that following endothelial injury, inflammatory processes take center stage as a result of the migration of macrophages, T-cells, and the release of cytokines (Libby, 2002; Ross, 1999). This process may be accelerated or exacerbated for individuals who are exposed to stress,

or who are high stress reactors (Bosch et al., 2003a; Goebel & Mills, 2000).

In comparison, the mechanisms linking stress to the exacerbation of disease may be related more to the induction of myocardial ischemia, arrhythmias, and thrombosis (Rozanski, Blumenthal, & Kaplan, 1999). Acute stress may precipitate ischemia because of hemodynamic changes in blood pressure (Rozanski et al., 1988), perhaps as a result of stress-induced increases in endothelial dysfunction and subsequent vasoconstriction (Goldberg et al., 1996; Yeung et al., 1991). Acute stress may cause changes in the autonomic nervous system (ANS) that lead to arrhythmia and sudden cardiac death (Kamarck & Jennings, 1991). Finally, stress may be linked to changes in endothelial function, platelet aggregation, and blood hemoconcentration that render plaques vulnerable to thrombosis (Strike et al., 2004; Veldhuijzen van Zanten et al., 2004). These data suggest that, although chronic stress increases the probability of these adverse effects, in theory, acute stressful events in and of themselves may be sufficient to induce problems in cardiac patients.

Although the prior literature has focused on stress reactivity and exposure, recent attention is also turning to indices of cardiovascular recovery from stress in predicting cardiovascular outcomes (Schuler & O'Brien, 1997). In theory, delayed recovery may be a result of the cumulative effects of stress (perhaps because of allostatic changes) or may be driven by ruminative thinking (Glynn, Christenfeld, & Gerin, 2002). Methods for calculating recovery differ and range from simple change or residualized change scores from baseline to measures of area under the curve and slope analyses (Llabre et al., 2001). Although many researchers statistically partial baseline levels from recovery indices, very few researchers control for levels of stress reactivity. Because reactivity and recovery may be correlated, it is difficult to distinguish the potential independence of recovery from the reactivity hypothesis.

There are currently few studies that examined the link between recovery and cardiovascular disease processes, and existing studies are heterogeneous in terms of its method of calculating recovery (Schuler & O'Brien, 1997). Despite this variability, a meta-analysis of recovery indices and cardiovascular risk factors showed small but significant associations between cardiovascular recovery and hypertension status, race, and lack of fitness (Schuler & O'Brien, 1997). In one study conducted over a three-year period, blood pressure and heart rate recovery indices predicted increases in ABP even when statistically controlling for corresponding reactivity levels (Rutledge, Linden, & Paul, 2000). Thus, although more data are needed, recent research suggest a role for recovery indices in shedding additional insight into how stress may be related to cardiovascular risk.

A final process that may be responsible for links between stress and cardiovascular disease is related to its effects on restorative processes (Cacioppo & Berntson, *in press*).

These anabolic processes are energy conserving and building, and include biological processes that help to refresh or repair the organism. Although not a main focus of prior stress research, evidence suggests the importance of such restorative processes. One important restorative process is sleep. Problems with sleep can have important consequences as it is linked to adverse changes in health (e.g., Mallon, Broman, & Hetta, 2002). Importantly, stress has been shown to have negative effects on sleep quality (Cartwright & Wood, 1991). In one study, participants were recruited for a night in a sleep lab and half of the participants were told they were to perform a stressful speech task in the morning (Hall et al., 2004). Results revealed that individuals expecting stress in the morning had less parasympathetic modulation of several sleep stages, and greater sympathovagal balance during nonrapid eye movement sleep, which in turn related to lower sleep maintenance. These data highlight the importance of stress on the restorative process of sleep and further suggest that ANS processes related to cardiovascular disease may be involved.

STRESS AND CANCER

Background information. Perhaps no diagnosis strikes more fear in people than that of cancer. Cancer is the second leading cause of death in the United States and over 1.3 million new cancer cases are expected to be diagnosed in 2004. In fact, one of every three individuals is predicted to be afflicted by cancer at some point in their lives (American Cancer Society, 2004). Cancer is a broad term used to describe many different diseases that are characterized by the uncontrolled growth and spread of abnormal cells (Abbas & Lichtman, 2003). A key to cancer appears to lie in the DNA of cells. DNA contains the genetic code that directs cell development and growth. However, carcinogens can cause damage to cells with subsequent changes in their DNA. In many cases, the body is able to repair such damages to DNA or the cell dies off before it replicates. However, in the case of cancer, uncontrolled replication of such cells leads to tumors that can ultimately result in death if not detected and treated. Cancerous tumors can also metastasize and spread cancerous cells to different parts of the body via blood or lymph.

There is no one cause of cancer and many factors seem to play a role in its initial development and progression. Research clearly suggests the importance of genetics in the risk for some forms of cancer (e.g., BRCA II gene for breast and ovarian cancer). Also important are carcinogens that include chemical factors and ionizing radiation that may damage cells and increase cancer risk. However, some of the main factors implicated in the development of cancer are behavioral or lifestyle in nature. These lifestyle factors include smoking, excessive alcohol consumption, diet, and sun exposure. In fact, several types of cancer could be almost completely eliminated (lung cancer by not smoking) or significantly reduced (skin cancer with the use of

sunscreen) just by altering one's behavior (American Cancer Society, 2004).

Fortunately, the body is not defenseless against cancer (Abbas & Lichtman, 2003; Dunn et al., 2002). According to the concept of immunosurveillance, the immune system plays an important role in destroying abnormal cells before they become tumors or killing tumors in the body once they are formed (Burnett, 1970). A number of specific immune cells have been implicated in playing a role in immunosurveillance. For instance, natural killer (NK) cells have the ability to nonspecifically kill certain tumor cell lines. Cytotoxic T-cells and the cytokine interferon- γ also appear to be important mechanisms of immunosurveillance because they can target tumors that express certain peptides or viral proteins (Shankaran et al., 2001).

There is some debate about whether the immune system defends the body adequately against most cancers. Animal models provide the clearest evidence for the protective effects of the immune system, although the strength of this effect may depend on the type of cancer (Abbas & Lichtman, 2003). More recently, Dunn and colleagues (2002) have proposed the concept of cancer immunoediting as a more comprehensive framework to describe immune processes related to tumor resistance and development. According to these authors, this term better describes the role of the immune system in initially protecting against cancer, and actively selecting for cancer variants that might eventually grow in an immunocompetent individual. For instance, the immune system may select for tumor that have less immunogenicity (i.e., ability to generate an immune response) by initially killing off more immunogenic tumors. However, these less immunogenic tumors can further mutate into more aggressive variants that "carry over" their initial advantage (i.e., Darwinian selection), and could eventually provide it with an advantage over the immune system.

The processes described above refer collectively to three postulated stages of cancer immunoediting: elimination, equilibrium, and escape (Dunn et al., 2002). Elimination coincides with the initial concept of immunosurveillance and T-cells, along with the production of interferon- γ , appear critical for the detection and elimination of immunogenic tumors. In the equilibrium stage, tumors with less immunogenicity survive elimination and are at equilibrium with the immune system. At this stage, immune processes invoked by T-lymphocytes and interferon- γ can keep the tumor in check but not eliminate it. However, mutating variants of these tumor cells are constantly arising and may carry mutations that make them even more resistant to immune processes (e.g., loss of MHC molecules, interferon- γ insensitivity). Finally, the phase of escape corresponds to resulting tumors that are much less immunogenic and can thus grow in an immunocompetent individual. This later stage of escape usually corresponds to clinically diagnosed malignant disease, and the immune system is less able to control it as a result of earlier selection processes. Although the concept of immunoediting

is still being refined, it provides a broad, developmental framework for interpreting prior research.

Evidence linking stress to cancer. The overall evidence linking stress to cancer outcomes is controversial. Animal models provide a stronger case for stress influencing some types of cancer (Fox, 1998; Sklar & Anisman, 1981). However, human studies have provided inconsistent findings linking stress to overall cancer outcomes (e.g., Cooper, Davies-Cooper, & Faragher, 1986; see review by Fox, 1998). As noted by others (e.g., Cohen & Herbert, 1996; Kiecolt-Glaser & Glaser, 1995), the evidence linking stress to cancer is complex and several issues are in need of greater consideration. First, past research has tended to focus on all cancers combined, or failed to consider the stage of cancer potentially impacted by stress. This is important because some cancers are more deadly than others (e.g., pancreatic cancer). It has further been suggested that psychosocial factors such as stress are less likely to influence survival from cancer in later stages of the disease (Kiecolt-Glaser & Glaser, 1995).

These points would suggest that studies examining certain types of cancers might provide a stronger test of the role of stress in the development of cancer. Of such studies most have focused on breast cancer. In a meta-analysis, McKenna, Zevon, Corn, and Rounds (1999) did find evidence of an association between stress and the development of breast cancer. Although the number of studies were not large (16 for separation/loss and 12 for stressful life events), significant stress effects on breast cancer development were found with overall mean effect sizes (Hedges's g) ranging from .25 to .29. Furthermore, these effect sizes were not moderated by various methodological factors such as type of control group and sample size.

Although there are studies that have failed to find a link between stressful life events and breast cancer development (e.g., Kvikstad et al., 1994), there is some evidence that increased stress exposure may be important to consider. In the Finnish Twin Cohort study, a comprehensive assessment of stressful life events was obtained for the five years preceding a baseline assessment (Lillberg et al., 2003). During a 15-year followup, the experience of five major life events predicted the incidence of breast cancer even after statistically controlling for social class, smoking, alcohol use, and exercise patterns. Further examination of the data suggested a cumulative effect of stress on breast cancer development as the number of life events increased.

There is also controversy about whether stress can influence subsequent survival following a cancer diagnosis (Fox, 1998). The strongest evidence for a link between stress and the course of cancer comes from intervention studies (Fawzy & Fawzy, 1998). Although the number of studies is not large, these interventions usually include an educational or stress management component and appear to have beneficial influence on health outcomes (Baum &

Posluszny, 1999). In one well-known intervention, Fawzy and colleagues (1993) evaluated the effects of a six-week structured group intervention that provided education, problem-solving skills, stress management, and social support to cancer patients. Importantly, a six-year followup revealed that only 9% of individuals in the structured group intervention had died compared to 29% of individuals in the no-intervention condition.

Potential mechanisms linking stress to cancer. The overall evidence linking stress to cancer development and survival is controversial (Fox, 1998), although studies that focus on specific cancers show some promise (Andersen, Kiecolt-Glaser, & Glaser, 1994; McKenna et al., 1999). In retrospect, these inconsistent results are not surprising given that modulation of the immune system is one of the primary proposed mechanisms linking stress to cancer, and the effectiveness of such immune processes may be dependent on the type of cancer (Abbas & Lichtman, 2003). The concept of immune system involvement in cancer is also undergoing development (Dunn et al., 2002). The emerging concept of cancer immunoediting suggests why stress may only be weakly associated with cancer outcomes later in the clinical course of disease. At this later "escape" stage, tumors with less immunogenicity have been selected and mutating variants may already have made them resistant to immune processes (Dunn et al., 2002). In such cases, stress-induced modulation of immune function may evidence little association with disease outcomes. The concept of cancer immunoediting highlights more generally the importance of modeling stress effects across the full course of cancer. In theory, by suppressing the immune system (e.g., interferon- γ production), chronic stress may hasten the progression through stages of cancer immunoediting. Of course, some cancers are more deadly than others (e.g., pancreatic cancer) and this complexity would also need to be considered in modeling the time course of stress effects on cancer outcomes.

Importantly, stress does appear to be related to early processes that in theory should be related to the development of cancer. As reviewed earlier, damaged cells may become cancerous following changes to their DNA. However, the cell is usually repaired or it dies off before it replicates (i.e., apoptosis). There is a small literature indicating that stress may influence both of these processes. In studies of medical students during high stress (i.e., exams), apoptosis of blood leukocytes in response to gamma irradiation is impaired (Tomei et al., 1990). In addition, rats exposed to rotational stress showed lower levels of a DNA repair enzyme in response to carcinogens (Glaser et al., 1985). These findings highlight the potential role of stress exposure, stress reactivity, and stress restoration in early biological events related to cancer development.

Evidence linking stress to direct changes in immune function may also have relevance for understanding the development and course of cancer. The elimination phase of cancer immunoediting is characterized by immune pro-

cesses that actively prevent and eliminate tumors (Dunn et al., 2002). Importantly, there is strong evidence indicating that stress can influence aspects of both innate and adaptive immunity (Segerstrom & Miller, 2004). However, it is clear that the chronicity of the stressor is one important dimension to consider. Studies modeling how short-term laboratory stress (three minutes to half hour) influences aspects of immunity mostly show increases in cytotoxic T-cells, NK cells, NK cell activity, and decreases in the proliferative response to the mitogens PHA and Con A (Cacioppo et al. 1995; Matthews et al. 1995). These changes appear short-term, reflect changes in cell trafficking, and are mediated by activation of the SNS (Bachen et al., 1995).

Given the short-term nature of these changes, it might be argued that these alterations have little relevance for understanding disease outcomes such as cancer. However, similar to research linking acute stress to cardiovascular disease, it is assumed that these laboratory studies model stress reactions during daily life. This is important because according to the concept of allostasis such changes may be adaptive initially, but, if extended to repeated experiences of stress, may lead to changes that place an individual at risk for disease (Sterling & Eyer, 1988; McEwen, 1998). Consistent with this perspective, there is preliminary evidence for the utility of examining both laboratory stress reactions and stressor exposure in understanding immune-mediated disease risk (Boyce et al., 1995).

The concept of allostasis is consistent with research suggesting that more chronic stress (weeks to years) is associated with decrements in immune function (Segerstrom & Miller, 2004). Aspects of immune function are decreased in survivors of natural or human disasters (Ironson et al., 1997; Solomon et al., 1997); caregivers for family members with Alzheimer's disease (AD) (Kiecolt-Glaser et al., 1991; Kiecolt-Glaser et al., 1995); individuals suffering marital discord (Kiecolt-Glaser et al., 1987); and recently bereaved individuals (Bartrop et al., 1977; Kemeny et al., 1995). The effects of chronic stress on the immune system appear stronger using measures that capture the functional ability of the immune system to respond to challenge (i.e., proliferative response to mitogen) rather than cell counts (Kiecolt-Glaser & Glaser 1995). Importantly, such functional measures are generally regarded as more health relevant (Kiecolt-Glaser & Glaser, 1995).

Stress has also been directly linked to decreases in immunity in cancer patients and hence may theoretically play a role in disease progression depending on the stage and time course of disease (Kiecolt-Glaser & Glaser, 1995). In one study, investigators examined if perceptions of cancer-related stress had an influence on immune measures following surgical treatment (Andersen et al., 1998). Cancer-related stress in these patients had uniform effects on immunity as it was related to lower NK cell activity, proliferative responses to mitogens, NK cell activation via interferon- γ , and T-cell proliferation to antibody (Ab) directed at the T-cell receptor. This study is consistent

with the results of interventions suggesting that stress-reduction may improve immune function in cancer patients, and has potential beneficial influences on survival (Fawzy et al., 1993). It is important to note, however, that direct evidence is still needed suggesting immune-related mediation of such effects (Cohen & Herbert, 1996), as well as the components of stress that might be impacted by such interventions.

One critically important pathway linking chronic stress to changes in immunity is through neuroendocrine activation. Cells of the immune system (e.g., lymphocytes) have functional receptors for endocrine hormones, which provide a mechanism by which stress may influence immunity (Sanders et al., 2001). It is now evident that immune cells have receptors for a variety of hormones including EPI, norepinephrine (NE), ACTH, cortisol, opioids, growth hormone, prolactin, and estrogen that provide a pharmacological basis for neuromodulation (Sanders et al., 2001).

The three major hormonal pathways linking stress to immune processes include activation of the HPA, SNS, and opioid systems. Of these, much focus has been placed on hormones of the HPA, such as cortisol, given its theoretical role in chronic stress processes (Selye, 1956). The major influence of HPA hormones on immune processes appears inhibitory (Munck, Guyre, & Holbrook, 1984). For instance, glucocorticoids inhibit aspects of antigen presentation (Baus et al., 1996) and pre-incubation of PBLs with glucocorticoids tends to decrease the proliferative response to mitogens as well as NKCA (Holbrook, Cox, & Horner, 1983; Wiegers et al., 1993). Many of these effects were blocked by the specific glucocorticoid receptor antagonist RU-486 (e.g., Wiegers et al., 1993).

HPA hormones may indirectly suppress *in vivo* cellular immune function in at least two ways. Central administration of CRH reliably decreases the proliferative response to mitogens (Johnson et al., 1994) and splenic NK cell activity (Irwin et al., 1989). Although central CRH activates the HPA axis, it also activates the ANS and the influence of central CRH on splenic NK cell activity appears mediated by activation of the ANS (Irwin et al., 1989). HPA hormones also appear to modulate cytokine production (Munck, Guyre, & Holbrook, 1984). The cytokines interferon- γ and IL-2 enhance the cytolytic activity of NK cells and cytotoxic T-cells, and appear to play an important role in the elimination phase of cancer immunoediting (Dunn et al., 2002). Importantly, HPA hormones, such as ACTH, appear to inhibit the synthesis of both interferon- γ and IL-2 (Arya, Wong-Staal, & Gallo 1984; Kelso & Munck, Guyre, & Holbrook, 1984).

Although the SNS is clearly involved in short-term changes in immunity, the longer-term consequences of SNS activation may also be significant. Sympathetic nerve fibers innervate both primary and secondary lymphoid organs (Felton et al. 1987), and provide a direct mechanism by which the SNS may influence aspects of immunity. Destruction of lymphoid sympathetic fibers via treatment

with 6-hydroxydopamine appears to potentiate immune responses to antigen. These observations have led some to argue that the SNS exerts a tonic inhibitory influence on lymphoid immune processes. In a sustained program of research, Ben-Eliyahu and Shakhar (2001) have found that stress decreases NK cell activity and increases tumor growth. These effects appear mediated by the SNS because β -adrenergic blockade or adrenal demedullation eliminated these stress-induced effects, whereas β -adrenergic agonists mimicked the effects of stress on tumor growth.

Another pathway of interest is through an opioid mechanism because stress has been linked to activation of the opioid system (Wang et al., 2002). *In vivo* studies suggest that infusion of morphine or implantation of morphine pellets decreases splenic NK cell activity and the proliferative response to mitogens (Bayer et al., 1990; Shavit et al., 1986). These effects appear partially eliminated by opioid antagonists (Bayer et al., 1990), with activation of the SNS and HPA as two potential indirect mechanisms also responsible for such effects (Fecho, Dykstra, & Lysle, 1993; Freier & Fuchs, 1994). Consistent with the role of opioid hormones on immune processes and tumor growth, fentanyl (an opioid analgesic) was associated with a suppression of NK cell activity and decreased resistance to tumor metastasis in rats (Shavit et al., 2004).

The data linking stress to immune function highlights the potential role for stress-reduction interventions in enhancing aspects of immune function, with potential beneficial influences on cancer-related processes. One cognitive-behavioral stress management intervention in early stage breast cancer patients found decreases in cortisol (Cruess et al., 2000), a finding mediated by changes in patients' perceptions of benefit finding. In general, interventions in chronically stressed populations such as cancer patients appear to have beneficial influences on immunity (Fawzy et al., 1993; Lutgendorf et al., 1997). However, little evidence exists suggesting that stress management interventions can increase immunity in healthy, nonstressed populations (Miller & Cohen, 2001).

The link between chronic stress and immune processes potentially highlights the role of stress reactivity, exposure, recovery, and restoration on cancer outcomes. Very little research has separated out the effects of these stress component processes on cancer outcomes, especially in regards to stress recovery. The association between stress and immune-mediated restorative processes is just being established, however, existing evidence is promising. As noted earlier, sleep is one such restorative process and chronic stress has been linked to poorer sleep quality (Cartwright & Wood, 1991). There is also strong evidence linking sleep disruption to decrements in immunity, including NK cell activity (Irwin, 2002). Although the mechanisms responsible for these changes in immune function are not yet clear, evidence implicates sleep-mediated changes in cytokines such as IL-1, IL-2, and IL-6 (Irwin, 2002). In one study, the stress of bereavement was associated with lower circulating NK cells, and

poor sleep was a mediator of this association (Hall et al., 1998).

During sleep, the release of certain hormones may play an important role in restorative processes (Epel, McEwen, & Ickovics, 1998; McEwen, 1998). Of these, growth hormone may be particularly important because most of it is released during sleep (Veldhuis & Aranmanesh, 1996). Importantly, growth hormone appears to augment aspects of immune function and hence may have a beneficial influence on tumor resistance (Koo et al., 2001). These data, however, need to be considered in light of epidemiological links between the growth promoting peptide IGF-I, which mediates the effects of growth hormone on tissue growth, and increased cancer incidence (Chan et al., 1998).

STRESS AND INFECTIOUS DISEASES

Background information. Although mortality as a result of infectious diseases has declined in industrialized countries, it nevertheless remains an important cause of morbidity and mortality. More specifically, the emergence of HIV has highlighted the importance of understanding links between stress and infectious disease processes. According to recent statistics, over 20 million people have died worldwide since the start of the epidemic in the early 1980s and an additional 40 million individuals are now living with HIV or AIDS (UNAIDS/WHO, 2004). With no known cure, it is clear that HIV and AIDS will continue to be a significant worldwide health problem. It is also important to note that infectious diseases such as influenza, even in industrialized countries, are an important cause of mortality in older adults (Effros & Walford, 1987). In addition, tuberculosis (TB) was responsible for an estimated 2 million deaths in 2002 and the incidence of new infections continues to pose major health risks in many countries (WHO, 2004).

The immune system plays an important role in the control of such infectious diseases. However, the specific effector mechanisms responsible for protection depend on the type of challenge (Abbas & Lichtman, 2003). Protection against viruses and bacteria begins with innate immunity to prevent them from entering the host (e.g., skin, mucous membranes). Innate immune processes such as complement activation, macrophage activity, and inflammation provide further protection once pathogens enter the host. For instance, some extracellular bacteria have features in their cell walls (e.g., LPS in gram-negative bacteria) that activate the alternate complement pathway that in turn can destroy the bacteria. Macrophages and NK cells may also play important roles in innate immunity because they are able to phagocytize some pathogens once they enter the host.

However, once the pathogen begins replicating inside the body, the adaptive immune response becomes the important mechanism for resolution of these infections. For extracellular pathogens such as some bacteria, the primary arm of adaptive immunity is humoral. Humoral

immunity refers to the activity of B-cells that replicate and produce Ab specific to the pathogen. Antibodies can facilitate the elimination of extracellular pathogens by neutralizing them and their toxins, marking them for destruction, or both (e.g., opsonization). Helper T-cells (i.e., TH2 subset) facilitate this process by aiding in the clonal expansion of B-cells.

However, viruses and some bacteria (e.g., TB) are intracellular pathogens and the resolution of these infections is primarily T-cell mediated via the cellular arm of adaptive immunity (Abbas & Lichtman, 2003). Cytotoxic T-cells recognize viral antigen in the context of MHC class I molecules and can directly lyse infected cells. In addition, helper T-cells (i.e., TH1 subset) aid in the clonal expansion of cytotoxic T-cells and secrete cytokines (i.e., IL-2, interferon- γ) that enhance NK lysis or phagocytosis of infected cells. Helper T-cells may also stimulate B-cells to produce Ab. Antibodies and complements may then directly lyse infected cells or opsonize them for subsequent killing.

One virus of particular interest is HIV, which is found in blood, semen, vaginal fluids, and breast milk of infected individuals at biologically relevant quantities. Upon entering the body, it infects cells possessing specific surface molecules (e.g., CD4+ cells). One of the important cells infected and destroyed by HIV is the helper T-cell. As illustrated above, helper T-cells are absolutely essential to coordinate both the cellular and humoral arms of adaptive immunity. By depleting helper T-cells, HIV cuts off the ability of the immune system to effectively fight against foreign invaders. Although the body mounts a vigorous immune response, the virus can reside in a "latent stage" that can last for years. During this phase, HIV may be diminished in blood, but disease progression continues in lymphoid organs. Ultimately, HIV infection can result in the destruction of this important cell line and the subsequent development of AIDS which is a condition in which the body's immune system eventually loses its ability to fight off foreign invaders (Abbas & Lichtman, 2003). As a result, the infected person is at risk for morbidity and mortality from pathogens that a healthy person would normally have no trouble fighting off. Although no cure is presently available, recent biomedical advances have successfully extended the lives of HIV+ individuals (Kelly et al., 1998). Although significant challenges exist (e.g., ability of HIV to mutate because of encoding errors), vaccines against HIV are now being evaluated in several large clinical trials and remains a high priority for biomedical research.

Evidence linking stress to infectious diseases. The overall evidence linking stress to infectious diseases appears strong (Baum & Poslusny, 1999; Cohen & Williamson, 1991; Kiecolt-Glaser et al., 2002). There have been two general approaches to examining the links between stress and infectious diseases. One approach has been to link stress to naturally occurring infections. Recent studies suggest that life stress, and chronic stress in particular, is related

to increased susceptibility to infectious disease (Dyck, Short, & Vitaliano, 1999; Kiecolt-Glaser et al., 1991). For instance, caregiving for a family member with schizophrenia was related to the risk of developing an infectious disease (Dyck, Short, & Vitaliano, 1999). Results of this study showed that patient symptoms during acute exacerbation of schizophrenia, but not more stable symptoms, was related to risk for infections in caregivers. In the context of long-term stress, these data suggest that exposure to less predictable sources of stress may be particularly important to consider.

Although the above data are consistent with the role of stress in the risk for infections, a more controlled approach has been to expose consenting adults to a viral challenge. Recent studies, which improved on the methodological limitations of prior research, provide strong evidence for a link between stress and susceptibility to infectious diseases (Cohen et al., 1998). In one study that examined different types of stressors prior to challenge, consenting adults were inoculated with the common cold virus and quarantined for five days (Cohen et al., 1998). Only stressors lasting over one month were associated with increased risk for verified colds. Of these, chronic interpersonal and work stressors were primarily responsible for the effects of chronic stress on infections. These effects were independent of prechallenge Ab status, demographic factors, personality processes, and various health practices. In another study, these investigators also reported the combination of high life stress and high cortisol responses to acute laboratory stress predicted an increase in verified upper respiratory illnesses (Cohen et al., 2002).

One of the hallmarks of immunity is memory in which pathogens that have been eradicated from the host are met with a more effective immune response upon subsequent exposure. However, some viruses (e.g., EBV) avoid elimination by going latent and "hiding" relatively inactive in certain cells. The exposed individual is infected for life, but the cellular immune response is usually successful at keeping the virus in check. However, individuals with compromised cellular immune processes (e.g., HIV+ populations or patients on immunosuppressive therapies) may experience reactivation of one or more of these latent viruses. In such cases, increased Ab titers to latent viruses suggest poorer cellular immunity because the reactivation of the virus triggers the humoral arm of adaptive immunity. Importantly, there is strong evidence from both animal and human studies that stress can result in reactivation of latent viruses (Padgett et al., 1998).

A final paradigm of interest is the handful of studies examining the link between stress and the progression of HIV infection. An early meta-analysis found that stress was not reliably associated with CD4+ counts, an important marker of disease progression in HIV+ individuals (Zorrilla et al., 1996). However, evidence was found for an association between stress and lower NK cells counts and NK cell activity in HIV+ populations. Although the links between stress and NK cell function were consistent with

poorer immune regulation of HIV, the lack of findings for CD4+ cells was unexpected. However, some researchers have argued that more long-term studies were needed in order to examine how stress is related to the entire course of disease. In one such study, Leserman and colleagues (1999) followed a sample of HIV+ individuals for up to seven and a half years. In their study, 37% of the sample had progressed to AIDS. Importantly, faster progression to AIDS was predicted by a total index of stressful events (i.e., number and severity). Although more research is needed, there is recent preliminary evidence linking stress to the progression of HIV infection (see Cole & Kemeny, 2001; Kopnitsky, Stoff, & Rausch, 2004).

In the context of HIV it is also important to discuss how stress may influence exposure to HIV infection (Baum & Poslusny, 1999). This is salient because the primary route of HIV infection is behavioral in nature (Kelly et al., 1993). Stress is linked to changes in health behaviors, including alcohol and drug use (Testa & Collins, 1997). The use of alcohol and illicit drugs may in turn increase risky sexual behavior through processes such as disinhibition and facilitation of sexual arousal (McCarty, Diamond, & Kaye, 1982; O'Keefe, Nesselhof-Kendall, & Baum, 1990). Thus, stress appears to influence behavioral factors that may place individuals at risk for HIV infection.

Potential mechanisms linking stress to infectious diseases. There is strong evidence linking stress to infectious disease susceptibility. The major protective mechanism in susceptibility to infectious disease is the immune system (Abbas & Lichtman, 2003). Thus, evidence linking stress to immune function can inform researchers about the stage(s) that stress influences susceptibility. One paradigm that lends clear evidence to the links between chronic stress and decreased immunity is research on caregivers of family members with AD. Caregiving for a family member with AD is characterized as a prototypic chronic stressor due to the long-term, severe, and unpredictable problems caregivers often deal with. In an important program of research, Kiecolt-Glaser and colleagues (1991) found that long-term caregiving for a family member with AD was associated with impaired adaptive immune processes (e.g., decreased proliferative response to mitogens, increased Ab titers to latent viruses) compared to demographically-matched controls. These changes did not appear to "rebound" upon termination of the chronic stressor. Caregivers whose family members had been deceased on average of two years still showed signs of a down-regulated immune response (Esterling et al., 1994).

Research further suggests that these stress-induced immune changes in caregivers are biologically relevant. Caregivers are less likely to seroconvert to influenza vaccination, have higher rates of infectious diseases, and evidence poorer wound repair (Kiecolt-Glaser et al., 1995; Kiecolt-Glaser et al., 1996). Fortunately, interventions aimed at decreasing stress in caregivers have shown some initial promise in terms of decreasing distress and

augmenting some immune processes (Bourgeois, Schulz, & Burgio, 1996; Hosaka & Sugiyama, 2003). It is important to note that caregiver stress paradigms implicate the role of both stress reactivity and stress exposure in infectious disease risk. Older caregivers show greater acute stress reactions, and are also exposed to a relatively high number of stressful events related to caregiving (Bourgeois, Schulz, & Burgio, 1996; Uchino, Kiecolt-Glaser, & Cacioppo, 1992). These data are consistent with the study by Cohen and colleagues (2002) that found the combination of high life stress and high cortisol reactivity predicted increases in upper respiratory illnesses (Cohen et al., 2002).

Studies examining the links between stress and vaccination provide a promising paradigm for understanding more specific biological mechanisms because increased Ab titers to such vaccines are related to lower risk for infection (Center for Disease Control, 1996). Importantly, stress predicts lower Ab production in response to influenza (Kiecolt-Glaser et al., 1996; Miller et al., 2004; Vedhara et al., 1999), hepatitis B (Jabaaïj et al., 1993; Glaser et al., 1992), meningitis C (Burns et al., 2002), and Pneumococcal Pneumonia vaccinations (Glaser et al., 2000). One preliminary study also found that a stress-management intervention was associated with higher seroconversion to an influenza vaccination compared to nonintervention caregivers, although there was no evidence that changes in stress perceptions mediated such differences (Vedhara et al., 2003).

The studies linking stress to Ab titers following vaccination clearly implicate the humoral arm of adaptive immunity as one important mechanism linking stress to infectious disease susceptibility. One question, however, relates to the kinetics of the Ab response and the phase in which stress may influence susceptibility to disease. In one of the only studies that we know of to examine this question, Miller and colleagues (2004) examined daily assessments of stress and its association to Ab production to an influenza vaccination in healthy participants. Daily levels of stress were followed for three days prior to and ten days postvaccination. Results of this intriguing study found that stress prior to and on the day of the vaccination was not related to subsequent Ab production. However, from the third day postvaccination, daily stress was associated with less Ab production, with the strongest independent effect evident on the tenth day postvaccination (Miller et al., 2004). Of course, the findings regarding the kinetics of the susceptible period need to be considered in light of the healthy population because these patterns may change as a function of an individual's immune status (e.g., caregivers).

In an attempt to model biological mechanisms, several studies have examined if neuroendocrine processes were responsible for some of these stress-induced vaccination effects. Cortisol is a prime candidate given its general immunosuppressive effects (Munck, Guyre, & Holbrook, 1984). In the case of Ab production following vaccination, one study found little evidence that changes in cortisol

were responsible for such differences in healthy participants (Miller et al., 2004). However, a study looking at the chronic stress of caregiving found associations between stress, cortisol, and Ab titers that were consistent with mediation (Vedhara et al., 1999). In addition, Cacioppo and colleagues (1998) reported that cortisol reactivity to acute psychological stress predicted a decline in the T-cell response to an influenza vaccination in older adults. These data suggest that cortisol may play a relatively larger role in stress-induced immune changes during chronic stress or in populations with more compromised immune systems.

Animal models may provide a stronger test of neuroendocrine mediation because of the increased experimental control and more detailed assessments that can be obtained. In a murine model of influenza infection, restraint stress was associated with a virus-specific decrease in IL-2, IL-10, and interferon- γ production (Dobbs et al., 1996). These effects were blocked by the glucocorticoid blocker RU-486. It should be noted that although hormones of the HPA axis appear important, there are other hormonal pathways that need to be considered. For instance, in one study stress was linked to a poorer Ab response to a novel antigen in rats (Shao et al., 2003). However, significant correlations were only found between Ab titers and norepinephrine levels ($r = -.56$) but not corticosterone levels. Sheridan et al. (1998) also reported that the effects of restraint stress on lymphocyte trafficking and cytokine responses in virus-infected rats were mediated by activation of the HPA axis. However, the decreased cytolytic T-cell response to stress was not influenced by treatment with RU-486 but by β -adrenergic blockade, which suggests a sympathetic mechanism for this effect.

Although many studies have examined cortisol levels at one point, or in some cases averaged over an extended period of time, some research suggests the importance of modeling repeated exposure to cortisol. Such studies would be consistent with the role of stress exposure in these disease processes. *In vitro* studies suggest that cortisol can reactivate latent EBV (Glaser et al., 1995), the kinetics of such changes were recently tested by Cacioppo et al. (2002). These researchers incubated latently infected cells in varying concentrations of dexamethasone (DEX) (i.e., 10^{-5} M to 10^{-9} M every 24 hours for three days). The different concentrations of DEX were thought to model the *in vivo* effects of pulsatile cortisol changes that are likely to occur with acute stressors. Control cells were incubated with media only, or a single concentration of DEX for three days. Replicating prior research, it was found that the control media alone resulted in only a small (2–3%) percentage of EBV antigen positive cells, while single concentrations of DEX were associated with greater reactivation of EBV as measured by antigen positive cells after three days (5.63–8.06%). However, varying the concentration of DEX over three days resulted in a threefold or greater increase in EBV antigen positive cells. These results are

consistent with the notion that pulsatile changes in HPA hormones, which covary with repeated exposure to stress, may have greater health consequences than tonic levels of these hormones.

Promising evidence for mechanism also exists regarding the neuroendocrine pathways potentially responsible for the links between stress and HIV infections (Kopnisky, Stoff, & Rausch, 2004). *In vitro* studies suggest that incubation of HIV infected cells with glucocorticoids can increase viral load in some cell lines (Markham et al., 1986). In work using a primate model of HIV infection (simian immunodeficiency virus, or SIV), Capitanio, Mendoza, Lerche, and Mason (1998) examined the influence of social stress on various outcomes. Results revealed that infected animals in stressful (unstable) social groups had lower basal cortisol and shorter survival. The investigators speculated that the lower baseline cortisol levels might indicate a dysregulation of the HPA axis as often seen with posttraumatic stress patients (e.g., Yehuda et al., 1990).

Research also suggests the importance of considering other neuroendocrine processes in HIV+ individuals. As reviewed earlier, both SNS and opioid processes appear to inhibit aspects of immune function and hence may play a role in HIV progression. *In vitro* studies suggest that NE can increase HIV replication, an effect that appeared mediated by a β -adrenergic mechanism (Cole et al., 1998). Similar *in vitro* effects of opioid hormones (e.g., morphine) on HIV replication have been found (Li et al., 2003). Moreover, opioids appear to increase macrophage susceptibility to infection, possibly by up-regulating CCR5 receptor expression which is an important coreceptor for HIV infection (Li et al., 2003).

Research also suggests the promise of modeling the coordination among the cardiovascular, neuroendocrine, and immune responses during acute stress and its association to infectious disease risk. It is assumed that these acute stress paradigms index how an individual responds to stress in their daily lives. In one study, older women participated in a combined math and speech stressor and were divided based on a median split on pre-ejection period (PEP) reactivity scores (Cacioppo et al., 2002). Consistent with the possibility that these paradigms tap into how individuals respond to stress in daily life, high PEP reactors (indicating greater sympathetic control of the heart) showed greater EBV titers than low PEP reactors. This research team also found that PEP reactivity to acute psychological stress predicted a decline in the T-cell response to vaccination three months later (Cacioppo et al., 1998). Given the association between PEP reactivity and cortisol changes during acute stress (Cacioppo et al., 1995; Uchino et al., 1995), these data suggest that individuals characterized by high cardiac sympathetic reactivity may be more at risk for infectious diseases because of co-activation of the HPA axis during daily stress. These data, again, highlight the importance of considering components of both stress reactivity and exposure in modeling infectious disease risk.

Although most research examining autonomic modulation of stress-induced immune responses has focused on the SNS, there is evidence to indicate that parasympathetic influences on immune function may also be important (Haas & Schauenstein, 1997; Tracey, 2002). Gordon, Cohen, and Wilson (1978) provided evidence that lymphocytes express muscarinic receptors. There also appears to be vagal innervation of lymphoid tissues (Najima, 1995; Rinner et al., 1994). In a preliminary study, PNS denervation resulted in a decreased antibody response to sheep red blood cells in mice (Alito et al., 1987). These data are opposite of those reported following SNS denervation and suggest that the PNS may potentiate lymphoid immune processes (but see discussion of methodological issues in Bellinger et al., 2001).

Although more data are needed, existing studies suggest that hormones of the PNS tend to potentiate aspects of the cellular immune response. For instance, incubation of cholinergic agonists (i.e., carbamylcholine) with T-cells resulted in greater cytotoxic activity (Strom et al., 1974; Katz, Zaytoun, & Fauci, 1982). Activation of muscarinic receptors appears responsible for the enhanced cytotoxicity because muscarinic antagonists (i.e., atropine) but not nicotinic antagonists (e.g., *d*-tubocurarine) blocked the effects of PNS agonists on cell-mediated cytotoxicity (Katz, Zaytoun, & Fauci, 1982; Strom et al., 1974). Consistent with the importance of PNS activation, one recent study found that a passive coping task, which resulted in co-activation of the SNS and PNS was associated with the largest increases in salivary proteins involved in innate immunity (Bosch et al., 2003b). These findings are important as such secretory processes serve to protect mucosal surfaces against initial infection.

The importance of not ignoring PNS influences on immune processes is further highlighted by the recently characterized "inflammatory reflex" (Tracey, 2002). In response to inflammation, activation of the PNS serves to blunt the inflammatory response in "real time." This reflex serves to limit pro-inflammatory processes that, if left unchecked, can in some cases be more dangerous than the initial pathogen (e.g., septic shock). This PNS reflex is mediated by nicotinic receptors on cytokine producing cells that decrease the synthesis of pro-inflammatory cytokines (e.g., macrophages, Tracey, 2002).

In terms of component stress processes, very little evidence exists on the role of stress recovery on immune-mediated disease processes. However, there is evidence indicating that restorative processes may play an important role in stress-induced susceptibility to infectious disease. Although critical data are just appearing, research appears consistent with the important role of sleep in immune function (Irwin, 2002). Even acute stress predicts decreased objective (e.g., rapid eye movement count) and subjective (e.g., sleep quality) aspects of sleep (Germain et al., 2003; Morin, Rodrigue, & Ivers, 2003). In one study, Lange and colleagues (2003) examined if sleep deprivation (i.e., 36 hours) following a Hepatitis A vaccination

influenced subsequent Ab responses. Results showed that the immediate effects of sleep deprivation included less release of growth hormone, prolactin, and dopamine. Sleep deprivation started to have an effect on the primary immune response about 14 days after vaccination and became larger up to 28 days postvaccination. The authors speculated that early immune processes related to IL-2 production, a cytokine that enhances both T- and B-cell differentiation, may have been responsible for these effects.

Importantly, several studies have now shown that sleep disturbances mediate the effects of stress on aspects of immunity for more chronically stressed participants (Cruess et al., 2003; Hall et al., 1998; Ironson et al., 1997). These studies have reported mediation of stress effects on aspects of immune function in victims of natural disasters (Ironson et al., 1997), bereaved participants (Hall et al., 1998), and HIV-infected patients (Cruess et al., 2003). For instance, researchers examined the impact of Hurricane Andrew one to four months after the disaster. The stress of Hurricane Andrew was associated with posttraumatic symptoms that in turn were related to lower NK cell activity. Importantly, the onset of new sleep problems statistically mediated the posttraumatic symptoms – NK cell activity relationship.

More recent evidence also implicates stress in the restorative process of wound healing (Kiecolt-Glaser et al., 1998). Following tissue injury, early immune responses play a key role in the wound healing process (Abbas & Lichtman, 2003). For instance, inflammatory cytokines (e.g., IL-1, IL-6) play an initial role in the recruitment of phagocytes (e.g., neutrophils) that then protect and prepare the wound for healing (Barbul, 1990). In one study, Kiecolt-Glaser and colleagues (1995) examined if the chronic stress of caregiving was associated with delayed wound healing following a punch biopsy. Results showed that caregivers produced less IL-1 β and took significantly longer to heal (also see Broadbent et al., 2003). These findings are consistent with animal models of stress and wound repair (Padgett et al., 1998). Such findings are important as delayed wound healing may be related to increased infections (Kiecolt-Glaser et al., 1998). Consistent with this possibility, researchers found that restraint stress in mice was associated with delayed wound healing, and greater levels of opportunistic bacteria compared to control animals (Rojas et al., 2002). These effects were significantly reduced by treating mice with the glucocorticoid blocker RU-486.

TOWARDS AN INTEGRATIVE ANALYSIS OF STRESS AND HEALTH

The research reviewed in this chapter suggests that stress may play a role in the leading causes of death worldwide. There appears to be a reliable link between stress and cardiovascular disease, as well as infectious illnesses. Evidence linking stress to cancer outcomes is controversial,

but progress regarding the concept of cancer immunoediting may be important for future progress by describing the more precise role of immune processes across the full course of the disease. Research linking stress to HIV progression is preliminary, but some evidence exists on such a link.

Because the complexity of these health outcomes, most research linking stress to health, or its underlying pathways, has focused on one disease. However, recent research is painting in broad strokes, a more integrative picture of how these stress-related health outcomes may be coordinated. This view highlights the linkages among the major biological stress systems, and how these processes unfold in the context of specific diseases. An integrative understanding of such processes may be important to identify common (potentially modifiable) pathways, as well as reconcile inconsistencies in prior research (e.g., protective or damaging effects). This more integrative approach is highlighted by research on (a) the role of inflammation in cardiovascular disease (Black & Garbutt, 2002; Libby, 2002; Ross, 1999), (b) coordinated central nervous system (CNS) involvement in the stress response (Chrousos & Gold, 1992; Dunn & Berridge, 1990), and (c) multilevel perspectives on stress and health (Cacioppo & Berntson, 1992).

The role of immune processes in cardiovascular disease. Traditionally, the immune system has been linked to infectious diseases and cancer. Cardiovascular disease can now be added to that list of disease processes with an immunologic component (Libby, 2002; Ross, 1999). Immune processes are implicated in just about every stage of atherosclerosis (Libby, 2002). In fact, inflammatory processes have been linked to more widespread health problems including diabetes, some cancers, and frailty more generally (Coussens & Werb, 2002; Kiecolt-Glaser et al., 2002; Papanicolaou et al., 1998).

One of the earliest events in the atherogenic process is endothelial damage (Ross, 1999). Factors such as differential shear stress at vessel walls, elevated low-density lipoproteins (LDLs), and some infectious organisms (e.g., Chlamydia Pneumoniae) may precipitate endothelial damage (Ross, 1999; Worthley et al., 2001). Although the specific mechanisms linking such triggers to damage are still under investigation, modified LDLs that undergo oxidation (or form immune complexes) can be trapped in vessel walls and injure the vascular endothelium, smooth muscle, or both (Steinberg, 1997). Oxidized LDL is in itself a direct and indirect chemoattractant for monocytes and T-cells via the release of monocyte chemoattractant protein-1 (MCP-1) from endothelial cells (Young & McEneny, 2001).

At early stages of damage, the endothelium begins to express adhesion molecules such as vascular adhesion molecule-1 that help in the binding of immune cells to the vasculature. Monocytes and T-lymphocytes are then recruited to sites of inflammation and migrate into vessel walls via various chemokines (e.g., MCP-1) that

are released from vascular cell walls (Charo & Taubman, 2004). Once inside of vessel walls, these immune cells proliferate and release a variety of growth factors (e.g., platelet-derived growth factors) and cytokines (e.g., IL-1) characteristic of the inflammatory response (Libby, 2002). The release of cytokines from these cells, as well as from vessel walls, further up-regulates the expression of adhesion molecules, while increasing the proliferation of smooth muscle cells (SMC). Macrophages expressing scavenger receptors begin to ingest lipids (e.g., oxidized LDL) to form the foam cell that is characteristic of the advancing lesion.

Of course, inflammation can be beneficial under “normal” conditions. For instance, the inflammatory response appears to play a role in the enlargement of existing vessels and the healing of plaque following thrombosis (Charo & Taubman, 2004; Libby, 2002). However, if the source of damage is not removed, these processes can lead to a vicious cycle of inflammation as cytokines further increase LDL binding to endothelial and smooth muscle walls (Ross, 1999). The resulting advanced lesion has a fibrous cap that protrudes into the lumen and contains elements of the inflammatory response including macrophages, T-cells, foam cells, and lipids (Ross, 1999). Vulnerable plaques have a large ratio of lipids to fibrotic components and such plaques may be responsible for as much as 75% of complications leading to acute coronary events (Worthley et al., 2001). Immune events at later stages can lead to the rupture of such plaques. For instance, macrophages are common in vulnerable plaques and can produce enzymes (e.g., metalloproteinases) that degrade the fibrous cap, while T-lymphocytes release interferon- γ that can impede collagen formation by SMC (Libby, 2002).

Importantly, stress can directly lead to the release of cytokines, which are crucial mediators of the cardiovascular inflammatory response (Black & Garbutt, 2002; Kop & Cohen, 2001). Animal models show that stress increases the release of inflammatory cytokines such as IL-1, IL-6, and tumor necrosis factor- α (TNF- α), as well as subsequent acute phase proteins such as C-reactive proteins (CRP) (Black & Garbutt, 2002). In a meta-analysis of human studies, Segerstrom and Miller (2004) found that IL-6 was significantly increased during both laboratory and brief real world stressors. Less data in humans exists on cytokine production during more chronic stressors (Segerstrom & Miller, 2004). However, existing studies do suggest that chronic stress is associated with increased inflammatory cytokine release (Brydon et al., 2004; Kiecolt-Glaser et al., 2002; Lutgendorf et al., 1999). For instance, Kiecolt-Glaser et al. (2003) examined age-related differences in IL-6 in caregivers of AD patients. These investigators found that the predicted rate of change in IL-6 for caregivers was almost fourfold higher than that of controls and not explained by various demographic factors or health behaviors (e.g., exercise or alcohol consumption).

Stress-induced cytokine production may be mediated by the release of neuroendocrine hormones that influ-

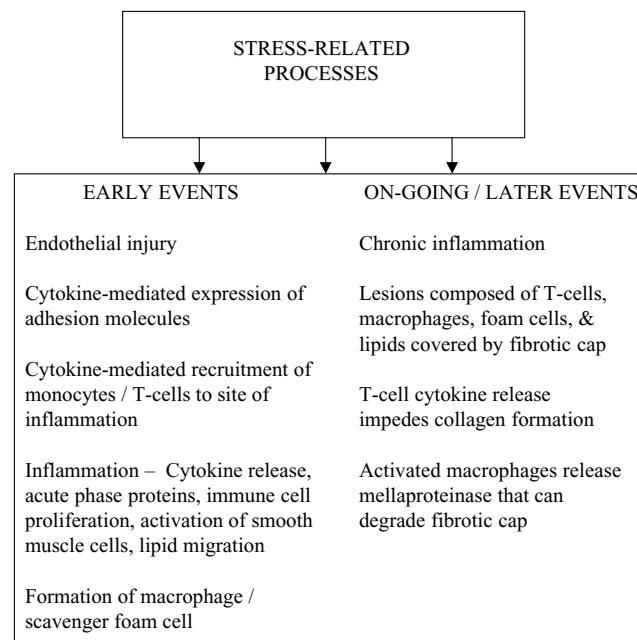

Figure 26.2. The potential role of stress-related immune processes in cardiovascular disease.

ence cytokine release and macrophage or T-cell function more generally (Sanders et al., 2001). However, it is important to note that inflammatory cytokines are not just produced from cells of the immune system (Papanicolaou et al., 1998). For instance, IL-6 is produced by bone marrow stromal cells, epithelial cells, SMCs, and cells of the anterior pituitary (Papanicolaou et al., 1998). When released, such cytokines can cause an increase in adhesion molecules that promote the migration of monocytes and T-lymphocytes characteristic of early endothelial damage (Libby, 2002). Moreover, Bosch and colleagues (2003a) found that acute psychological stress was associated with a selective increase in T-cells that express chemokine receptors. These changes were most pronounced in high cardiac sympathetic reactors and further highlight the importance of a more integrative analysis of stress effects across systems.

Illustrative steps in which stress can influence inflammation and cardiovascular disease risk are provided in Figure 26.2. As detailed above, stress-induced cytokine release can influence early inflammatory processes that are related to cardiovascular disease. Cytokine release during stress may also influence cardiovascular disease processes as the lesion advances. The cytokine macrophage colony-stimulating factor (M-CSF) is implicated in the development of the foam cell as it can augment scavenger receptor expression on macrophages (Libby, 2002). M-CSF, as well as IL-1 and TNF- α , can also increase the binding of LDL to vessel walls, and up-regulate the LDL-receptor gene (Libby, 2002; Ross, 1999). At later stages of the lesion, plaque disruption can be influenced by cytokines (Libby, 2002). Activated T-cells produce interferon- γ that can decrease collagen production by SMC. Cytokines such as IL-1 and

TNF- α can increase the production of the protein metalloproteinase that in turn can degrade the fibrotic cap of advanced lesions (Rajavashisth et al., 1999). The result is a weaker fibrotic cap that is susceptible to rupture due to factors such as increased hemodynamic stress (Libby, 2002).

An additional pathway by which stress-induced inflammatory cytokine release can influence cardiovascular disease is via the subsequent release of acute-phase proteins (Papanicolaou et al., 1998). IL-6 is a potent stimulator of CRP and fibrinogen production from the liver. CRP has received much recent attention as it has been shown in a number of large prospective studies to predict future coronary risk, even in participants with normal levels of cholesterol (Libby, 2002). Although CRP can be thought of as a clinical marker of inflammatory processes, recent research is showing that CRP may play a direct pro-inflammatory role in the atherogenic process (Khireiss et al., 2004; Verma, Szmitsko, & Yeh, 2004). For instance, CRP may decrease nitric oxide production and increase cytokine production (Verma, Szmitsko, & Yeh, 2004). These factors can up-regulate adhesion molecules and increase monocyte recruitment (Khireiss et al., 2004; Verma, Szmitsko, & Yeh, 2004). Although the release of CRP via IL-6 seems to be an important factor in inflammation and cardiovascular disease, consistent with the crucial role of cytokines in all phases of the atherogenic process, IL-6 continues to predict cardiovascular risk even after statistically controlling for CRP (Ridker et al., 2000).

The more precise mechanisms responsible for cytokine release during stress, and its implications for health more generally, are actively being investigated (Black & Garbutt, 2002; Kiecolt-Glaser et al., 2002). One cytokine of recent interest is IL-6 given its diverse physiological role in inflammation as well as the adaptive immune response (Hawley et al., *in press*; Kiecolt-Glaser et al., 2002). IL-6 predicts a range of health problems including cardiovascular disease, diabetes, osteoporosis, and some autoimmune disorders (Papanicolaou et al., 1998).

The links between stress, IL-6, and other health-relevant physiological changes are starting to be understood. A key first step in this process appears to be stress-induced changes in SNS processes (Papanicolaou et al., 1998). Both stress and SNS agonists increase the production of IL-6 (Soszynski et al., 1996), and β_2 -adrenergic blockade eliminates these effects (Soszynski et al., 1996; van Gool et al., 1990). Importantly, the mechanism of action appears to be central β_2 -adrenergic receptors as agonist more selective to such central processes (e.g., L-propanolol), but not more peripheral processes reduce the stress-induced increase in IL-6 (Soszynski et al., 1996).

Following SNS release, IL-6 is a potent stimulator of the HPA axis (Papanicolaou et al., 1998; Webster et al., 1998). Administration of IL-6 is associated with an increase in glucocorticoids that can occur through a CRH-dependent or independent mechanism (Kariagina et al., 2004). For instance, Bethin, Vgot, and Muglia (2000) found IL-

6 receptors on both pituitary and adrenocortical cells. These investigators also found that knockout mice deficient in IL-6 produced less corticosterone during stress. However, knockout mice deficient in both CRH and IL-6 produced the lowest levels of corticosterone (also see Kariagina et al., 2004). Under normal conditions, the subsequent increase in glucocorticoids serves as a negative feedback mechanism to down-regulate the inflammatory response (Papanicolaou et al., 1998). However, high levels of stress can decrease the sensitivity of immune cells to the inhibitory effects of glucocorticoids (Miller, Cohen, & Ritchey, 2002; Stark et al., 2001). One mechanism for this effect may be high or prolonged cytokine release that can directly modulate important isoforms of glucocorticoid receptors on cytokine producing cells (Webster et al., 2001).

Although IL-6 can influence the release of CRH, there is good evidence that the links between IL-6 and CRH are bidirectional. CRH plays an important role in the *in vitro* and *in vivo* regulation of IL-6 (Webster et al., 1998). Incubation of LPS-challenged macrophages with CRH leads to an increase in inflammatory cytokines, including IL-6 (Agelaki et al., 2002). Similar findings were demonstrated *in vivo* as mice given antalarmin (a CRH-receptor antagonist with both central and peripheral effects) showed decreased inflammatory cytokine responses to LPS. Moreover, the biological significance of these CRH-induced processes was shown as antalarmin prolonged survival in mice challenged with LPS-induced septic shock (Agelaki et al., 2002). Thus, IL-6 can activate and be activated by CRH, and CRH is in turn a major coordinator of the biologic and behavioral responses seen following stress (Habib et al., 2000; Webster et al., 1998).

Despite links between stress and inflammation, there are several complexities in these associations that require further discussion. First, although evidence does exist on the pro-inflammatory influences of IL-6 (e.g., via induction of CRP, see Verma, Szmitsko, & Yeh, 2004); the ability of IL-6 to activate the HPA axis suggests that it may also have important anti-inflammatory properties. In fact, Hawley and colleagues (*in press*) have argued that the primary function of IL-6 may be anti-inflammatory. Consistent with this view, IL-6 in itself does not appear to up-regulate inflammatory mediators (e.g., prostagladins) or the expression of adhesion molecules (Barton, 1997). IL-6 can also down-regulate the synthesis of pro-inflammatory cytokines (i.e., IL-1, TNF- α), and increase the synthesis of IL-1ra and the soluble TNF receptor factor p55 (Tilg et al., 1994). IL-6 knockout mice also produced higher levels of TNF- α in response to endotoxin challenge, and administration of IL-6 in these knockout mice eliminated the observed differences in TNF- α production (Xing et al., 1998). These IL-6 knockout mice also had a 50% lower survival rate in response to endotoxin challenge. Interestingly, levels of IL-10 were not different in the IL-6 knockout mice suggesting that IL-10 could not compensate for the deficiency in IL-6 (Xing et al., 1998). As a result of existing data, Hawley

and colleagues (*in press*) caution researchers in interpreting the results of correlational studies because it is possible that elevated levels of IL-6 may be co-activated in an attempt to control inflammation. Future research will be necessary to determine the disease-relevant contexts in which IL-6 has pro- or anti-inflammatory effects.

A second complexity related to links between stress and inflammation that requires increased attention relates to the conditions under which normal control points can be disrupted (Hawley et al., *in press*). One important control mechanism is activation of the HPA axis that tends to suppress immunity (Munck, Guyre, & Holbrook, 1984). However, chronic stress can also lead to a state of glucocorticoid resistance (Miller, Cohen & Ritchey, 2002; Hawley et al., *in press*). For instance, pro-inflammatory cytokines such as TNF- α can modulate important isoforms of glucocorticoid receptors on cytokine producing cells (Webster et al., 2001). The cytokine macrophage migration inhibitory factor (MIF) is also receiving attention as an important mechanism of glucocorticoid resistance (Hawley et al., *in press*). MIF is a pro-inflammatory cytokine that is released from the anterior pituitary, as well as from macrophages during glucocorticoid release (see reviews by Baugh & Donnelly, 2003; Hawley et al., *in press*). It has been shown to override the suppressive effects of glucocorticoids and may control the “set-point” of the inflammatory response (e.g., via modulation of NF- κ B activity).

CNS coordination of the stress response. Evidence for coordinated central pathways involved in the stress response provides further impetus for a more integrative view of the association between stress and health. Of course, the central pathways involved in the stress response are complex and moderated by a number of factors including the duration of exposure, prior experience, and the social environment. These moderational influences are not surprising given the role of multiple brain structures (e.g., hippocampus, amygdala) with reciprocal connections that are crucial to interpreting, responding to, and receiving feedback about potential threats (Chrousos, this volume, Dunn & Berridge, 1990; Gray, 1993). However, there are identifiable brain structures and pathways that appear critically important in the coordinated stress response.

One promising integrating mechanism linking stress to health outcomes may involve the activation and release of central CRH (Dunn & Berridge, 1990). Central administration of CRH mimics many of the physiological and behavioral states seen during stress. For instance, central CRH activates both the ANS and HPA axis (Irwin et al., 1989) and stimulates the release of β -endorphins (Rivier et al., 1982). Increased CRH in brain regions involved in emotional responses, such as the amygdala, paraventricular nucleus, locus coeruleus, and cortex, mediate many behavioral responses to stress (Dunn & Berridge, 1990). These include increased freezing behavior (Swiergiel, Takahashi, & Kalin, 1993), decreased appetitive behavior (Krahn et al., 1986), decreased sexual behavior (Sirinaths-

inghi et al., 1983), increased grooming behavior (Holahan, Kalin, & Kelly, 1997), and an enhanced startle response (Lee & Davis, 1997). In fact, the CRH receptor antagonist antalarmin attenuates both biological and behavioral responses during stress (Habib et al., 2000).

A simplified version of central stress pathways is depicted in Figure 26.3. CRH containing neurons and receptors are prevalent in the amygdala, hypothalamus, and the locus coeruleus (Gray, 1993; Menzaghi et al., 1993; Valentino, Foote, & Page, 1993). Subsequent efferent pathways provide one mechanism by which stress may be coordinated to influence health. For instance, the amygdala has direct projections to the hypothalamus (Gray, 1993). Release of CRH from the hypothalamus activates the HPA axis. As reviewed earlier, cortisol has been linked to some of the stress-related changes in immune function. Prolonged stress can down-regulate hippocampal glucocorticoid receptors that are responsible for turning off the cortisol response, which is a process postulated to play a role in the biological aging process (Sapolsky, 1996). The hypothalamus also has efferent projections to the ANS via the sympathetic preganglionic neurons of the intermediolateral cell column, the ventral lateral medulla, and the nucleus tractus solitarius (Menzaghi et al., 1993). In combination, the release of HPA hormones and activation of the ANS may account for many of the stress-induced changes in health detailed earlier in this review.

Although CRH activates the noradrenergic system, it is also apparent that reciprocal interactions exist (Chrousos & Gold, 1992; Dunn & Berridge, 1990). For instance, catecholaminergic inputs are evident to hypothalamic cell regions containing CRH and appear to stimulate central CRH release via an α_1 -adrenergic mechanism (Al-Damluji et al., 1987; Cunningham & Sawchenko, 1988). As discussed earlier, central adrenergic mechanisms are also implicated in the release of IL-6 (Soszynski et al., 1996; van Gool et al., 1990) and IL-6 can activate the HPA axis (Papanicolaou et al., 1998). The central coordination of these stress-related inflammatory processes may further explain variance in the links between stress and health (Papanicolaou et al., 1998).

It is also important to emphasize that there are critical afferent (ascending) pathways to brain structures that may be activated in stressful circumstances. Vagal afference appears to play an important role in the immune response to infection that may then have implications for stress processes (Maier & Watkins, 1998). Berntson, Sarter, and Cacioppo (2003) also reviewed evidence for the role of these afferent pathways in modulating anxiety-related physiological reactions. According to their model, these ascending pathways provide an opportunity for anxiety or stress-induced physiological reactions to influence cortical information processing (e.g., attentional functions). For instance, activation of the locus coeruleus via afferent pathways is linked to increased EEG arousal and vigilance to significant stimuli (Aston-Jones et al., 1996). Many of these “bottom-up” processes appear mediated by the basal

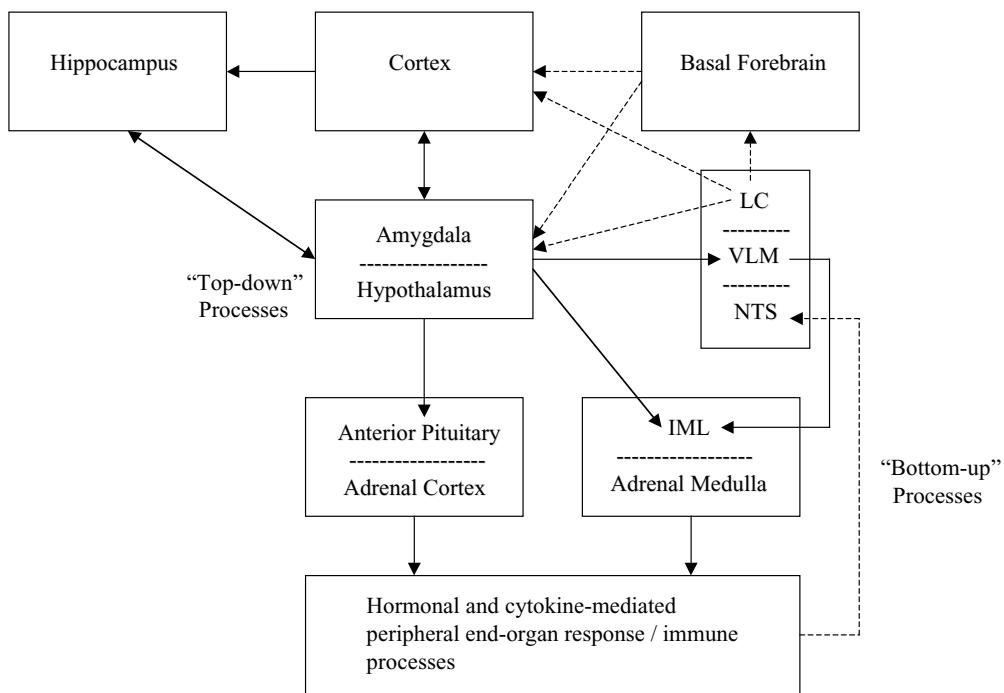

Figure 26.3. Illustrative model of central mechanisms potentially underlying stress-induced health links, including efferent (solid lines) and afferent (broken lines) projections. Abbreviations: IML = sympathetic preganglionic neurons of the intermediolateral cell column, LC = locus coeruleus, NTS = nucleus tractus solitarius, and VLM = ventral lateral medulla.

forebrain cholinergic system that has (a) reciprocal connections with the amygdala, and (b) widespread projections to the cerebral cortex (Berntson, Sarter, & Cacioppo, 2003). As a result it is well situated to participate in the potentiation of stress-related responses.

Multilevel analyses of stress and health. Although not a focus of this review, a more integrative view of stress and health will also need to consider diverse but complementary levels of analyses. Although most of the emphasis has been on biological mechanisms, understanding stress effects on disease may require similar attention to the social, personologic, psychological, and behavioral levels of analyses (Cacioppo & Berntson, 1992). In many cases, these different functional levels are embedded; hence, processes at more macrolevels can influence the more microlevel processes and vice versa (Cacioppo & Berntson, 1992).

Integrative research on the mechanisms linking stress to health across functional levels of analyses is in its infancy. However, the prior literature does provide some data on these processes. At a more macrolevel of analysis, there is evidence that social stressors may be particularly important sources of stress explaining variations in health outcomes (e.g., Kiecolt-Glaser et al., 1996; Padgett et al., 1998). For instance, Padgett and colleagues (1998) exposed latently infected HSV rats to either social stress (i.e., social group reorganization) or physical stress (i.e., restraint stress). Results revealed that only social stress was associated with significant reactivation of HSV (i.e.,

over 40% of socially stressed animals). These findings are consistent with research indicating that social stressors appear to have relatively large and lasting effects on mood (Bolger et al., 1989) and immunity in humans (Cohen et al., 1998) and nonhuman primates (Coe, 1993).

There are also potential personality factors that may influence the links between stress and health. Personality factors such as neuroticism are linked to greater subjective stress and hence may be responsible for the results of stress on some health outcomes (Bolger & Eckenrode, 1991). Cohen and colleagues (1998) reported that self-esteem and the big-five personality factors could not account for the effects of stress on susceptibility to the common cold. However, a likely role for personality factors is in the moderation of stress-induced health processes. Prime candidates for examination include trait hostility and optimism that appear to influence physiological processes and health-related outcomes (Scheier & Bridges, 1995; Smith & Gallo, 2001).

Stress has been linked to changes in health behaviors such as exercise and alcohol consumption (Ng & Jeffrey, 2003). Therefore, it is also important to evaluate the effects of health behaviors as pathways responsible for the effects of stress on health outcomes. In most of the studies detailed earlier, health behaviors including exercise and alcohol did not explain much of the variance in the effects of stress on health (Cohen et al., 1998; Kiecolt-Glaser et al., 1995, 1996). However, it is clear that stress influences health behaviors, and health behaviors are tied to similar physiological processes that are linked to health

risks (Kiecolt-Glaser et al., 2002). Better measurement and conceptualization of health behaviors in light of more integrative mechanisms may allow a clearer test of their mediational role in explaining links between stress and health.

One discussion that bears on these different levels of analyses involves the stress components reviewed in this chapter. These components linking stress to health include exposure, reactivity, recovery, and restoration (Cacioppo & Berntson, *in press*). Of these components, relatively little research exists on stress recovery, especially in regards to immune-mediated disease processes. Although the components of stress reactivity and stress exposure were often confounded, there was good evidence for links to disease outcomes, with interactive effects apparent when modeling both processes (e.g., Cohen et al., 2002). Research on chronic stress and sleep disturbances also highlights the potential direct role of reactivity and exposure on restorative processes (Figure 26.1). Beyond this, little empirical evidence exists in these studies on how these stress components may have cascading or reciprocal effects as depicted in Figure 26.1. Future research will need to take a more integrative approach to modeling these stress components and clarify their related (mediated), independent, or interactive effects on disease processes.

Of these components, restorative processes are particularly interesting given their potential unique association with health outcomes. Indeed, preliminary evidence exists linking restorative processes such as sleep and wound healing to health-related stress outcomes (Irwin, 2002; Kiecolt-Glaser et al., 1998). Although the concept of restorative processes is promising, several questions will be important for future research to address. One question relates to what indices or outcomes are most relevant to restorative processes. Restoration is linked to anabolic (energy conserving) processes and a number of potential indicators seem relevant such as growth hormone release and PNS processes (see Hawkley & Cacioppo, 2004). Integrating measurement and conceptual issues related to restorative processes at different functional levels would provide more guidance to future research. A second question concerns the balance of anabolic to catabolic processes that is health relevant (Epel et al., 1998). Anabolic processes play an important role in physiological regulation, but direct research on how it counteracts harmful catabolic processes is needed. A final, related question is how anabolic and catabolic processes unfold over time in ways that are health relevant. Epel and colleagues (1998) have argued that one process relates to having sufficient time following catabolic processes to recuperate. In general, research on restorative processes as they relate to stress and health is just beginning, but process questions will soon begin to take on added importance.

CONCLUSIONS

In this chapter, we reviewed evidence linking stress to illness. These diseases include the leading causes of mor-

bidity and mortality: cardiovascular disease, cancer, and infectious illnesses. There was strong evidence linking stress to cardiovascular and infectious diseases. The literature linking stress to cancer was controversial, but future research guided by the emerging concept of cancer immunoediting may prove informative. Importantly, impressive evidence exists on the biological mechanisms potentially linking stress to these disease processes. Of these, immune processes (e.g., inflammation) appear to play a critical role across these diseases and, along with an examination of CNS processes, may provide the impetus for an integrative approach to the study of stress and health. The time is ripe for such an approach. Research that elucidates the complex links outlined in this chapter at different functional levels of analyses may play a crucial role in helping us better understand, in Selye's (1956) words, the "secrets of health and happiness" and the "penalties for failure in this great process of adaptation."

Sleep and Dreaming

R. T. PIVIK

INTRODUCTION

The majority of our behavioral and cognitive lives are spent in the waking state – a time during which activities viewed as essential to personal existence and continuation of the species is accomplished. It is, therefore, to be expected that for many the waking state is likely to be considered “the sole portion of...existence that ‘counts’ in any way, sleep appearing as ‘time out’ from the game of living” (Kleitman, 1963, p. 3). However, although sleep may appear to constitute an interruption of the critical activities of wakefulness, it is indisputable that the alternation between sleep and wakefulness is essential to “normal” existence in higher life forms. The importance of sleep to normal waking activities can be immediately appreciated when the well-documented adverse effects of sleep reduction on waking behavioral and psychological functions are considered – effects extending from decreased alertness and impaired performance (Gillberg & Akerstedt, 1994; Monk, 1991) to death (Bentivoglio & Grassi-Zucconi, 1997; Everson, 1995; Horne, 1988; Rechtschaffen et al., 2002). There is gathering evidence as well that specific aspects of learning and memory during wakefulness may benefit from, or require, sleep-dependent processes (Fischer et al., 2002; Born 2002; Mölle et al., 2004; Stickgold, James, & Hobson, 2000). Clearly, these two states interact in a complementary and synergistic relationship to maintain and extend life, and although the precise nature of this codependence has, to a great extent, been obscured by a lack of detailed knowledge regarding the physiology and psychology of sleep, recent advances in these areas have provided significant insights into these puzzling within- and between-state variations and relationships.

It is at the same time surprising and revealing that sleep should support any form of cognitive activity – surprising because at first glance it is difficult to imagine the purpose of mental activity during such sustained periods of disengagement from the environment, and revealing because of the unexpected psychophysiological relationships the presence of such activity implies. Still, if concepts subscribing to the interaction or psychophysi-

ological parallelism of mind-body relationships are even closely approximated, then it would be expected that the marked behavioral and physiological sleep-wakefulness differences would be reflected in equally marked differences in the characteristics of associated cognitive activity. In this instance, state-dependent expectations are apparently reinforced because, unlike the generally more organized, rational, and self-directed nature of waking cognition, cognitive activity during sleep is seemingly disorganized, distorted, and subject to little volitional control. This distinctive cognitive behavior – not associated with an abnormal-state or condition, yet so apparently different from waking mental activity – has been provided with an appropriately distinctive name: dreaming.

HISTORICAL BACKGROUND

The relative inaccessibility of processes underlying sleep and dreaming fostered wide-ranging speculation regarding the nature and function of these activities. Early theories attributed sleep to various changes in the distribution, temperature, or constitution of blood, and many considered the difference between sleep and death simply a matter of degree (Kleitman, 1963; Nitz, 1993). Later concepts extending into the early twentieth century localized sleep to the brain and ascribed many functions to this state, including enhancing digestion, creating new “animal spirits” required for waking behavior, and eliminating potentially harmful “humors” from the body (Wittern, 1989). Paralleling these notions were beliefs that dreams contained messages foretelling the future, revealed cures for illnesses, or provided unique access to the unconscious (Kramer, 1994; Webb, 1993). These various conceptualizations had in common a view of sleep as a unimodal state, and dreams as sporadic, relatively rare events.

Although sleep and dreaming have long been sources of fascination and speculation, scientific interest in these behaviors significantly intensified in the twentieth century. In the second edition of his classic text summarizing information regarding sleep and wakefulness Kleitman (1963) listed over 4,000 references – less than 2% of which referred

to publications before the twentieth century. However, the most marked acceleration of experimental studies into the nature of sleep physiology and psychology can be traced to the mid-twentieth century when Eugene Aserinsky, a physiology doctoral student at the University of Chicago, observed episodes of eye movement activity during sleep in what were the first whole-night polygraphical recordings of such activities (Aserinsky, 1953). Although slower than waking eye movements of comparable amplitude, and more impressed with the “jerkiness” than the velocity of these eye movements, Aserinsky nevertheless elected to characterize this as Rapid Eye Movement (REM) activity in large part to avoid “the anticipated taunts relative to the popular slang meaning of ‘jerk’” (Aserinsky, 1996; p. 218).

This observation, utilizing a newly emerging technology that made possible longterm recordings of electrophysiological activities, led to a series of publications that revolutionized and redirected thinking regarding both the nature of sleep and the occurrence of dreaming (Aserinsky & Kleitman, 1953, 1955; Dement, 1955; Dement & Kleitman, 1957a, 1957b; Dement & Wolpert, 1958a, 1958b). The finding of recurring episodes of physiological activation embedded within sleep that were unlike either wakefulness or the remainder of sleep flew in the face of existing concepts of sleep as a unitary, passive state. So unique were these rapid eye movement periods, that they prompted investigators to consider REM sleep as a third state of existence (Dement, 1969; Snyder, 1966; Steriade & McCarley, 1990). Not only did these REM periods deviate in their physiological characteristics from other normal states, but upon awakening from these episodes subjects commonly reported dreaming – suggesting that an objective index had been identified for determining “the incidence and duration of periods of dreaming” (Aserinsky & Kleitman, 1953, p. 274).

Although electrographic recordings of brain wave and oculomotor activities assisted in the discovery of REM sleep and its association with dreaming, these observations did not require such technologic assistance. Determination of whether an individual is asleep can be made subjectively with reasonable reliability, and movements of the eyes are readily apparent from associated displacements of the corneal bulge under the eyelids. Furthermore, because of the prominence of visual images in dream reports, it had long been speculated that dreams would be accompanied by eye movements (Griesinger, 1868; Ladd, 1892). Given such considerations, why had these remarkable periods of physiological and cognitive activation – which occur nightly, are distributed across the night, and may last 20 minutes or longer – not been previously discovered? In a publication in which he chronicles the discovery of REM sleep, Aserinsky (1996) considered this question, with the following observations:

the obvious answer must lie in human behavior. Since the first REM period is not obvious during the first couple of hours of sleep, and cyclicity would require a still longer period of observation, the discovery of REM would have required an

obsessive, highly motivated individual to peer continually for hours at a sleeper’s eyes. This would explain the failure of the layman to discover REM, but what about scientists who are infamous for both obsessiveness and motivation, and thus should have looked for the eye movements? My guess is that no one was sufficiently driven to spend an inordinate amount of time to fill in the gaps of sleep studies in which the position of the eyes was noted by occasional lifting of the sleeper’s eyes. (pp. 226–227)

The technologic capability of recording physiological measures over long periods of time may not have been required for the discovery of REM sleep, but it was essential for the subsequent exploration and detailing of the general physiology of sleep. Although Aserinsky (1996) considered the relationship of rapid eye movements in sleep to dreaming as “almost incidental with respect to its import in understanding brain function” (p. 226), it was the linkage of sleep-state physiology to sleep-state cognitive activity that provided the major impetus for the next two decades of sleep and dream research, and established the foundation for what could be considered the “new sleep research.” Furthermore, this focus on psychophysiological relationships during sleep presented an opportunity to determine if such relationships are maintained across states and, consequently, to provide a broader understanding of mind-body relationships. Even before specific physiological sleep-wakefulness differences were determined it was apparent that these states differed along significant dimensions, among which was the profound change in level of consciousness. Relative to wakefulness, there is a dramatic decrease in awareness of both the external and internal physical environments during sleep as reflected by increased sensory thresholds to external and internal stimulation, as well as by an absence of appreciation of significant physiological variations, for example, galvanic skin response activation during slow wave sleep or breathing cessation associated with sleep apnea (Guilleminault, 1994; Johnson, 1973). With few exceptions (e.g., lucid dreaming), this decrease in awareness is accompanied by a general loss of volitional control over physiological and psychological processes. The relative inaccessibility of sleep processes, together with the associated greatly diminished awareness and control, created both real and apparent obstacles to the scientific study of these behaviors. Still, the very factors that complicated the study of these processes also removed or attenuated potentially confounding variables commonly associated with investigations during wakefulness (e.g., stress, expectations, and undefined variations in level of arousal), raising the possibility that relationships either obscured by or absent during wakefulness would be unmasked during sleep.

PHYSICAL CONTEXT

Questions concerning why and how wakefulness-sleep state alternations occur have motivated speculation and inquiry into the mechanisms of these variations. Early

views of sleep as the passive behavioral default which results when wakefulness-maintaining activities from specific sensory (Bremer, 1937, 1938) or nonspecific brain-stem reticular pathways (Moruzzi & Magoun, 1949) were withdrawn, had to be modified to incorporate evidence of active sleep promoting processes. This evidence was provided by brainstem and cortical stimulation and lesion studies (reviewed in Jones, 2000; Steriade & McCarley, 1990) as well as by indications of active control processes effecting and modulating sleep, such as recurring periods of activated (REM) sleep and predictable sleep pattern variations across the night (i.e., the sleep cycle). The separation of sleep promoting mechanisms into passive and active categories provided a conceptual framework within which studies could be formulated and interpreted. However, technologic advances permitting more discerning anatomical and neurophysiological evaluations of systems and processes underlying sleep and waking behavior made it apparent that the passive-active dichotomy was too simplistic, and that sleep initiation and maintenance most likely involved cascading effects and interactions resulting from both the passive effects of functional deafferentation as well as activation of structures with hypnogenic properties. The search for specific brain regions or centers, the activation of which are essential to the occurrence or promotion of sleep, identified several candidates, for example, the solitary tract nucleus in the medulla, the preoptic basal forebrain area, the anterior hypothalamus, and the brain stem raphe nuclei for nonrapid eye movement (NREM) sleep, and the pons for REM sleep (for reviews see Jones, 2000; McCarley, 2004; Steriade & McCarley, 1990).

Paralleling and complementing these studies were those capitalizing on developments in the detection and localization of biochemicals in the peripheral and central nervous systems and how these compounds were related to state determination. Although the notion of a chemical hypnogenic factor had been hypothesized early in the twentieth century (Pieron, 1913), the technology necessary to effectively pursue this line of inquiry did not begin to become available until the 1950s and 1960s, and since that time this technology has become increasingly sensitive and sophisticated. Studies using these techniques have implicated interactions among a wide range of chemicals that exert sleep or wakefulness promoting influences, and have reinforced research focused on anatomical or neurophysiological aspects of sleep in demonstrating the complexity of systems involved in sleep-wakefulness state determination. These compounds, produced centrally and peripherally and acting as neurotransmitters, neuromodulators or neurohormones, have been variously localized to neurons, cerebrospinal fluid, and blood (see Basheer et al., 2004; Jones, 2000; Krueger & Kamovsky, 1995; Steriade & McCarley, 1990 for reviews). These quests for sleep centers and chemical sleep factors have proven to be highly informative and heuristically beneficial, and the outcomes of these studies have been summarized as follows: "no sleep or wake state *in toto* can be said to have a center and... few,

if any, components of waking-sleep states have 'a center'" (Steriade & McCarley, 1990, pg. 21), and "no single chemical neurotransmitter, neuromodulator, or neurohormone has been identified that is necessary or sufficient for the generation and maintenance of sleep or waking. Instead, multiple factors and systems are involved in the onset and maintenance of these states" (Jones, 2000, pg. 149). The idea of distributed and interacting systems is being increasingly utilized in theoretical formulations integrating neuronal and neurochemical processes that attempt to explain state determination (Krueger & Karnovsky, 1995; McCarley & Hobson, 1975). Ultimately, understanding the mechanisms responsible for state determination and the relationship of these mechanisms to behavior will provide insights into the function of sleep – an enigma that continues to elude resolution (Greene & Siegel, 2004; Rechtschaffen, 1998).

SOCIAL CONTEXT

It requires little reflection to appreciate that scientific investigations may be unintentionally influenced by aspects of the experimental process such as the laboratory environment, measurement apparatus, experimental demands, and the presence of investigators. These factors may exert what has been termed "reactive measurement effects" (Campbell, 1957) on study outcome measures. Recognizing that the sleeping environment, sleep behavior, and associated personal thoughts (dreams) of individuals are usually considered among the most private of behavioral domains, attempts to study these behaviors would seem to require obtrusive intervention and present multiple opportunities for reactive measurement effects. In attempts to control for or at least minimize such effects, investigators have applied several techniques or procedures. For example, in addition to assuring subject confidentiality with respect to study results, it has proven helpful to introduce subjects to the laboratory environment, procedures and personnel prior to undertaking sleep recordings, or to minimize the number of sensors (e.g., Stickgold & Hobson, 1996). Still, in view of the apparent intrusiveness of procedures necessary to evaluate sleep physiology, statements referring to such procedures as "noninvasive" and "minimally sleep disturbing" would seem to underestimate the sleep disturbance expected under these conditions. However, studies of sleep in populations across the pediatric to geriatric age range during the past half-century have clearly established that most subjects can, and do, sleep well under these circumstances. Commonly, the initial nights in the laboratory are accompanied by sleep disturbance in the form of increased latencies to sleep onset, more body movements, and fragmentation of sleep patterns. Because sleep patterns normally stabilize subsequent to this initial period, these variations have been considered to be transient responses to the novel sleeping environment and instrumentation. This adaptation phenomenon has been termed the "first night

effect" (Agnew, Webb, & Williams, 1966). Once adaptation has occurred, the night-to-night stability of many sleep measures is remarkable. This consistency is expressed across several variables, including the amounts and cyclic characteristics of sleep stages (Figure 27.3), autonomic measures (heart rate and variability: Pivik et al., 1996; Figures 27.5 and 27.6), and specific electrographic events (K-complexes: Johnson, 1973; ponto-genicul-o-occipital spike activity: Jouvet, 1972). The development of portable instrumentation to record physiological parameters necessary for sleep-wakefulness differentiation and sleep staging has allowed the comparison of results from recordings made in subjects' home environments with those obtained from the same subjects studied in the laboratory. The fact that such comparisons have revealed minimal between-condition differences (Sewitch & Kupfer, 1985) attests to the general robustness of sleep processes and the adaptability of subjects.

Concerns regarding the influence of experimental factors on sleep mentation reports have focused on possible confabulation by subjects in the interest of pleasing the investigator, and the extent to which the laboratory environment may directly affect the content in these reports. The potential for experimental confounds because of confabulation is always of concern in situations where other measures, such as those provided by physiological or performance variables, cannot provide corroborative indexes. This issue, of long-standing concern to investigators studying sleep mentation, was effectively addressed by Rechtschaffen (1967) in a series of logical considerations to be used as guidelines for evaluating the acceptance of such reports as true representations of sleep experiences. These guidelines have been summarized as follows:

- 1. Parsimony** – interpretations requiring the fewest assumptions are favored.
- 2. Prevalence** – phenomena known to occur most frequently are favored over those of rare occurrence. For example, in the absence of indications of impaired memory in the recall processes in wakefulness, the subject's postarousal report is accepted as a valid representation of his or her experience, rather than questioned on the grounds of cognitive impairment.
- 3. Plausibility** – an extension of the prevalence guideline, which, however, "gives special emphasis to frequency and occurrence in given situations" (Rechtschaffen & Kales, 1968, p. 7). For example, although it could be assumed that subjects are lying when questioned about the presence and details of dream experiences, one would consider it unlikely that subjects would lie so consistently about dream reports, given the current understanding of the motivational factors promoting lying.
- 4. Private experience** – "in the absence of objective indices, there is a strong tendency to accept the existence of phenomena if they have been part of one's own experience." (Pivik, 1986, p. 393).

As might be expected, elements of the experimental environment or procedures may be incorporated into dream reports (Domhoff & Kamiya, 1964; Okuma, Fukuma, & Kobayashi, 1975) and, although some content differences may exist between dreams collected at home relative to those collected in the laboratory (Lloyd & Cartwright, 1995; Stickgold, Pace-Schott, & Hobson, 1994; Weisz & Foulkes, 1970), these differences are minor. A more major issue relates to whether dreams collected in the laboratory are so influenced by the experimental conditions that they provide an unfaithful representation of the subject's dreamlife, depicting it as more mundane, realistically oriented, and coherent than it may be (Dorus, Dorus, & Rechtschaffen, 1971; Snyder, 1970). The studies cited above indicating content similarities between home and laboratory dreams when collected under similar sampling conditions suggest that reports collected in the laboratory do not provide an unrepresentative view of dream content and processes. Furthermore, it has been argued (Foulkes & Cavalero, 1993) that spontaneous recall of dreams in the home environment may, in fact, present an atypical view of dream content because laboratory dreams are better sampled and home dreams that are remembered may be so because of bizarre, emotional, or vivid characteristics.

INFERENTIAL CONTEXT

Every area of scientific endeavor is confronted with unique methodological challenges, but for sleep research the usual challenges (e.g., satisfying criteria fundamental to the reliable and valid measurement of physiological and cognitive processes) are compounded by the need to obtain these measures from the sleeping organism while maintaining state integrity and continuity. This state maintenance is, and continues to be, critical to the recognition of physiological indices that may be used as more discrete and objective correlates of sleep behaviors, and to the valid assignment of behaviors to their proper state domain.

In this regard, it is instructive to consider how demand characteristics differ between studies conducted during wakefulness and sleep, the methodological challenges these differences create, and how some of these challenges have been resolved. During waking investigations, which generally extend for a few minutes up to perhaps two hours, subjects are aware of physiological transducers attached to their bodies and can comply with instructions to avoid or minimize behaviors, such as body movements and eye blinks, which might compromise the quality of the recordings. By comparison, sleep recordings normally last at least six to eight hours, and while asleep subjects do not have volitional control over biological sources of artifact, such as frequent adjustments in body position which take place during the course of a normal night of sleep (Altshuler & Brebbia, 1967; DeKoninck, Lorrain, & Gagnon, 1992; Kleitman, 1963). Accordingly, procedures have had to be developed to more securely attach transducers for reliable recordings over these extended periods

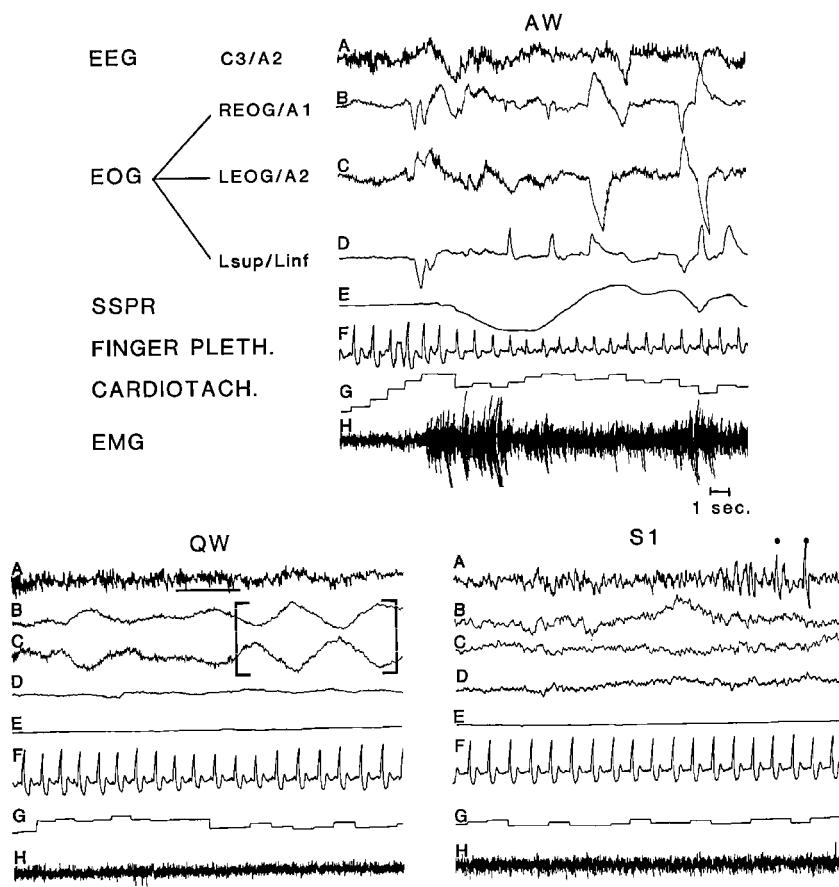

Figure 27.1. Polygraphical tracings of physiological measures associated with sleep-wakefulness state variations. Eight channels of activity (A-H) are depicted during active and quiet wakefulness (AW and QW, respectively) and the first stage of sleep (NREM Stage 1, or S1). The recorded variables include the electroencephalogram (EEG; C3/A2, channel A), the electrooculogram [EOG; horizontal (right and left outer canthi) and vertical (placements superior and inferior to right eye orbit), channels B, C, and D, respectively], autonomic activity [spontaneous skin potential response, (SSPR), channel E]; finger plethysmogram (channel F); cardiotachometer recordings (channel G)] and the facial (orbicularis oris) electromyogram (EMG; channel H). In these examples the passive decrease in EMG activity, which commonly occurs at sleep onset (S1), does not become evident until slow wave sleep (Figure 27.2, S3 and S4). Electrophysiological features of note are alpha activity (underscored, channel A) and slow rolling eye movements (channels B and C) preceding sleep onset in QW, and vertex sharp waves in Stage 1 (see dots, channel A). See text for discussion of sleep stage definitions and electrophysiological composition. (Reprinted with permission from Pivik, 1986, © The Guilford Press.)

of time, and it has often been necessary to design special devices or techniques to access measures of interest while minimizing sleep disturbance. For example, electrodes used to record the electrooculogram (EOG) also detect brain waves or electroencephalographic (EEG) signals (see Figures 27.1 and 27.2; S1-S4), and to obtain eye movement recordings not contaminated by these signals required transducers which could be applied to the eyelids to register mechanical movements of the eye (Baldridge, Whitman, & Kramer, 1963; Conduit, Crewther, & Coleman, 2004; Gross, Byrne, & Fisher, 1965). Although such crosstalk is diminished when low amplitude, fast frequency EEG activity predominates (e.g., during waking and REM sleep) and does not generally compromise

state identification, even at these times EEG events may influence EOG recordings (Iacono & Lykken, 1981) and EOG events may influence EEG recordings (see chapters 3 and 4 of this volume). To investigate variations in spinal monosynaptic reflex activity recorded from leg musculature, a method of leg restraint was devised which maintains the positions of stimulating and recording electrodes without altering reflex responses or disturbing sleep as a result of excessive restraint (Mercier & Pivik, 1983; Pivik & Dement, 1970; Pivik, 1971). A variety of devices, which can be comfortably inserted into the external auditory canal, have been developed for controlling stimulus delivery in sleep auditory arousal threshold (Busby, Mercier, & Pivik 1994) or evoked potential (Campbell & Bartoli, 1986) studies, providing measures of middle ear muscle activity by converting changes in sound pressure level to variations in impedance (Pessah & Roffwarg, 1972), or measuring core body temperature by means of a thermistor positioned near the ear drum (Palca, Walker, & Berger, 1981). In addition to these examples, the field of sleep disorders medicine has developed many novel approaches to assess physiological functioning during sleep (see Kryger, Roth, & Dement, 1994, 2000).

The amount of data collected in even the most fundamental of sleep studies using electrographic techniques is formidable. Over an eight-hour period, a single channel of EEG recording (at the recommended paper speed of 10 mm/sec) will trace a trail on paper extending .2 miles or, if digitized, will require approximately 25 megabytes

of computer storage space. When it is considered that multiple channels of physiological information are commonly recorded for two to five nights, the magnitude of the associated information acquisition, processing, and storage requirements can be appreciated. Increasingly, sleep investigations are utilizing new developments in computer technology, which make these challenges more manageable and greatly facilitate associated data analysis (Armitage, 1995a; Kubicki & Herrmann, 1996). Examples of the application of computerized methods of analysis to an autonomic measure (heart rate) and EEG are presented in Figures 27.4–27.6 and 27.7–27.8, respectively.

The organizing principle, which imposed meaning on these extensive data and was key to the recognition of REM

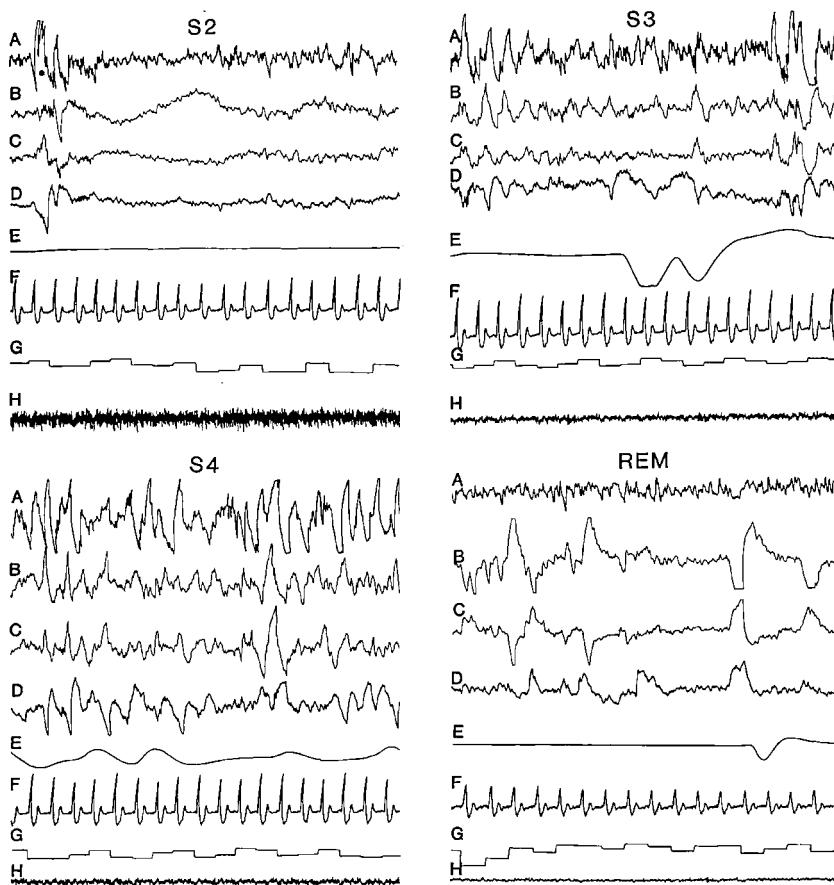

Figure 27.2. Polygraphical tracings of physiological measures associated with variations in sleep stages [NREM Stages 2–4 (S2-S4) and REM]. For explanation of channels A-H, see Figure 27.1. Of note is the occurrence of Stage 2 K-complexes (see dot, channel A). See text for discussion of sleep stage definitions and electrophysiological composition. (Reprinted with permission from Pivik, 1986, © The Guilford Press.)

sleep as a discrete entity, involved discerning and clustering patterns of activity into larger blocks of behavior termed “states and stages.” These concepts, often loosely applied, are important to differentiate because of the significantly different implications they carry for the conceptualization and understanding of behavior. In the physical world the differentiation between state and stage is often quite distinct, for example, the defining state characteristics of H_2O when it exists in a liquid, frozen, or gaseous form are clearly evident. However, in living organisms where behaviors are based on complex interactions among a variety of systems, state definition is often more equivocal and more judgmental. Still, as indicated by the following definitions, even under these more complex conditions there is common agreement regarding criteria for state determination. That is, a state may be defined as “a cluster of attributes whose simultaneous and repeated occurrence is highly unique” (Dement & Mitler, 1974, p. 278); “a recurring temporally enduring constellation of values of a set of indicator variables of the organism” (Steriade & McCarley, 1990, p. 8,); or “constellations of functional patterns and physiological variables which may be relatively stable

and which seem to repeat themselves” (Prechtl et al., 1968, p. 200). According to these criteria, existence in mammals may be partitioned into three general states: wakefulness, REM sleep, and NREM sleep.

If a state may be likened to the gestalt that emerges from associated, defining attributes, then a stage represents the identification of progressive within-state changes in these attributes. These component stages are defined by relatively precise, but nevertheless arbitrary, criteria. Referring again to the different states H_2O may assume, it is possible to define stages of transition bridging these states as a function, for example, of precise temperature and pressure variations. By analogy, NREM sleep in the human beings has been divided into four stages based on EEG criteria. Although REM sleep has been differentially examined on the basis of the presence or absence of various activities (e.g., eye movements or autonomic activation), further fragmentation of REM sleep into stages has not been proposed.

To arrive at valid and enduring state and stage criteria necessitates the development of an adequate and reliable descriptive database from which such criteria can be derived. The initial set of such criteria for sleep states and stages was proposed within five years of the discovery of REM sleep and the use of

all-night polygraphical recordings of sleep electrophysiology (Dement & Kleitman, 1957a), but it would be more than another decade before standardized scoring manuals would be developed. These manuals defined criteria for the reliable scoring and interpretation of electrophysiological sleep recordings based on the evaluation of 20–30 second epochs (Anders, Emde, & Parmelee, 1971; Rechtschaffen & Kales, 1968), and provided a reasonable solution for managing the large datasets associated with such studies. The choice of the specific scoring epochs for chunking sleep behavior, although not specifically rationalized, did not reflect a validated 20–30 second behavioral sleep unit. Instead, it was most likely based on several practical factors, including discriminability of recordings, reduction of an extensive database to more manageable dimensions, and providing the best fit between physiological data and technical parameters of recording instrumentation. It is of historical interest in this regard that the early electrographic recordings of human sleep were conducted using a recorder that cut a moving strip of paper on which variations in brain potentials were traced every 20 or 30 seconds (Loomis, Harvey, & Hobart, 1938).

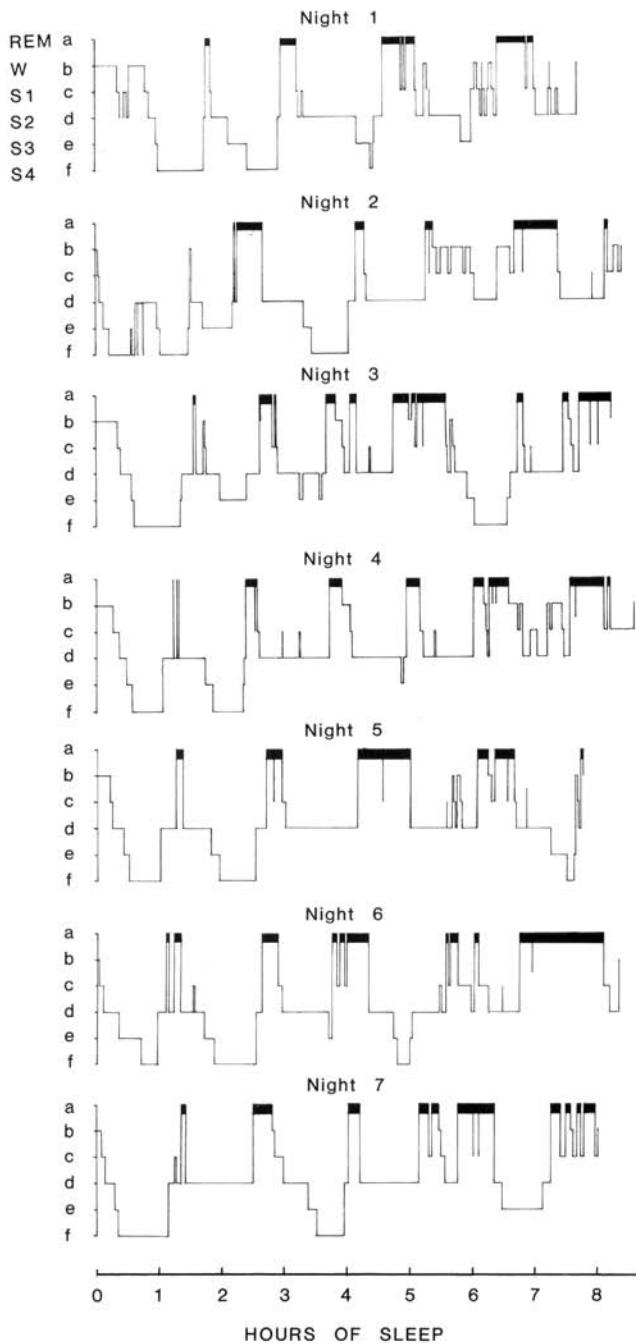

Figure 27.3. Sleep profiles depicting variations in sleep stages (ordinate) as a function of time asleep (abscissa). These profiles, based on seven consecutive nights of baseline sleep in a young adult, illustrate the stability of sleep patterns across nights, the presence of patterned oscillations between REM (darkened rectangles) and NREM sleep (i.e., sleep cycle), and the decrease in Stage 4 and increase in REM sleep as a function of sleep time within a given night. (Reprinted with permission from Pivik, 1986, © The Guilford Press.)

A caveat to the use of such relatively long scoring epochs is the resultant smoothing of the dynamic flux of physiological changes that occurs within briefer time intervals, which gives the impression that sleep states are played out in a very stable and continuous manner and

that state and stage transitions are relatively abrupt. The extent to which the duration of the scoring epoch contributes to this impression was underscored in an investigation in which 24-hour recordings of sleep in the cat were analyzed using a three-second scoring interval (Ferguson et al., 1969). With this procedure it was found that uninterrupted intervals of either wakefulness or NREM sleep were quite brief, in the range of one to two minutes. Briefer scoring intervals have also been applied in humans to provide more precise assessments of variations in normal (Ogilvie & Wilkinson, 1984; Pivik, Busby, & Brown, 1993) or disruptive physiological processes during sleep (ASDA, 1992). However, obtaining information of such temporal precision presents additional data processing and conceptual demands. For example, in terms of data processing, using three-second scoring intervals in the 24-hour animal recordings increases the number of individual data samples to be analyzed tenfold (i.e., from 2,880 to 28,800). Focusing on increasingly briefer intervals also requires determining valid and reliable scoring criteria for these intervals and, most importantly, raises the question of what is the smallest meaningful unit of sleep behavior that can be practically determined. Although the feasibility of analyzing extended datasets using more discrete time intervals has been significantly facilitated by computer technology, when such technology has been applied to studies of sleep the convention of reporting computerized results based on 20–30 second or longer intervals has generally been maintained (Armitage, 1995b; Itil, 1970; Sussman et al., 1979).

Microepoch analyses of physiological variables during sleep not only provide a more faithful representation of the actions and interactions of these variables, but the resulting enhanced microstructural view of sleep variables may help resolve questions relating to sleep-wakefulness interactions which continue to go unanswered. For example, the basis for what constitutes a refreshing night of sleep remains undetermined, but there is growing emphasis on sleep continuity as an important contributing factor (Carskadon, Brown, & Dement, 1982; Stepanski et al., 1984). In this regard, it has been shown that discrete interruptions of sleep, either spontaneously occurring or resulting from external stimulation, can be associated with enhanced daytime sleepiness and reports of significantly reduced sleep quality, even though these disturbances may not effect a significant reduction in total sleep time (Roehrs et al., 1994; Stepanski et al., 1987).

As new methods of data acquisition and analysis have developed, the descriptive picture of sleep physiology has become increasingly detailed and has provided information relevant to the study of psychophysiological relationships during sleep. Still, accounts of thought processes can be directly accessed or confirmed only by means of verbal communication. Although verbalization may occur during both REM and NREM sleep, intelligent dialogue with a sleeping subject has not been initiated or maintained, and attempts to provide subjects with posthypnotic suggestions to relate ongoing mentation without awakening

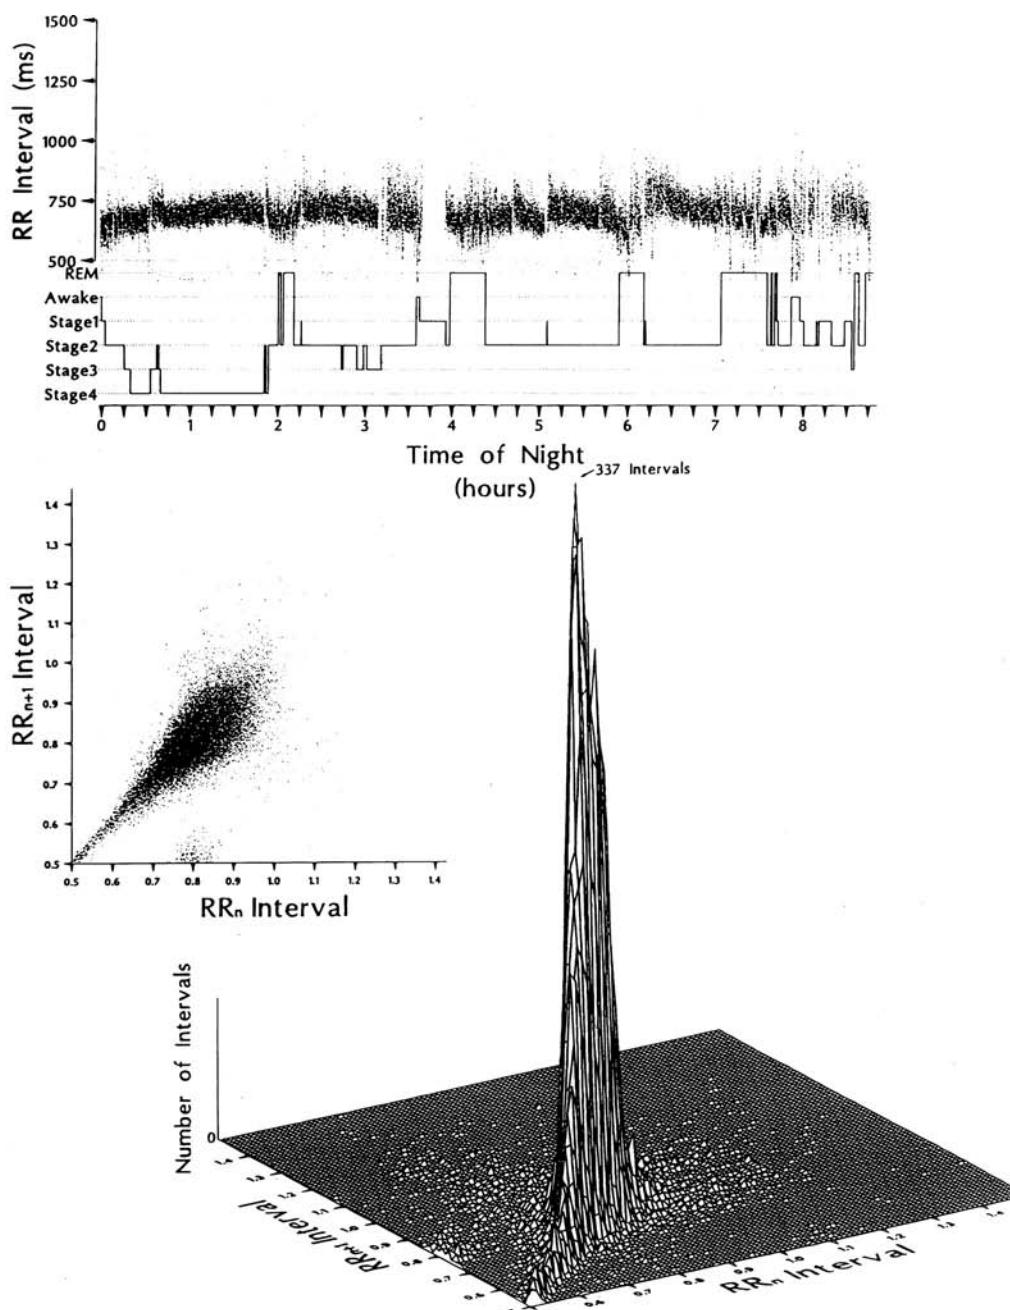

Figure 27.4. Analyses of heart rate across a night of sleep based on computer-determined beat-to-beat (RR) intervals. The upper graph depicts a sleep histogram with associated RR interval plots. In the middle graph, each RR interval (RR_n) is plotted against the subsequent interval (RR_{n+1}) to produce a graph known as a Poincaré plot reflecting the beat-to-beat dispersion for specific heart rate intervals as well as inter-beat interval variability as heart rate changes. Expanding the two dimensional Poincaré plot into three dimensions (lower figure) more clearly illustrates the density distribution of graphed values. In this Poincaré plot and those in Figures 27.5 and 27.6, RR interval values (both axis) extend from 0 to 1.4 seconds in 100 millisecond intervals.

have been unsuccessful (Arkin et al., 1970; Arkin, 1978). Inferences can be made about thought processes from non-verbal measures, for example, motor (Berger & Oswald, 1962b; Dement & Wolpert, 1958b; Shimizu & Inoue, 1986) or autonomic responses (Hobson, Goldfrank, & Snyder, 1965; Laberge, Greenleaf, & Kedzierski, 1983), but such inferences are most reliably determined during wakeful-

ness in the context of a controlled experiment (see Chapters 4, 7, 8, and 10 of this volume), as opposed to sleep in which directional control over subjects' behavior and associated thought processes is minimal if not absent. Although some variation in state can be said to occur when subjects are required to provide a verbal report of immediately preceding experiences, this shift is much greater for

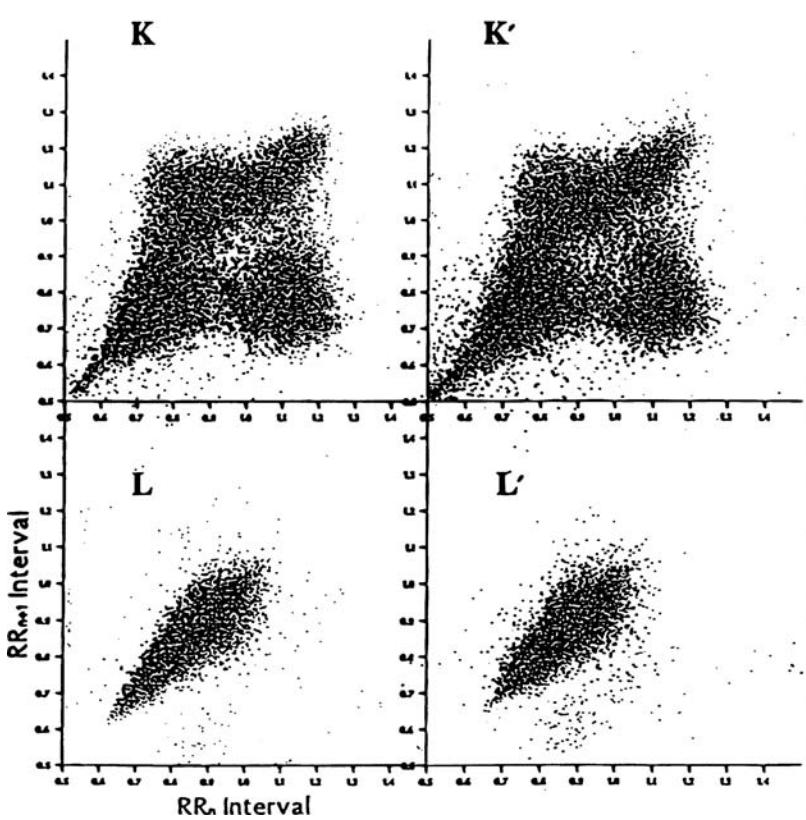

Figure 27.5. Whole-night Poincaré plots for two subjects (K and L) on two consecutive baseline nights (night 3: left column; night 4: right column). In these graphs, the within-subject consistency and between-subject variability across nights are notable. the reporting of sleep mentation where a major between-state change must occur (sleep to wakefulness) compared to the relatively minor within-state change associated with reports of waking experiences in wakefulness. Furthermore, this state-change is a gradual process (Balkin et al., 2002). The more extreme nature of the state change required to access reports of sleep cognition distinguishes studies of sleep mentation from others not characterized by such marked differences between conditions at the time of the experience relative to those at the time of reporting. The inability to more directly and immediately access cognitive activity in the sleeping subject, coupled with aspects of sleep physiology that differ remarkably from those commonly associated with cognitive activity during wakefulness, has prompted skepticism regarding whether postawakening reports reflected cognitive activity occurring during sleep. Alternative explanations considered included suggestions that the reports reflected hypnopompic experiences generated in the process of waking up (Goblot, 1896) or were intentionally contrived in the interest of pleasing the experimenter. Experimental data addressing these concerns will be presented once fundamental attributes of sleep physiology and psychology have been considered.

SLEEP PHYSIOLOGY AND PSYCHOLOGY: DESCRIPTIVE ASPECTS

Nearly two decades before the discovery of REM sleep, Loomis, Harvey, and Hobart, (1937, 1938) recorded EEG

activity in sleeping subjects and described five sequential brain potential patterns, which they referred to as “stages or states of sleep” (Loomis, Harvey, & Hobart, 1938, p. 421). These patterns, designated A, B, C, D, and E, generally similar across subjects and occurring reliably across recording sessions in the same subjects, were characterized as follows: A: intermittent alpha activity; B: low voltage potentials (theta); C: the occurrence of 14 Hz spindles; D: spindles in conjunction with 1 Hz delta waves; and E: increased delta activity with less conspicuous spindling (Loomis, Harvey, & Hobart, 1938). It was noted that “during the night of sleep a sleeper continually shifts back and forth from one state to another, either spontaneously or as the result of stimuli.” (p. 422). These investigators did not comment on the remarkable implication of their findings that sleep was not the unitary phenomenon it had been traditionally considered to be. Two decades passed before a more comprehensive differentiation of EEG patterns during sleep appeared – using numbers rather than letters to designate stage and including the newly discovered state of REM sleep (Dement & Kleitman, 1957a). It was also at this time that a second fundamental characteristic of sleep was recognized, namely, that sleep stage pattern variations across the night were largely predictable from night-to-night, indicating the existence of the sleep cycle (Dement & Kleitman, 1957a; Figure 27.3).

The discovery of REM sleep and the sleep cycle had far-reaching implications for both biological and psychological processes during sleep. Physiologically, in contrast to previous thinking that sleep occurred passively in response

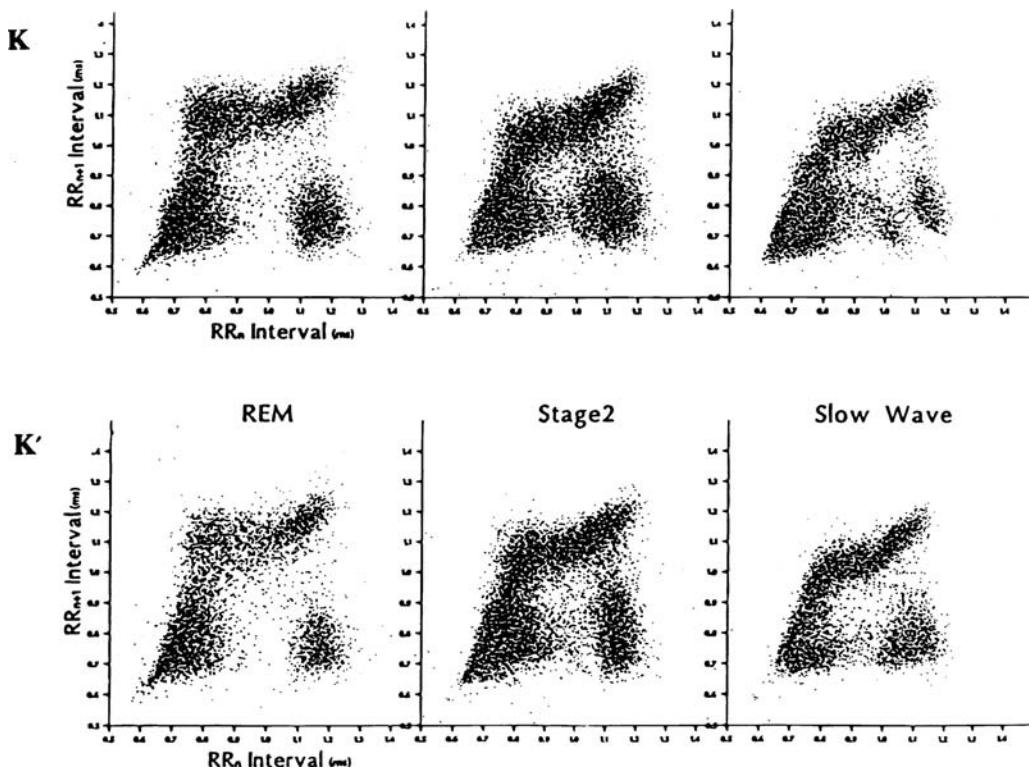

Figure 27.6. Sleep-stage Poincaré plots illustrating night-to-night similarities for subject K (upper and lower plots derived, respectively, from whole-night plots). (Reprinted with permission from Pivik et al 1996, p. 126, © American Sleep Disorders Association and Sleep Research Society.)

to the absence of wakefulness, these findings indicated that sleep was governed by active mechanisms. Furthermore, since the extended time intervals involved in stage and cycle variations could not be explained by short-term neurophysiologic processes, it was necessary to invoke neurochemical mechanisms with longer time constants. In terms of concepts of sleep cognition, these discoveries had equally dramatic effects. Now that dreaming could be associated with a physiological state recurring predictably across each night and which, in the adult, normally accounted for one quarter of each night of sleep, beliefs that dreams occurred only sporadically and under special conditions had to be rejected.

Although the scoring criteria in the Dement & Kleitman (1957a) publication provided descriptions of EEG frequency, amplitude, and waveform characteristics associated with sleep stages, a study by Monroe (1969) revealed an unacceptable level of scoring differences across laboratories. Monroe's findings were instrumental in the development of guidelines for scoring human sleep (Rechtschaffen & Kales, 1968), which presented more precise definitions of sleep states and stages, and provided the standardized criteria since used for the recording and reliable analysis of adult human sleep. Figures 27.1 and 27.2 provide examples of physiological variations characteristic of sleep-wakefulness and within-sleep stage differentiations described in that manual. These figures illustrate basic measures required for sleep evaluation (EEG, EOG, and

EMG; channels A, B, C, and H), but also include optional measures, such as recordings of vertical eye movements (channel D) and autonomic activity (channels E, F, and G). In these tracings, wakefulness (AW and W) is associated with a low-voltage, mixed frequency EEG, which may contain varying amounts of alpha (8–12 Hz) activity. Wakefulness is also usually associated with blinking, rapid eye movements, and variations in the levels of tonic facial EMG activity.

As accurately described 30 years previously (Davis et al., 1938), alpha activity is attenuated in the transition from wakefulness to sleep. Concurrently, there is a slowing of EEG activity with an increase in 4–7 Hz theta activity coupled with the sporadic occurrence of vertex sharp waves (see Figure 27.1, S1). The transition from wakefulness to Stage 1 is also accompanied by slow horizontal eye movements (see Porte, 2004 for a systematic evaluation of this activity), and facial muscle tonus is usually decreased relative to that of relaxed wakefulness (Figure 27.1). Stage 2 is characterized by the intermittent occurrence of K-complexes and 12–14 Hz spindle activity against relatively low amplitude, mixed frequency background (Figure 27.2). Stages 3 and 4, which together constitute “slow-wave sleep,” differ from Stage 2 and from each other in the amount of delta activity (.5–4 Hz) present in each scoring epoch. Stage 3 epochs must contain 20–50%, and Stage 4 epochs more than 50%, of this activity (Figure 27.2). Defining characteristics of REM sleep include a relatively

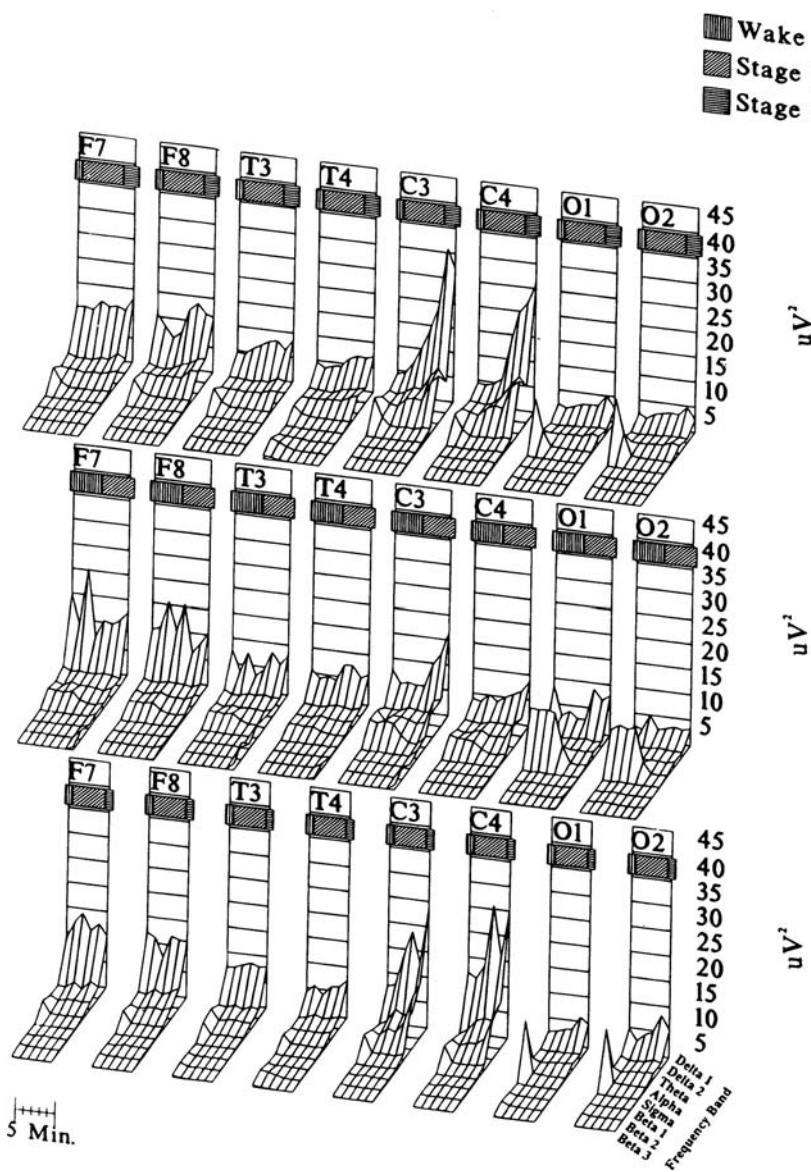

Figure 27.7. Variations in sleep onset EEG and as reflected in computerized analysis of activity from eight homologous scalp placements (frontal: F; temporal: T; central: C; and occipital: O) across three nights in the same subject. The graphs display these data in absolute (μV^2) values following FFT and power spectral analysis. These figures show within-subject differences as a function of recording site and night. (Reprinted with permission from Pivik, 1991 © John Wiley & Sons, Ltd.)

low-voltage, mixed-frequency EEG without K-complexes or spindles, sporadic eye movements, and reduced levels of submental and facial EMG activity (Figure 27.2). Although not required for REM sleep determination, other distinctive EEG features that may be present include bursts of theta activity (sawtooth waves) preceding clusters of eye movements (Berger, Olley, & Oswald, 1962), and alpha activity which is 1–2 Hz slower than subjects' waking alpha frequency (Johnson et al., 1967).

The above criteria underscore the emphasis on EEG activity for discriminating state and stages – an emphasis, which for NREM sleep, is absolute, but for REM sleep includes a requirement of relatively reduced EMG activity. Paradoxically, REM sleep can occur in the relative (i.e., epochs within REM periods without eye movement) or absolute (as in the congenitally blind; Berger et al., 1962) absence of the very parameter for which the state was initially named (i.e., rapid eye movements).

The following statements place the Rechtschaffen and Kales scoring criteria in broader physiological context. Note the fundamental ways in which these criteria describe sleep-wakefulness differences:

1. The presence of waveforms unique to sleep – for example, endogenously determined K-complexes, 12–14 Hz spindle activity, vertex sharp waves, and frontal sawtooth waves.
2. The prevalence and concentration of activities – for example, the enhancement of slower EEG frequencies (delta and theta), and the concentration of these and other activities, such as eye movements or galvanic skin responses (GSRs), at specific times of the night. With respect to EEG activity, computerized analyses have shown that in only rare instances is the EEG composed of a single frequency. Even in the desynchronized low-voltage EEG of wakefulness in normal individuals there

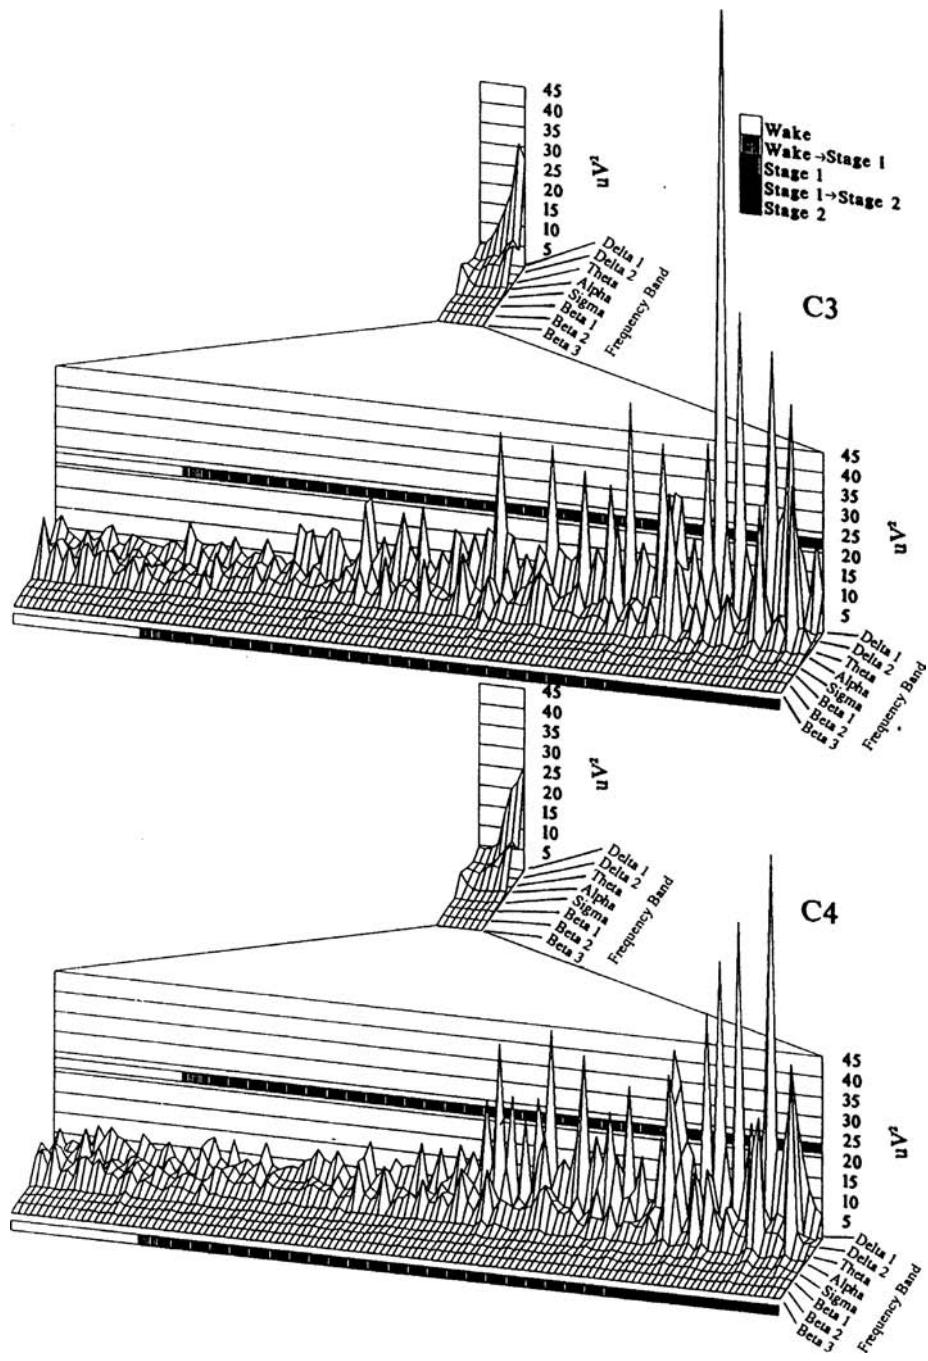

Figure 27.8. These illustrations expand the eight minute time base charted for bilateral central recordings depicted in the upper and middle panels in Figure 27.7 and present absolute power data in four-second bins. Using modified Rechtschaffen and Kales (1968) criteria, each four-second bin was classified into state categories as indicated in the legend. These figures demonstrate the complexities in EEG variations across hemispheres and nights in a single subject during the transition from wakefulness to sleep. (Reprinted with permission from Pivik, 1991, © John Wiley & Sons, Ltd.)

is a small but nonetheless real component of delta activity present (Lubin, Johnson, & Austin, 1969; Hoffman et al., 1979). The shift away from the higher frequencies associated with arousal during wakefulness and the concentration on slower activities are what make sleep unique.

3. The predictable constellations of physiological patterns that occur – for example, concentrations of delta

activity are associated with high GSR activation during slow-wave sleep, and indices of cortical, ocular-motor, and autonomic arousal are associated with sustained muscular inhibition during REM sleep (Pivik, 1986, p. 384).

Sleep profiles (Figure 27.3) are useful for representing general sleep characteristics, such as latencies, cyclicity,

stage distribution, and relative amounts of sleep disturbance. However, these graphs do not communicate more rapid physiological variations that occur as sleep patterns play out across the night and which are often most frequent during shifts between states and stages. These transitional periods reflect shifting physiological priorities for which the determinants are not well understood. Among these state transitions one has been the focus of great interest: the sleep onset period. Although most investigators identify sleep onset with the presence of Stage 1 EEG patterns, because of inconsistencies in the covariation of psychological and behavioral measures with EEG criteria for sleep, others have argued for considering initial Stage 2 as sleep onset (Agnew & Webb, 1972; Johnson, 1973; Ogilvie, Wilkinson, & Allison, 1989). It is clear that the EEG changes that take place at sleep onset (Figures 27.1, 27.7, and 27.8) do not occur in physiological isolation. For example, several measures, including oculomotor activity (slow horizontal eye movements: Foulkes & Vogel, 1965; Rechtschaffen & Kales, 1968), variations in skin potential (Hori, 1982), decreased ventilation (Naifeh & Kamiya, 1981; Tinder et al., 1992), and decreased heart rate (Pivik & Busby, 1996; Zemaityte, Varonockas, & Sokolov, 1984), may accompany or even anticipate Stage 1 EEG changes by several seconds. Furthermore, distinctive variations in cerebral blood flow differentiate relaxed wakefulness and Stage 1 sleep (Kjaer et al., 2002). Such systematic and coordinated changes across systems are consistent with concepts of physiological state. However, the relationship between these physiological changes and the point of perceptual disengagement from the waking environment is imperfect, as indicated both by studies of sleep onsetmentation (Foulkes & Vogel, 1965; Rowley, Stickgold, & Hobson, 1998; Vogel, Foulkes, & Trosman, 1966) and the ability to elicit behavioral responses to external stimulation in some individuals in Stage 1 and, to a lesser extent, in the initial moments of Stage 2 (Ogilvie & Wilkinson, 1984; Ogilvie, Wilkinson, & Allison, 1989). Another indication that transitions between states or stages are commonly not achieved abruptly is reflected in the practice of many investigators to require several consecutive epochs of Stage 1 or Stage 2 for sleep onset determination (Born, Muth, & Fehm, 1988; Mercier, Pivik, & Busby, 1993; Reynolds et al., 1983).

Associated with global patterns of state change across the night are predictable variations in the presence and distribution of physiological activity within sleep stages. For example, Stage 4 occurs predominantly in the first third of the night, and REM sleep in the last third (Williams, Agnew, & Webb, 1964, 1966; Figure 27.3). These observations are reflected in the exponential decrease in delta activity across the night as determined from more recent computerized analyses of EEG sleep data (Feinberg, Fein, & Floyd, 1980). Other notable stage-related physiological variations include: increases in body movements and K-complexes just prior to REM periods (Dement & Kleitman, 1957a; Halasz et al., 1977; Pivik & Dement, 1968);

reduced incidence of K-complexes and increased spindle activity in the few minutes subsequent to REM periods (Azumi, Shirakawa, & Takabashi, 1975; Pivik & Dement, 1968); the relative difficulty in engaging REM mechanisms early in the night, as indicated by the brevity or even omission of a REM period within the first two hours of sleep (Berger & Oswald, 1962a; Dement & Kleitman, 1957a; Roffwarg, Muzio, & Dement, 1966); and increased density of eye movements as a function both of time within individual REM periods and within REM periods across the night (Aserinsky, 1969, 1971).

It might be expected that state and stage distinctions made in the 1950s would undergo significant modification when subjected to the scrutiny of intense investigation over several decades. However, those definitions have been preserved and the ensuing research has detailed characteristics of physiological measures which, although not integral to stage determination, have nevertheless served to reinforce and extend our understanding of state physiology. Prominent among these is the presence of generalized physiological activation during REM sleep, including increases in the rate and irregularity in respiratory (Aserinsky, 1965; Snyder et al., 1964) and cardiovascular (Pivik et al., 1996; Snyder, Hobson, & Goldfrank, 1963; Snyder et al., 1964) activities. Electrodermal activity in REM sleep is limited in incidence and more similar in form to responses of this system during wakefulness (Broughton, Poire, & Tassinari, 1965; Hauri & Van de Castle, 1973b). These variations occur against a background of centrally mediated inhibition of facial and submental musculature and spinal monosynaptic reflexes (Berger, 1961; Hodes & Dement, 1964; Jacobson et al., 1964; Jouvet & Michel, 1959; Pompeiano, 1966).

Relative to REM sleep, physiological activation in the majority of NREM sleep is unremarkable. Exceptions to this generalization are the unusual levels of autonomic, hormonal, and motor activation present during slow wave sleep, particularly during Stage 4. During Stage 4, there is commonly a dramatic increase in electrodermal activity (Broughton, Poire, & Tassinari, 1965; Johnson & Lubin, 1966; Figure 27.2) which, in its extreme, has been referred to as "GSR storms" (Burch, 1965). Normally, electrodermal activation of this intensity would suggest an enhanced level of arousal, yet arousal threshold during Stage 4 is the highest of all sleep stages (Bonnet & Moore, 1982; Busby, Mercier, & Pivik, 1994; Goodenough et al., 1965; Lammers & Badia, 1991). Consequently, the excessive electrodermal activity during Stage 4 has been considered to result from the release of subcortical brain areas involved in the production of these responses from inhibition by higher centers rather than indexing enhanced physiological arousal (Johnson, 1973; Johnson & Lubin, 1966; see Chapter 7 of this volume). Slow-wave sleep is also the time when approximately 80% of the total daily secretion of growth hormone is released (Born, Muth, & Fehm, 1988; Sassin et al., 1969) and during which a variety of arousal disorders termed "parasomnias" occur (Roffwarg, 1979).

The latter disorders are characterized by varying degrees of motor and autonomic activity, and include such behaviors as sleep-walking, sleep-talking, enuresis, night terrors, and confusional arousals. For the interested reader more detailed considerations of the nosology, description, and treatment of these and other sleep-related disorders are available (ICSD, 1990; Kryger et al., 1994, 2000).

The initial wave of psychophysiological studies of sleep following the discovery of REM sleep was driven by the emphatic physiological distinctions between REM and NREM sleep and were essentially studies of state relationships. They were significantly influenced by the belief that REM sleep provided an objective measure of dreaming, and that dreaming occurred only during these periods. For the most part, these studies reported a high incidence of recall following arousals from REM sleep (approximately 80%) – although subsequent investigations also detected subjects who typically fail to recall dreams (Goodenough, 1978; Goodenough et al., 1959) – and a relative mental void in NREM sleep (less than 10% recall). However, reports suggesting that mental activity was present during NREM sleep (Goodenough et al., 1959) continued to accumulate, and by 1967 Foulkes reviewed data from nine studies reporting NREM recall values ranging from 23–74%. To some extent, the apparent discrepancy between the early and later studies regarding the presence of NREM mentation can be attributed to differences in what investigators were willing to accept as a dream. The early studies relied on an intuitive and implicit understanding of the nature of the dream and consequently did not provide an operational definition of this variable. The first study to provide some clarification in this regard was published in 1957, and entitled “The Relation of Eye Movements During Sleep to Dream Activity: An Objective Method for the Study of Dreaming” (Dement & Kleitman, 1957b). In this study, upon awakening subjects were queried as to “whether or not they had been dreaming,” and only those reports which related a “coherent, fairly detailed description” (p. 341) of the sleep mental experience qualified as dreams. Reports of having dreamt “without recall of content, or vague fragmentary impressions of content” (p. 341) were considered negative and disregarded. Based on these criteria, the commonly reported REM-NREM recall differentiation (80% recall in REM and 7% from NREM) was observed. These early studies, restrictive as they were with respect to dream definition, nevertheless provided an important insight into the nature of the dreaming process, namely, that in most individuals this process occurred with its greatest intensity during REM sleep.

It became obvious that a systematic and effective evaluation of mental activity during sleep would require a more detailed operational definition of what would be accepted as a dream, and a variety of such definitions has been advanced. For example, the dream has been variously characterized as a “verbal report describing an occurrence involving multisensory images and sensations, frequently of a bizarre and unreal nature and involving the narrator

himself” (Berger, 1967, p. 16); “the presence of any sensory imagery with development and progression of mental activity” (Kales et al., 1967, p. 556); “any occurrences with visual, auditory, or kinesthetic imagery (Foulkes, 1962, p. 17); a “multidimensional conglomerate of a hallucinatory belief in the actual occurrence of an imagined experience which, in turn, tends to be an extended visual, sometimes bizarre, drama” (Antrobus et al., 1978, p. 40); or simply “thinking” (Foulkes, 1978, p. 3).

The range of definitions represented by these examples places various constraints on which reports would be accepted into the “dreaming” dataset, consequently tailoring the perception of the general nature of cognitive activity during sleep and more profoundly affecting the incidence of acceptable reports of dreaming occurring outside the confines of REM sleep. However, when reports elicited from arousals during sleep were examined using more permissive criteria that allow more fragmentary and less perceptual reports to be accepted as data, the presence of a much more extensive mental life during sleep was revealed. Lifting these definitional restrictions primarily affected the amounts of recall from NREM sleep arousals, with observations of more than 50% recall not being uncommon (Foulkes, 1962; Goodenough et al., 1959; Herman, Ellman, & Roffwarg, 1978; Molinari & Foulkes, 1969; Pivik & Foulkes, 1968; Zimmerman, 1970). As suggested by the substantial increase in amounts of NREM recall, which become apparent when a more relaxed definition of sleep mentation is allowed, there are qualitative distinctions that differentiate REM and NREM reports. The major differences that have been repeatedly observed (Antrobus, 1983; Foulkes & Rechtschaffen, 1964; Pivik, 1971; Rechtschaffen, Verdone, & Wheaton, 1963) have been summarized as follows:

reports obtained in periods of REM activity showed more organismic involvement in affective, visual and muscular dimensions and were more highly elaborated than non-REMP reports. REMP reports showed less correspondence to the waking life of the subjects than did reports from spindle and delta sleep. The relatively frequent occurrence of thinking and memory processes in spindle and delta sleep was an especially striking result. (Foulkes, 1962, pp. 24–25)

REM-NREM distinctions in amounts of recall and associated qualitative characteristics of reports seemed to imply a fundamental difference in cognitive activity during these states, with more complex, vivid and bizarre “dreaming” during REM sleep and less developed, more mundane “thinking” during NREM sleep. However, NREM reports of dreaming have been observed to be as common (Goodenough et al., 1965) or more common (Bosinelli et al., 1968; Foulkes, 1960, 1962; Pivik, 1971; Pivik & Foulkes, 1968; Rechtschaffen, Vogel, & Shaikun, 1963) than NREM thinking reports. Still, when reports from the two kinds of sleep are contrasted directly using a method of paired comparison, judges are generally able to reliably discriminate REM from NREM reports (Bosinelli et al., 1968; Monroe

et al., 1965). An exception to this discriminability is the NREM mentation elicited following arousals during sleep onset. Reports of mental activity at this time share many features with REM sleep reports that make it difficult to discriminate between them, including incidence, hallucinatory dramatic quality, and report length (Foulkes, Spear, & Symonds, 1966; Foulkes & Vogel, 1965; Vogel, 1978; Vogel, Foulkes, & Trosman, 1966), as well as perceptual and emotional qualities (Vogel, Barroclough, & Giesler, 1972). Recognition that dream-like mentation occurred outside REM sleep implied that REM sleep deprivation could not be equated with dream deprivation (Dement, 1960) and called into question claims that REM sleep dreams were vital to psychological normality during wakefulness (Sampson, 1965, 1966; Vogel et al., 1975).

The characteristics of NREM mentation outlined in cognitive sleep studies conducted during the initial 15 years following the discovery of REM sleep have been confirmed by subsequent research. Yet, despite the weight and persistence of such evidence, there was substantial reluctance to acknowledge the validity of mental activity during sleep occurring outside REM sleep. Although it was necessary to consider other plausible explanations for reports of NREM mentation – such as viewing them as artifacts of arousal generated in the process of waking up, confabulating in an effort to please the investigators, or reflecting recall of mental activity from previous REM periods – even when such possibilities had been effectively countered (Foulkes, 1967) skepticism remained. Foulkes (1967) offered several probable reasons for this persisting unwillingness to accept the authenticity of NREM mentation despite convincing arguments to the contrary:

- a)** while the low-voltage random EEG of REM sleep is compatible with the existence of ongoing thought processes, the high-voltage, low-frequency EEG of NREM is not;
- b)** a report of a mental experience is not credible unless supported by public behavioral or physiological observation; and,
- c)** REM sleep is so vastly different physiologically from NREM sleep that there must also be a vast psychological difference between the two, such as vivid dreaming versus. little or no mental activity (p. 31).

These statements are consistent with the emphasis on physiological correlates as validating indices of psychological experience. Although providing useful guidelines, the dependence on such physiological correlates can, in the extreme, demand an unsupportable degree of mind-body isomorphism. The points outlined by Foulkes serve to illustrate the extent to which prevailing theoretical thinking can promote expectations that interfere with scientific objectivity. The concept of NREM mentation was no more iconoclastic than that of recurrent phases of physiological activation occurring during sleep, yet the latter reports were not met with the same degree of skepticism as

reports of NREM mentation. Even though the association between REM sleep and dreaming dramatically altered existing views regarding the nature of dreaming, dreaming was already accepted as a sleep-related cognitive event. Furthermore, because visual experiences are perhaps the most common and compelling components of dreams, the finding that the experience of dreaming appeared to be associated with these periods of rapid eye movements during sleep simply confirmed prior expectations. Aserinsky (1996) explicitly refers to this situation when he notes that “the prospect that these eye movements may be associated with dreaming did not arise as a lightening stroke of insight” (p. 217) because the notion of “an association of the eyes with dreaming is deeply engrained in the unscientific literature and can be categorized as common knowledge” (p. 218). Although not extensive, there was evidence of the kind of linkage between NREM reports and pre-awakening events, which provided precisely the kind of “public evidence” demanded to validate NREM mentation, for example, spontaneously occurring activity, such as sleep talking (Arkin et al., 1970; Rechtschaffen, Goodenough, & Shapiro, 1962) or experimentally induced incorporations (Foulkes, 1967; Foulkes & Rechtschaffen, 1964; Rechtschaffen, Verdone, & Wheaton, 1963).

It is likely that a detailed search for observable physiological events that correlate with, validate, and perhaps explain psychological activity during sleep would have occurred regardless of the REM-NREM mentation controversy. However, if the presence of cognitive activity during NREM sleep had been dismissed these studies would have focused exclusively on REM sleep, and our appreciation of the physiological conditions and requirements underlying cognitive activity would have been significantly diminished. In this search for psychophysiological measures which might best predict the presence of mental activity during sleep, it is not surprising that EEG activity, despite limitations in understanding the precise nature and origin of such activity (Niedermeyer & Lopes da Silva, 1993), would be a primary focus.

The similarity between EEG activity during waking and REM sleep has been previously noted, and Dement and Kleitman (1957a) suggested that generally this pattern was a better correlate of dreaming than eye movements. Subsequent research has supported this impression, and indicates that as EEG activity becomes more desynchronized there is greater recall and the reports obtained contain more vivid and bizarre dream-like material. Accordingly, arousals from sleep with low-voltage, mixed-frequency EEG patterns (Stage 1 and REM) produced the highest incidence of recall and recall of the most vivid, bizarre, and emotional nature (Dement, 1955; Dement & Kleitman, 1957b; Foulkes & Vogel, 1965; Vogel, Foulkes, & Trosman, 1966) relative to that obtained from arousals where the sleep EEG is characterized by slower and higher amplitude patterns (Armitage, 1980; Pivik, 1971; Pivik & Foulkes, 1968). The positive relationship between levels

of EEG activation and the quantity and quality of recall is consistent with findings of increased recall of more dream-like material across the night (Foulkes, 1960; Goodenough et al., 1959; Pivik & Foulkes, 1968; Verdone, 1963, 1965) because there is marked reduction in slower EEG activity and a greater presence of faster frequencies in the second half of the night. As indicated in Figure 27.3, these variations reflect a concentration of slow wave sleep early in the night and more Stage 2 and REM sleep later. This confounding of sleep stage and time of night frustrates attempts to determine independent relationships between these variables and aspects of sleep cognition. One approach to circumventing this confound has been to focus on Stage 2, which, although more prevalent later in the night, nevertheless normally occurs throughout the night. When Stage 2 mentation is sampled across the night, increases in both recall and dream-like quality in reports elicited later in the night have been observed (Arkin et al., 1978; Pivik & Foulkes, 1968). Although these findings suggest a time of night rather than background EEG influence on sleep mentation, computer analyses of all-night sleep EEG recordings have shown a covariation between EEG activity and time of night – for example, linear decreases across the night in alpha (Harman & Pivik, 1996) and delta (Feinberg, Fein, & Floyd, 1980) bands – which indicates that Stage 2 early in the night contains greater amounts of slow EEG activity relative to that occurring later in the night. These observations underscore the importance of supplementing, where possible, standard analyses with procedures that may provide additional information. In this case, computer analysis more precisely quantifies not only the above-threshold delta activity (scoring criteria for Stage 2 allow up to 20% per epoch of $\geq 75 \mu\text{V}$ delta activity), but includes activity occurring below the criterion level and thereby provides a more faithful representation of the amount of this activity within each epoch (Armitage, 1995b).

Recently, attention has been drawn to the occurrence of synchronized fast EEG rhythms (20–40 Hz) during both wakefulness and sleep in animals and humans (Cantero et al., 2004; Franken et al., 1994; Llinás & Ribary, 1993; Steriade, Amzica, & Confreres, 1996). These rhythms are most prevalent during wakefulness and REM sleep, but have been detected as well during NREM sleep. The involvement of this activity in state- and event-related aspects of consciousness and cognition is still being defined (Behrendt, 2003; Hobson et al., 1998; Kahn, Pace-Schott, & Hobson, 1997).

The global time-of-night, EEG-sleep mentation relationships noted above indicate variations in mental activity over relatively long periods of time, but short-term temporal relationships between recall and physiological events have also been reported. For example, recall of REM sleep mentation is reduced if awakenings are made soon after a gross body movement (Dement & Wolpert, 1958b; Wolpert & Trozman, 1958). Duration of time in a sleep stage prior

to arousal may also influence the amount and quality of recalled material. Arousals made early in REM periods produce fewer reports and reports of less dream-like quality relative to those obtained from arousals later in REM (Foulkes, 1962; Kramer, Roth, & Czaya, 1975; Whitman, 1969), and although arousals from Stage 4 generally produce less recall and recall that is less dream-like than that from other sleep stages, such differences between Stage 4 and Stage 2 are minimized when the amount of within-stage time prior to awakening is controlled (Tracy & Tracy, 1974). Furthermore, recall rates between REM and slow wave sleep (SWS) are not as widely discrepant when temporal factors (time of night and time into stage) are regulated (REM: 89%; SWS: 65%; Cavallero et al., 1992).

The general differences in incidence and qualitative aspects of REM and NREM mentation favor the more “awake-like” Stage 1 pattern as a reasonable predictor of dream-like cognitive activity, but the fact that NREM sleep stages with quite different EEG patterns also support an extensive amount of cognitive activity – often dream-like – forces the conclusion that these tonic background patterns are at best only global correlates of mental activity during sleep. This conclusion is further underscored by observations of within-state variations and between-state similarities in the frequency and characteristics of recalled material. Clearly, the psychophysiological relationship between sleep cognition and EEG activity is imperfect.

The characterization by early sleep cognition studies of REM sleep mentation as visual, bizarre experiences and NREM mentation as more thought-like and mundane seemed to fit well with an extensive and developing literature in waking subjects indicating cortical hemispheric specialization for different features of cognitive activity. Neurophysiological and psychophysiological studies in waking subjects assigned linguistic and analytical processes to the left hemisphere, and visuospatial and holistic processes to the right hemisphere (Geschwind & Galaburda, 1987). Accordingly, global REM-NREM variations suggested differential cerebral hemispheric involvement, with the visuomotor loading of REM sleep dreams suggesting greater right hemisphere involvement during REM sleep (Broughton, 1975; Goldstein, Stolzfus, & Gardocki, 1972).

At a strictly electrophysiological level using the amount of alpha activity as a primary index of differential hemispheric EEG activation (because alpha increases have been related to decreases in attention or effort), findings with respect to REM-NREM hemispheric activation have been inconsistent in supporting the right hemispheric nature of REM sleep (Armitage, Hoffman, & Moffitt, 1992; Bertini & Violani, 1992; Doricchi & Violani, 1992). The few studies documenting the extent of EEG lateralization in conjunction with concomitant sleep mentation have, with few exceptions (e.g., Angeleri, Scarpino, & Signorino, 1984), not supported the REM right-hemisphere, NREM left-hemisphere dichotomy (Armitage, Hoffman, & Moffitt,

1992; Cohen, 1977; Guevara et al., 1995; Moffitt et al., 1982; Pivik et al., 1982). It should be emphasized, however, that interpretation of interhemispheric EEG sleep data is complicated by variations in subject characteristics, scalp recording sites, EEG frequency bands considered, and the analytical procedures used (Armitage, Hoffman, & Moffitt, 1992; Pivik et al., 1982; see Chapter 3 of this volume), as well as by the fact that the sleep EEG sleep may vary dynamically with specific features of ongoing mentation (Bertini & Violani, 1992; Doricchi & Violani, 1992).

In addition to EEG variables, efforts to determine physiological correlates of mental activity during sleep have also examined autonomic and motor variables. Among autonomic measures investigated in this respect are heart and respiratory rates, electrodermal activity, and penile erections. In general, robust relationships between tonic levels of autonomic activity and either the incidence or qualitative aspects of recalled mentation have not been observed. Furthermore, when positive correlations have been observed, they have often been in association with transient changes in these measures (for reviews see Rechtschaffen, 1973; Pivik, 1991).

Perhaps most remarkable are the apparent dissociations between certain autonomic measures and cognitive activity during sleep. Prominent in this regard is the "storm-like" occurrence of electrodermal activity during Stages 3 and 4 (Burch, 1965). It would be expected that these high rates of electrodermal activity would impact on associated mental activity, either in terms of enhanced recall or qualitative aspects of recalled mentation, but such relationships have not been observed (Hauri & Rechtschaffen, 1963; Pivik, 1971, Tracy & Tracy, 1974). Similarly, the increased blood flow to the genitalia during REM sleep resulting in penile erections (Fisher, Gross, & Zuch, 1965; Karacan et al., 1966) or clitoral engorgement (Cohen & Shapiro, 1970) would suggest that the great majority of REM reports would contain overt sexual content. However, with the exception of lucid dreaming (LaBerge, 1985; LaBerge, Greenleaf, & Kedzierski, 1983), REM reports with manifest sexual features are relatively uncommon (Fisher, 1966; Hall & Van de Castle, 1966). Interestingly, lucid dreams containing sexual activity are associated with expected variations in some (e.g., respiration and skin conductance), but not all (e.g., heart rate) autonomic measures (LaBerge 1985, 1992).

To the casual observer, with the exception of occasional twitches and body movements, sleep would appear to be a state of general motor quiescence – an impression physiologically documented for trunk and limb musculature (Jacobson et al., 1964). Not apparent to the observer would be the previously noted tonic inhibition of face and neck muscles that accompany, and may slightly anticipate the onset of, REM sleep (Berger, 1961; Jacobson et al., 1964). Because tonically reduced EMG activity is a defining characteristic of REM sleep, it is not possible to determine the relationship between this variable and ongoing mentation

independent of that in other systems also tonically active at this time, for example, EEG. However, because of the variability in the timing of EMG inhibition and EEG desynchronization signaling REM sleep onset, it has been possible to systematically examine characteristics of NREM sleep mentation (generally Stage 2) immediately preceding REM sleep as a function of the presence or absence of tonic EMG inhibition. It was expected that the preREM decrease in facial and submental muscle activity might signal a shift to more REM-like mental activity, but instead these lowEMG, preREM periods yielded fewer reports and reports which were less dream-like than those from awakenings with high EMG levels (Larson & Foulkes, 1969; Pivik, 1971).

TONIC-PHASIC DISTINCTIONS

As indicated by the above review and commented upon by others (Antrobus & Bertini, 1992), the relationship between tonic physiological activation and cognitive activity is complex, with the strongest psychophysiological association to emerge being that between the presence of a Stage 1 EEG pattern and recall of dream-like mentation. Although the psychophysiological sleep studies conducted during the decade and a half following the discovery of REM sleep emphasized general state relationships, it had been apparent that, though sleep stages were defined primarily in terms of tonic physiological criteria, these stages were nevertheless characterized by transient variations in these measures. In fact, a closer psychophysiological correspondence was generally obtained when reports were elicited following such abrupt variations. This improved relationship was reflected both in increased recall and qualitative variations in recalled material and was observed across EEG, autonomic, and motor systems (Pivik, 1986, 1991). Among such phasically occurring activity, the relationship of one type of discrete motor activity (namely, eye movements) to REM sleep mentation has been most intensively investigated. These studies have evaluated this relationship in terms of both general associations as well as trying to determine if a strict relationship existed between eye movements and dream images. In terms of the more nonspecific approach, although increased eye movement activity is commonly associated with enhanced recall, the magnitude of this relationship is not particularly remarkable (Pivik, 1991). Similarly, reports obtained in association with increased eye movement are often, but not consistently, more vivid and emotional (Ellman et al., 1974; Hobson, Goldfrank, & Snyder, 1965). Interestingly, increased eye movement density may not always be a good predictor of the amount of activity reported in the dream (Berger & Oswald, 1962a; Firth & Oswald 1975; Hauri & Van de Castle, 1973a; Pivik & Foulkes, 1968).

The discovery of the association between REM sleep and dreaming not only confirmed the expectation that visual

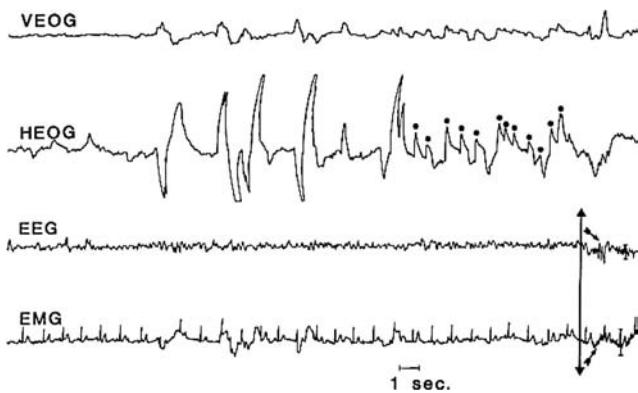

Figure 27.9. An example of the correspondence between eye movements and dream content. Immediately following a series of horizontal nystagmoid eye movements (designated by dots) during REM sleep, the subject was awakened (vertical line, lower channels) and related a dream experience (viewing parallel parking lines while riding by in a car) that provided the precise perceptual conditions required to elicit optokinetic nystagmus. In this example, the EMG recordings contain EKG artifact made more prominent by the tonic EMG inhibition during REM sleep. However, this artifact does not interfere with the general purpose of EMG recordings during sleep (i.e., stage differentiation). (Reprinted with permission from Pivik, 1986, © The Guilford Press.)

dreams would be accompanied by eye movements, but suggested the corollary hypothesis that these eye movements were not random but were functioning as they would during wakefulness to view the perceived images – in this case dream images. This precise relationship between the eye movements and dream imagery of REM sleep has come to be known as the scanning hypothesis (Roffwarg et al., 1962). Although intuitively appealing and appearing to provide an ideal opportunity for demonstrating the extent to which psychophysiological isomorphism can occur during sleep, attempts to substantiate this relationship have met with mixed success. Examples of highly specific correspondence have been noted (Figure 27.9), but demonstrating this relationship as a general feature of REM sleep has been largely unsuccessful (reviewed in Pivik, 1991; Rechtschaffen, 1973). However, interpretation of these generally negative results needs to be tempered with an appreciation of the experimental demands inherent in these studies. These include having investigators highly skilled in interviewing procedures and techniques with a detailed understanding of head-eye movement relationships and highly motivated subjects who can awaken quickly and provide high quality detailed recall of dream imagery and associated gaze shifts. Insight into the difficulty in determining whether, or the extent to which, eye movements during REM sleep are scanning dream images was provided by an investigation conducted during wakefulness (Bussel, Dement, & Pivik, 1972) in which eye movements were recorded and subjects were periodically interviewed and requested to detail their eye movements in the few seconds prior to the interview. These reports were then

correlated with the associated eye movement recordings. It was observed that subjects' reports during wakefulness could not be related to polygraphically recorded eye movement activity with any greater reliability than has been possible in the REM dream-eye movement studies. More positive eye movement-dream imagery associations have been reported in lucid dreams (LaBerge, 1992), and indirect support for these associations is suggested by studies using imaging technology indicating involvement of the same cortical areas in the control of both waking and REM sleep eye movements (Hong et al., 1995), as well as studies using more nonspecific, correlational techniques associating numbers of eye movements with the amount of visual imagery in dream reports (Hong et al., 1997).

Interest in the association between more discrete variations in physiological activity during sleep and concurrent mentation became part of a more general shift in focus from state to event relationships that impacted significantly on both physiological and psychophysiological sleep studies. The critical differentiation which was made focused on the duration and temporal clustering of events with sustained or tonic activities lasting several seconds or minutes (e.g., background and EEG and EMG stage correlates) being contrasted with sporadic or phasic activities lasting less than a second (e.g., muscle twitches, rapid eye movements, or K-complexes) or, at most, a few seconds (e.g., isolated transient autonomic variations). Initially based on such events during REM sleep in the cat (Moruzzi, 1963), this reconceptualization was soon extended to NREM sleep events as well (Grosser & Siegal, 1971). Notable influences of this tonic-phasic distinction on psychophysiological studies of sleep included: 1) providing a structured physiological framework within which to consider these studies, 2) the suggestion that REM-NREM physiological differences were quantitative and not absolute, and 3) providing what came to be considered a prototypic phasic event which served as a model in the search for the human analogue of such activity (namely, the PGO spike). This event is named for the brain regions from which it was most readily recorded – the pons, lateral geniculate bodies, and occipital cortex – and acquired psychophysiological prominence in part because of the anatomical and sleep stage distribution of this activity. Consistent with both the visual emphasis in dreams and the high incidence of dream reports from REM sleep, PGO spikes were most prominent in the visual system during REM sleep (Brooks, 1967, 1968; Jouvet, 1972). Furthermore, the occurrence of this activity during NREM sleep, most intensely just prior to REM onset and less frequently at other times in the NREM cycle, held out promise that this activity might provide a physiological correlate of NREM mentation.

This tonic-phasic distinction provided the theoretical orientation which dominated the field for many years and which continues to influence psychophysiological sleep studies (Antrobus & Bertini, 1992; Conduit, Crewther, &

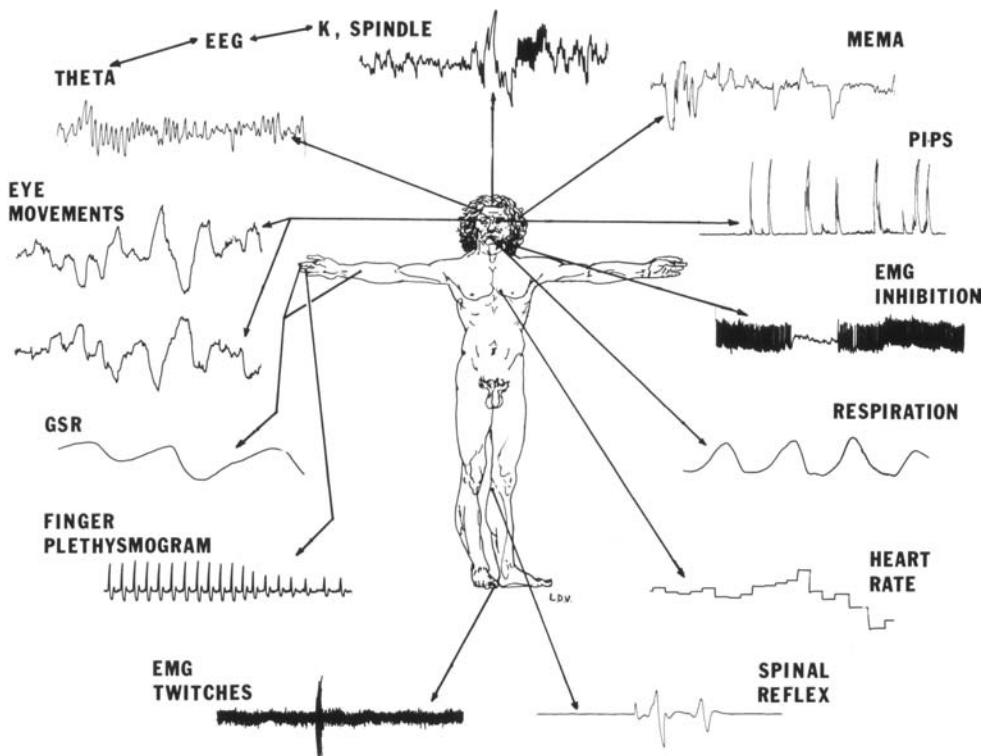

Figure 27.10. Illustrations of various physiologically occurring electrophysiological measures that have been investigated in the context of psychophysiological studies of sleep. These variables, with approximate designations of anatomical areas from which they are recorded, include the following: EEG measures (K-complex, spindle, and theta activity); expressions of muscle activity from auditory middle ear muscle activity (MEMA)], visual [eye movements, periorbital integrated potentials (PIPS)], and skeletal musculature (facial EMG inhibition, spinal reflexes, and EMG twitches) systems; and autonomic activity [galvanic skin response (GSR), finger plethysmogram, respiration, and heart rate]. (Reprinted with permission from Pivik, 1986, © The Guilford Press.)

Coleman, 2004; Pivik, 1991; Rechtschaffen, 1973). This model prompted increasing numbers of studies comparing reports obtained from awakenings following episodes of tonic or phasic physiological activation during sleep, stimulated the search for physiological measures which might reflect activity of the phasic event system proposed by Moruzzi (1963; see Figure 27.10 for examples of events examined in these studies), and led to the formulation of new proposals regarding the relationship between phasic events and sleep mentation (Hobson, 1992; Hobson & McCarley, 1977). These investigations provided new insights into sleep physiology and psychophysiology, but failed to indicate either that phasic events were a prerequisite for the presence of cognitive activity during sleep or that these events could be reliably related to specific qualitative measures of sleep mentation, for example, the degree of cognitive processing of dream-experiences (Foulkes & Pope, 1973; Molinari & Foulkes, 1969) or the presence of discontinuity and bizarreness within reports (Antrobus, 2000; Foulkes & Pope, 1973; Ogilvie et al., 1982; Reinsel, Antrobus, & Wollman, 1985; Watson, 1972). Furthermore, there are unusual features differentiating sleep from waking cognitive activity, which have received little attention in

terms of either general or tonic-phasic physiological sleep correlates. Among these are what has been termed the “single-mindedness” and “nonreflectiveness” of dreams. Single-mindedness refers to “the strong tendency for a single train of related thoughts and images to persist over extended periods without disruption or competition from other simultaneous thoughts and images” (Rechtschaffen, 1978, p. 97). It has been suggested that this attribute is a reflection of a combination of increased sensory thresholds and cortical activation during sleep (Reinsel, Antrobus, & Wollman, 1992). Nonreflectiveness refers to the attenuation or arrest of judgmental processes during dreaming (Kleitman, 1967; Rechtschaffen, 1978), that is, the general acceptance of events or images during dreaming without the critical evaluation that normally takes place during waking. This characteristic may reflect the possibility that an inherent feature of dreaming is the absence of the need for “a constant regulating function of self-evaluation” (Meier, 1993, p. 64). The apparent limited use of evaluative information from waking cognitive experiences in this context implies either restricted access to such information during sleep or a discontinuity between selective waking and sleeping cognitive processes (Foulkes, 1993).

SLEEP COGNITION: RECONCEPTUALIZATIONS

For the first 25 years following the discovery of the REM sleep-dreaming relationship investigations into the psychology of sleep were largely physiologically driven. There were, nevertheless, concurrent lines of research which provided information regarding more general issues concerning both the circumstances under which dreaming occurs and the nature of dreams, observations from which is emerging a significantly modified view of dreaming. In the process of documenting the apparent pervasiveness of mental activity across sleep stages, investigators provided insights into what may generally be considered necessary and sufficient conditions for dreaming to occur. Studies of variations in mental activity during the transition from waking to sleep were particularly revealing in this regard. Early investigations identified four stages of EEG-EOG patterns occurring sequentially during this sleep onset period and studied the variations in mental activity associated with these stages (Foulkes & Vogel, 1965). These stages defined a progression of decreases in alpha, which could be accompanied by eye movements (rapid in the initial stage, and slow in later stages), and included initial epochs of Stages 1 and 2 EEG patterns. Mental activity – much of it dream-like – was reported on 90–98% of arousals from these stages. The similarities between these reports and those from REM sleep were later emphasized (Foulkes, Spear, & Symonds, 1966; Vogel, Barrowclough, & Giesler, 1972). Furthermore, the reports of mental activity changed in a systematic way as subjects progressed from the alpha REM stage to Stage 2. These variations began with subjects initially relinquishing control over the course of mental activity, then becoming unaware of the environment, and finally losing reality orientation and having hallucinatory experiences (Vogel, Foulkes, & Trosman, 1966). These results suggested reduced sensory input and subsequent abrogation of voluntary ideational control are essential for dream production. It is notable that when these conditions have been established in waking subjects, either in the context of classic sensory deprivation studies (e.g., Freedman, Grunebaum, & Greenblatt, 1971) or under more benign conditions (Foulkes & Fleischer, 1975; Foulkes & Scott, 1973; Reinsel, Antrobus, & Wollma, 1992; Singer, 1978), dream-like, bizarre, and hallucinatory experiences have occurred. These observations, coupled with accumulating evidence that REM and NREM reports were not so qualitatively dissimilar (Antrobus, 1983; Cavallero et al., 1992; Foulkes & Schmidt, 1983), have led to the proposition of a single dream system or process which functions across states at different levels of activation (Cavallero & Cicogna, 1993; Cicogna et al., 2000; Foulkes & Cavallero, 1993). This conceptualization identifies REM sleep as one condition among many which would be expected to accompany dreaming, and thereby minimizes the expectation that REM sleep physiology will provide an explanation for dreaming (Foulkes & Cavallero, 1993).

However, just as brain injury may impact on the characteristics of cognitive activity during both wakefulness and sleep (Kerr, 1993), so too must characteristics of sleep cognition be influenced by alterations of the functional architecture of the sleeping relative to the waking brain. Brain imaging studies in humans (Braun et al., 1997, 1998; Hong et al., 1995; Kjaer et al., 2002; Maquet, 2000; Maquet et al., 1996) are beginning to document similarities and differences in cortical and subcortical activation between the waking and sleeping brain that may offer new possibilities for understanding specific dream characteristics. For example, the reported deactivation during REM sleep of areas of the frontal cortex known to be involved in integration of sensory information during wakefulness (Braun et al., 1997; Maquet, 2000), may be consistent with the absence of reflectiveness which is characteristic of REM dream reports.

In addition to the findings indicating qualitative similarities between REM and NREM mentation, there have been additional reports contradicting the generally accepted view of dreams as characteristically bizarre, unusual, and dramatic experiences that differ significantly from waking thought (Dorus et al., 1971; Foulkes et al., 1967; Snyder, 1970). On the basis of these reports and others comparing, for example, the nature of dreams collected in home or laboratory environments, Foulkes (1996) concluded that “representatively sampled dream experiences, in both content and form, have a texture not so vastly different from, or unfamiliar to, waking experience.” (p. 615). These observations effectively demystify the dreaming process but, while acknowledging variations that occur as a consequence of state differences, nevertheless suggest fundamental cross-state similarities between waking and sleeping cognitive systems. Although the determinants of waking-life representation in sleep mentation are still not well understood (Nielsen et al., 2004; Schredl & Hofmann, 2003), support for cross-state commonality of cognitive systems has been provided by studies indicating that individuals with waking cognitive or sensory defects (e.g., resulting from brain damage) show deficits consistent with these impairment in dream experiences (Doricchi & Violani, 1992; Kerr, 1993). Another source of support comes from developmental studies of dreaming. The latter are particularly relevant, not only because of their normative nature, but because features of the ontogeny of physiological aspects of sleep offer unusual opportunities to investigate the development of dreaming. Many of the physiological characteristics of sleep in the adult are not present in the newborn, but perhaps the most dramatic difference is the predominance of REM sleep at this time (40–70% of total sleep time) with an approximation of adult levels of REM sleep not occurring until after the first year (Louis et al., 1997; Pivik, 1983; Roffwarg, Muzio, & Dement 1966; but see Frank & Heller, 2003 for a modified view of sleep ontogeny). The presence of large amounts of this state at a time in development when neuronal processes underlying CNS maturation are highly active prompted

Roffwarg, Muzio, and Dement (1966) to suggest that REM-associated activity provided a source of endogenous stimulation important for aspects of normal CNS development. This hypothesis, which is consistent with the influence of activity dependent factors on neural development, has received support from animal studies demonstrating that interruption of REM sleep phasic influences early in the postnatal period, either by REM sleep deprivation or suppression of PGO spike activity, impairs the course of visual system development (Marks et al., 1995; Oksenberget al., 1996). However, to expect that the REM sleep-dreaming association, which is so prominent in adults, would be present in early development when waking sensory and cognitive skills are only beginning to form requires ascribing extraordinary psychological functions to the REM state. At what point does the REM sleep-dreaming relationship become evident, and with what implications for the relationship between cognitive processes during wakefulness and sleep? Given the emphasis in early postREM discovery sleep research on sleep physiology and psychology in adults, it is not surprising that answers to these questions were not immediately forthcoming. When the results of studies of dreaming in early childhood were presented (Foulkes, 1982; Foulkes et al., 1990, 1991) they revealed that reports of REM dreams with formal properties of adult dreams only became evident by the age of eight or nine, and that the processes required for imagery during waking and sleep develop in parallel. It was concluded that dreaming "is a symbolic process with strong cognitive prerequisites and with a developmental history much like that of waking symbolic thought [and waking consciousness]" (Foulkes, 1996, p. 19). Consistent with this parallelism between waking and sleeping cognitive processes is the observation that visual imagery is absent in the dreams of the congenitally blind or those blinded before the age of five (i.e., before dreaming can be demonstrated), but present in those blinded at or after this time when dreaming with properties essentially similar to those in adults occurs (Foulkes, 1993; Kerr, 1993).

CONCLUSIONS, UNANSWERED QUESTIONS, AND FUTURE DIRECTIONS

Overviews of research fields too often emphasize unresolved issues or areas of contention and neglect to emphasize accomplishments. In little more than one generation, research into the related topics of sleep and dreaming has produced remarkable achievements and revelations. These areas, once almost exclusively the topic of anecdotal and speculative discussion, have been redefined by the application of rigorous scientific investigation with resulting significant empirical revelation regarding the physiological and psychological nature of these ubiquitous human experiences. At the physiological level, enough has been discovered about sleep mechanisms, influences on these mechanisms, and normative aspects of sleep (McGinty et

al., 1985; Montplaisir & Godbout, 1990; Steriade & McCarley, 1990) to permit the extensive differentiation of a variety of sleep abnormalities, many of which can now be effectively treated (ICDS, 1990; Kryger et al., 1994, 2000). Nevertheless, questions remain regarding the processes underlying virtually every aspect of sleep control, including the initiation, maintenance and termination of sleep as a state, as well as between- and within-sleep stage variations. These are truly complex questions, but the coupling of new molecular and genetic methods with those of anatomy, neurophysiology, and biochemistry (Cirelli, Pompeiano, & Tononi, 1996; Pack & Mackiewicz, 1996; Thakkar, 1996) to address these issues offers real promise that they may be resolved.

Unmasking the mechanisms underlying these sleep-specific processes will undoubtedly provide information essential to understanding an equally challenging and important mystery, namely how the states of sleep and wakefulness, which together constitute the entirety of normal human existence, are effectively interfaced to determine our physiological and cognitive status and capabilities. In this regard, studies related to sleep debt are particularly relevant. Sleep debt – a construct inferred from influences of "inadequate sleep" on neurobehavioral and metabolic measures during wakefulness – ultimately relates to an ideal, but likely individualized (Van Dongen et al., 2004), balance between optimal daily amounts of sleep and wakefulness (Dinges, 2004; Horne, 1988; Van Dongen et al., 2003). Whether current society suffers from a debilitating curtailment of sleep amount continues to be debated (Dinges, 2004; Horne, 2004). However, negative effects of sleep reduction on neurocognitive (Belenky et al., 2003; Drake et al., 2001; Van Dongen et al., 2003), metabolic (Spiegel, Leproult, & Van Cauter, 1999), and health-related variables, including appetite control (Spiegel et al., 2004), cardiovascular modulation (Ayas et al., 2003; Spiegel et al. 2004), socioeconomic status (Van Cauter & Spiegel, 1999), loneliness (Cacioppo et al., 2002), and longevity (Kripke et al., 2002), continue to be documented. There is evidence of compensatory adaptive mechanisms that function to counter sleep restriction effects (Drake et al., 2001; Spiegel et al., 2000), but these adaptive changes may persist beyond the period of sleep restriction, thereby maintaining performance at reduced, but stabilized levels, and effectively delaying recovery (Belenky et al., 2003).

Studies of sleep cognition have produced results that are no less remarkable than those of sleep physiology. These investigations have broadened our understanding not only of the organization and formal characteristics of dreams, but have demonstrated that dreaming is a pervasive behavior that is not restricted to a particular sleep stage or even to sleep (Antrobus & Bertini, 1992; Cavallero & Foulkes, 1993; Ellman & Antrobus, 1991; Foulkes, 1985). Furthermore, the evidence showing that this behavior requires cognitive abilities, which normally are not developed until well into the first decade of life (Foulkes, 1982; 1993), indicates that dreaming is not an automatic and inevitable

consequence of REM sleep. The many empirical accomplishments resulting from years of research into sleep cognition have significantly informed us regarding many aspects of dreams and the dreaming process, but have also raised new questions (e.g., what features and processes are common to, or distinguish between, cognitive activity during wakefulness and sleep) and left us still contemplating fundamental questions such as why dreams are so readily forgotten or whether dreaming has an adaptive function.

Of relevance to this question of possible adaptive consequences of sleep cognition is a recent resurgence of interest into relationships between sleep and learning. Although the function(s) of sleep remain a matter of debate and research, it seems highly improbable that the biological and behavioral costs associated with maintaining such a state would be tolerated without the realization of significant benefits essential to normal functioning. Given the basic dependence on learning and memory for daily functioning and survival, it would seem judicious to allocate resources associated with these processes to a protected time, such as sleep, when interactions with the environment and the related need for online processing of new information are minimized. Consistent with this sleep-related reduction in sensory appreciation, sleep learning, or at least the memory for materials presented to the sleeping subject, has been shown to be generally impaired (Goodenough, 1978). The new emphasis on sleep, learning, and memory focuses rather on the enhanced consolidation of learning processes set in motion during wakefulness. Evidence is gathering indicating an important facilitating effect of sleep processes on learning and memory [see special issues of *Science* (294, 2001) and *Learning and Memory* (11, 2004) for current reviews]. A basic premise underlying these studies is the reactivation and extended processing during sleep of waking memories. Animal studies have provided support for this reactivation process by showing the replay, during sleep, of ensemble activity patterns of neuronal activity observed during specific waking experiences (Pennartz et al., 2004; Skaggs & McNaughton, 1996).

Among the many questions about memory processes and sleep to be addressed by future research are those related to possible functions of dreams beyond the reported memory enhancement by strengthening old memories and forming new memory connections. Is the dream narrative simply epiphenomenal to the memory functions being accomplished, or does the matrix of associations generating the specific dream experience also reflect the operation of adaptive processes involved for example, in the formulation of basic behavior strategies used to deal with daily problems (Cartwright, 2004)? An example of the failure of mental activity during sleep to provide a psychological adaptive resolution of an existing problem can be found in the dreams of posttraumatic stress disorder patients. Dreams of this group are atypical in two important respects: first, whereas dreams are generally com-

posed of the integration of new and old memory fragments (Fosse et al., 2003; Paller & Voss, 2004), these consist of the replay of intact episodic memories; and secondly, these dreams may occur repetitively over long periods of time (Van der Kolk et al., 1984). These recurrent anxiety dreams may reflect the disruption of adaptive memory-modulating mechanisms (Wiedenmayer, 2004). When taken together with the effects of sleep restriction on waking neurobehavior, these indications of an important involvement of sleep with memory processes suggest an even more profound effect of sleep deprivation on behavior because it compromises both the effective processing of recent information as well as the acquisition of new information.

REM sleep remains the state from which dreaming is most likely to be reported but, except for the general association between REM sleep state physiology and dreaming, attempts to determine reliable links between sleep physiology and sleep cognition have been largely unsuccessful. Perhaps, as suggested by Rosenlicht and Feinberg (1997) for REM sleep, but probably applicable to any situation where dreaming occurs, this apparent "gross psychophysiological mismatch" may reflect an inherent dissociation during dreaming which relates to both physiological and psychological state function at this time. If, as Foulkes (1997) suggests for "minds capable of conscious representational and self-representational intelligence" (p. 4) that "dreaming is the form assumed by consciousness whenever there is residual but somewhat dissociated cognitive/cerebral activation in the relative absence of direction either from the person's environment or from voluntary self-control" (p. 3), then perhaps these dissociations may be better understood in terms of the functional activation of various brain areas and systems at the time of the dream relative to that during nondream experiences. Promising indications that such relationships may indeed be the case can be found in the application of sophisticated EEG analyses (Cantero et al., 2004; De Gennaro et al., 2004; Mölle et al., 2004) and functional imaging technology to the study of physiological and cognitive processes during sleep (Balkin et al., 2002; Braun et al., 1997, 1998; Hong et al., 1995; Kjaer et al., 2002; Maquet, 2000; Maquet et al., 1996), in the array (Domhoff, 2000, 2003) and refinement of instruments and procedures to evaluate such features of these cognitive experiences as bizarreness (Reinsel et al., 1992) and sensory qualities (Antrobus et al., 1987; Rechtschaffen & Buchignani, 1992), and in the development of heuristic theoretical models that integrate these complex data (Antrobus, 1993; Kahn et al., 1997). The continuing development of such technologic and methodological procedures and their combined application in the same subjects at times associated with the occurrence of sleep mentation, as well as during wakefulness under conditions where levels of perceptual processing and symbolic cognition are controlled, will facilitate the identification of similarities and differences in cross-state processes. Such studies will most likely reveal that the sleep-wakefulness state barrier is more permeable than

once thought, and the biological and cognitive processes defining these states are more meaningfully related than many previously imagined.

GLOSSARY

dreaming A manifestation of human consciousness consisting of the symbolic representation of knowledge that occurs when appreciation and processing of environmental stimuli are minimal and voluntary control of thought processes is lost.

nonrapid eye movement (NREM) sleep includes all sleep other than REM and collectively refers to sleep stages 1–4.

ponto-genicul-o-occipital (PGO) spikes as reported from animal studies, this activity consists of monophasic potentials, most readily recorded during sleep from the pons, lateral geniculate bodies, and occipital cortex just prior to and during REM sleep, which are considered to be a primary source of phasic activity during REM sleep.

rapid eye movement (REM) sleep a periodically occurring sleep stage characterized by low voltage, mixed frequency EEG, rapid eye movements, autonomic variability, motor inhibition, and commonly associated with frequent dream recall.

scanning hypothesis the proposition that eye movements during REM sleep are examining dream images as they would visual images during wakefulness.

sleep cycle the recurrent alternation of REM and NREM sleep occurring across the night with a periodicity of approximately 60 minutes in infants and 90 minutes in adults.

slow wave sleep (SWS) sleep characterized by low frequency EEG activity, particularly in the delta band (0.5–4 Hz), and generally refers to sleep stages 3 and 4 combined.

Psychophysiology in Research on Psychopathology

J. CHRISTOPHER EDGAR, JENNIFER KELLER, WENDY HELLER,
AND GREGORY A. MILLER

Psychophysiological measures such as hemodynamic imaging, electromagnetic source imaging, startle blink, eye movement, and autonomic responses provide diverse and sometimes unique views of an individual's functioning. Psychophysiological findings can corroborate (or contradict) findings from more traditional psychological measures of functioning, including self-report scales, behavioral performance, informant data, and diagnostic interviews as well as complement traditional biological measures spanning endocrine, genetic, and other domains. Psychophysiological findings are also useful in monitoring the time course of mental processes involved in task performance, in measuring mental processes the individual does not report, and in assessing behavior when the production of an overt response is undesired or unavailable (Coles, 1989). In psychopathology research psychophysiological measures are increasingly used as endophenotypes, and researchers increasingly examine the use of psychophysiological measures rather than subjective symptoms to define diagnostic subtypes.

A goal of this chapter is to consider some of the theoretical and practical issues associated with the use of psychophysiological techniques to study psychopathology. The chapter provides a discussion of several theoretical concepts underpinning early psychophysiology studies and some philosophical issues that currently confront psychophysiology researchers, a selective review of psychophysiological studies examining three disorders (anxiety, depression, and schizophrenia), and proposals for how to handle some of the practical difficulties associated with psychophysiological research. The review is necessarily limited, largely ignoring some types of psychopathology and some psychophysiological measures. However, most of the practical problems discussed are not specific to studies discussed below.

HISTORICAL CONTEXT OF PSYCHOPHYSIOLOGICAL STUDY OF PSYCHOPATHOLOGY

Theories of psychopathology often explicitly encompass physiological phenomena, and psychophysiology has been

a useful tool for the investigation of clinical phenomena. Much of the best psychophysiological work on psychopathology has been driven by prevailing theory. In order to gain insight into the history of psychophysiological investigation of psychopathology it is important to consider the work in the context of the theoretical concepts of the time.

The concept of nonspecific reactivity was an early influence in psychophysiological research on psychopathology. Individuals with schizophrenia and depression were often noted to appear withdrawn and to exhibit blunted affect. Much early work attempted to account for this behavioral hypoactivity by looking for physiological hyporeactivity. This was consistent with the James-Lange theory of emotion, which defined emotions not merely as correlates of but actually as being peripheral physiological changes. In an attempt to understand emotional abnormalities in psychopathology researchers sought abnormal physiology (e.g., Malmo & Shagass, 1949).

Landis (1932) conducted an extensive review of electrodermal studies looking for a consistent pattern of abnormal physiology in schizophrenia, but none was apparent. Cohen and Patterson (1937) found that changes in pulse rate tended to be larger in patients than controls. Malmo and Shagass (1949, 1952) examined heart rate, electrodermal activity, respiration, and blood pressure in patients with acute or chronic schizophrenia. First-episode patients showed greater reactivity to stressors than either chronic patients or controls, who were similar. These findings were taken as evidence against the notion that behavioral hyporesponsiveness can be attributed to physiological hyporesponsiveness.

Lang and Buss (1968) reviewed the literature on physiological reactivity and found evidence that some individuals with psychopathology were physiologically hyporesponsive to particular stressors. The fact that the hyporesponsiveness was limited to certain types of stressors argued against a generalized deficit in physiological reactivity and accounted for the pervasive deficits seen in psychopathology. Overall, early studies of physiological reactivity in psychopathology suggested that

hyporeactivity is more prevalent in more chronic individuals, but that generally patients react normally under higher levels of stimulus intensity.

Many early studies examining reactivity did not provide critical methodological information, such as an adequate description of the patient sample or the stimuli. Diagnostic criteria were not uniform and have evolved considerably. In addition, poor description of stimuli, tasks, or data analysis is problematic given that comparing physiological reactions across groups can be a challenge because differences in basal levels can complicate interpretation of the response (Lacey, 1956).

Over time, the concept of nonspecific physiological reactivity proved not to be broadly viable as a central organizing principle. Lacey (1967), Lang (1968), and others (see Miller & Kozak, 1993) argued convincingly that different response systems too often diverge for the concept to be of general use. Remarkably, to this day the overwhelming evidence for that conclusion is not widely appreciated, and vague concepts of generalized arousal are still invoked all too often in studies of psychopathology and psychophysiology. This usage should be distinguished from arousal concepts applied more defensibly in domains such as in self-report measurement of the dimensions of emotion or theories of region-specific brain activity in emotion and psychopathology (reviewed below) for which "arousal" is more narrowly defined and operationalized.

Another theoretical concept guiding early research was physiological activation. Clinical observations suggested that some psychiatric groups differ from controls in baseline level of physiological activity as opposed to responses to specific stressors. Muscle tension was a common measure of activation, and the general finding was that some patients demonstrated greater skeletal tension than controls (Duffy, 1962). EEG was also used to assess activation, on the assumption that brain activity is inversely and monotonically related to activity in the 8–13 Hz range (alpha band). Davis and Davis (1939) found that patients demonstrated less alpha than did control subjects. Other studies found less resting alpha and more activity in higher and lower bands in anxious subjects (see Duffy, 1962, for review of early EEG findings in psychopathology). Although finding group differences in EEG has not been uncommon in subsequent studies, the functional significance of such differences is often unclear. Global EEG activity as a measure of resting, nonspecific activation has not proven very useful in psychopathology research. For example, more recent work on region-specific alpha has rendered the nonspecific activation concept obsolete (e.g., Salmelin & Hari, 1994), like what had happened to the related but distinct concept of nonspecific arousal.

A third concept that has received substantial psychophysiological attention is physiological dysregulation in psychopathology. In contrast to traditional concepts of arousal and activation, dysregulation has often been conceptualized narrowly rather than as a nonspecific phenomenon operating more or less indiscriminately across

peripheral physiological systems or brain regions. Perhaps as a result, the concept of physiological dysregulation has remained a prominent focus in psychopathology research. The early work investigated not only how physiological patterns were disrupted but circumstances that could influence the regulation. Buck, Carscallen, and Hobbs (1950, 1951) reported lower and less variable body temperature in schizophrenia. Ax (1962) analyzed physiological regulation in schizophrenia and suggested that dysregulation was best observed when comparing multiple systems that typically operate together (such as heart rate and respiration). The dysregulation appeared between multiple systems that were not coordinating properly rather than within a single system. Because respiration affects heart rate by means of proprioceptive signals from the chest, diaphragm, and lungs, Ax (1962) suggested that such signals are impaired in schizophrenics. A more recent view of schizophrenia suggested that an impairment of proprioceptive information is involved in the development of positive symptoms (Frith, 1992). These findings on dysregulation are a few of many that reinforce the approach of examining multiple systems. This theme recurs in the review of modern work on psychopathology presented below.

CURRENT PHILOSOPHICAL ISSUES IN PSYCHOPHYSIOLOGICAL RESEARCH

The potential of psychophysiology to contribute to the study of psychopathology has been undermined historically by two common, problematic assumptions. First, naively reductionistic conceptualizations of the relationship between psychological and physiological phenomena have been a consistent embarrassment in psychopathology research for decades. Approaches that aim to identify either the biological or the psychological phenomena "underlying" psychopathology fail to recognize that psychopathology must be understood in terms of both biological and psychological factors. Indeed, it is not clear whether biology underlies psychology, whether psychology underlies biology, or whether the concept "underlie" is even a valid representation of the relationships among psychological and biological phenomena (for further discussion see Miller, 1996; Miller & Keller, 2000; Miller, in press).

A second problematic assumption is grounded in the psychological realm but has implications for the selection and interpretation of biological measures. Phenomena of interest in psychopathology (and in psychology more generally) are often dichotomized into emotion and cognition. In psychophysiology, this dichotomy often plays out as an implicit assumption that central nervous system measures are appropriate for the study of cognition, whereas peripheral nervous system measures are better suited to the study of emotion. Yet there is very little theoretical need or empirical support for this dichotomy or for limiting which physiological measures to associate with which psychological

events. A common misstep in research on psychopathology, especially research emphasizing cognitive processes, is to seem to differentiate emotion from cognition without carefully articulating the distinction and then to invoke "emotion" as some qualitatively distinct phenomenon or process that drives or is driven by (and in any case is quite distinct from) cognition. It is far more parsimonious to assume that emotion processing involves the same types of psychological and biological computations that accomplish cognition and to employ emotion in one's model accordingly (for further discussion see Miller, 1996; Miller & Keller, 2000; Miller, Engels, & Herrington, *in press*).

The growing appeal of psychophysiological measures in research on psychopathology reflects their specificity to the operation of mental processes associated with symptoms of psychopathology. An exclusive focus on behavioral symptoms can be a frustrating basis for identification of related mental events. Similar disturbances in mental processing can be associated with different symptoms, just as disturbances of different mental processes can lead to similar symptoms. By studying mental processes as opposed to symptoms or traditional diagnoses alone, it is possible to determine diverse manifestations of a disease process in cognitive and emotional function. Although the present chapter reflects the historical emphasis on psychological processes in psychophysiology, psychophysiological measures are equally valuable for research questions emphasizing physiological processes (Miller, 2000; Miller & Ebert, 1988). Thus, for example, psychopathology is by definition a disorder of psychological functioning and not of biological function (Miller & Keller, 2000; Kozak & Miller, 1982; Miller, 1996). However, the value of understanding the neurobiology of normal and abnormal psychological functioning is now widely appreciated. Because of its noninvasive technology and its sophistication in psychological theory and experimental design, psychophysiology remains at the forefront of the increasingly biological agenda in psychopathology research.

PSYCHOPHYSIOLOGICAL STUDIES OF PSYCHOPATHOLOGY: SELECTED EXAMPLES

There is an ongoing debate in the psychopathology literature about whether to view psychological disorders as discrete categories or within a dimensional framework (Clark, Watson, & Reynolds, 1995; Millon, 1991; Widiger & Samuel, 2005), but the bulk of psychophysiological research has assumed a categorical approach. The present focus on three diagnostic categories that have received the most attention from psychophysiological studies (anxiety disorders, depression, and schizophrenia) is not intended as an endorsement of a categorical approach over a dimensional approach or a judgment that standard categories are most appropriate for psychophysiological study.

For each disorder, rather than a cursory overview of the many different psychophysiological techniques that have been used to examine each disorder, a detailed review of

the use of psychophysiological measures to examine particular constructs (e.g., selective attention) or brain regions (e.g., hippocampus) is provided. In providing an in-depth examination of particular research areas – comparing and contrasting findings across studies – conceptual and pragmatic difficulties associated with research in each area are highlighted. As will become evident, the difficulties discussed (e.g., dealing with patients with comorbid disorders) are common to all psychophysiological studies of psychopathology.

Anxiety disorders

Fourteen anxiety disorders are listed in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR; American Psychiatric Association, 2000, pp. 754–755). That list does not take into account potential dimensions of anxiety suggested in the literature (e.g., Barlow, 1988, 1991; Heller et al., 1997; Koven et al., 2003), subclinical forms, or degrees of anxiety studied in the personality literature and probably of great clinical relevance. The debate about whether mental disorders should be seen as discrete categories or as points on a continuum of normal behavior is prominent in the anxiety literature because it is unclear whether subclinical anxiety and the various anxiety disorders are best conceptualized in terms of one or more dimensions or as qualitatively distinct phenomena. Even if healthy and pathological anxiety represents distinct phenomena, there may be some overlap between them including their physiology. Thus, it is useful to study nonclinical individuals under stressful and anxiety-provoking conditions as well as individuals with pathological anxiety.

When studying psychopathology with psychophysiological measures, one issue that arises is whether the focus of study is mechanisms of the psychopathology itself or the consequences of the psychopathology. Physiological differences are often discussed as if they are due to anxiety rather than being part of anxiety. Such a view may misrepresent the role of physiology in anxiety or in any emotion. Lang (1968, 1978) addressed the study of emotions by proposing the "three-systems" model, which suggests that emotions are expressed in three observable domains: verbal, physiological, and behavioral activity. Thus, a complete picture of normal and pathological emotion requires assessment of all three. Although the three-systems model is widely cited, a more subtle but equally fundamental recommendation in Lang's work is less widely appreciated (see Miller & Kozak, 1993, for discussion). Lang suggested that the activity of all three systems is part of anxiety, and not due to anxiety. For example, elevated heart rate or lateralized EEG patterns are not responses to an anxious state, but part of what it means to be in an anxious state. Similarly, physiological events during fear-provoking imagery are not responses to imagery stimuli but part of the process of imagery.

Psychophysiological approaches to anxiety long focused on autonomic measures (see Zahn, 1986). Interest has grown in modulation of the startle reflex (Blumenthal

et al., 2005; Bradley, *in press*; Cuthbert, *in press*) and in brain regions (Bradley, *in press*; Davidson, Jackson, & Larson, 2000) that become more or less active during periods of anxiety. Although some early studies found no relationship between anxiety and cerebral metabolism (Giordani et al., 1990), most have suggested that one hemisphere is more active during anxiety than the other. However, the direction of this effect has been inconsistent (for reviews see Nitschke et al., 1999; Heller et al., 1997; Heller et al., 2002).

In light of these inconsistencies, Gruzelier (1989) and Heller and colleagues (Heller, Etienne, & Miller, 1995; Heller et al., 1997; Heller, Koven, & Miller, 2003; Nitschke et al., 1999) suggested that anxiety can favor either hemisphere, and the direction is dependent on the severity and type of anxiety. They suggested that left-hemisphere involvement is associated with anxious apprehension, which is reflected in cognitive processes such as worry, rumination, and obsessional thinking, whereas right-hemisphere involvement is associated with anxious arousal, which is reflected in sympathetic nervous system activity and cognitive processes such as vigilance and enhanced hemispatial attention. These types reflect lateralized EEG findings and behavioral data from lateralized tasks, although evidence using autonomic measures also suggests that subtypes of anxiety can be dissociated (Zahn, 1986). Studies of both central and autonomic measures associated with anxiety will be necessary to develop a more complete theory of these dimensions and how they relate to DSM subtypes (Keller, Hicks, & Miller, 2000).

Diagnostic categories of anxiety are distinguished in part by whether there is a specific eliciting event. Research on anxiety disorders in which specific stressors or circumstances are found to elicit anxiety, such as simple phobias, social phobia, and post-traumatic stress disorder (PTSD), has noted a number of psychophysiological changes during exposure to anxiety-eliciting stimuli. When anxiety has a specific prompt, the individual generally responds with increased sympathetic autonomic activity (see Hugdahl, 1989, and Öst, 1989, for reviews on simple phobias and panic disorder, agoraphobia, and social phobia). However, an unusually large clinical case series documented considerable differential somatic physiology as a function of type of anxiety (Cuthbert et al., 2003). Importantly, the pattern of self-reported symptoms did not align well with the differential physiology, which suggests distinct and somewhat complex relationships of various observable indicators of anxiety to underlying processes that may speak to the responsiveness of different types of anxiety to various types of therapy.

Whereas research on generalized anxiety has used central nervous system measures such as EEG and rCBF, the vast majority of research on stimulus-specific anxiety disorders employed autonomic measures until recently. This emphasis on autonomic measures in the study of emotion may reflect two arguable assumptions. The first assumption is that anxiety is an emotional disorder as opposed to a disorder of cognition. As discussed above, it is unnecessary to assume that a given psychological phenomenon should be understood in exclusively emotional or exclusively cognitive terms. The second problematic assumption is that, if anxiety is a disorder of emotion, it is more appropriate to study it using physiological measures historically associated with emotion rather than those typically associated with cognition. As noted above, this historically common assumption is unnecessary. Anxiety can be investigated with either central or peripheral measures.

Posttraumatic stress disorder (PTSD). To illustrate roles for both central and peripheral measures when researching anxiety disorders, psychophysiological findings for PTSD will be selectively reviewed. This is a rapidly growing research area, and the number of reviews of psychophysiological studies on PTSD continues to grow (McNally, 2003; Shin, Rauch, & Pitman, *in press*; Shin et al., 2004a; Karl, Malta, & Maercker, 2006).

In autonomic studies, PTSD patients have consistently been found more reactive to trauma-related stimuli than a variety of groups, including nonPTSD trauma victims, nonpsychiatric controls, and other anxiety-disordered patients. This has been observed across a variety of experimental contexts, including paradigms using auditory and visual traumatic stimuli and script-driven imagery (e.g., Pitman et al., 1987; Prins, Kaloupek, & Keane, 1995).

With PTSD patients clearly hyperresponsive to trauma-related stimuli, it is important to determine whether the hyperresponsiveness is limited to trauma-related stimuli. Some studies have found that PTSD patients are not hyperresponsive in trauma-neutral contexts, such as mental arithmetic (e.g., Blanchard et al., 1996; Gerardi, Blanchard, & Kolb, 1989; Pallmeyer, Blanchard, & Kolb, 1986), whereas others have found an exaggerated startle response to neutral auditory stimuli (see Prins, Kaloupek, & Keane, 1995).

EEG studies examining PTSD patients' responses to nontrauma stimuli have found differences in various ERP components. P50 auditory sensory gating, augmenting-reducing P200, and P300 in target detection oddball tasks are the most frequently studied ERP components. For example, employing a paired-click task to examine auditory gating processes, Gillette et al. (1997) observed impaired P50 gating in individuals with combat-related PTSD, with gating ratios correlating with intensity of PTSD re-experiencing symptoms (e.g., trauma-related nightmares and flashbacks). Although the finding of abnormal P50 gating in subjects with PTSD has been replicated (e.g., Ghisolfi et al., 2004; Neylan et al., 1999; Skinner et al., 1999), the relationship between PTSD symptoms and impaired gating is unclear. For example, Metzger et al. (2002), examining female Vietnam nurse veterans with and without current PTSD, observed that reduced P50 suppression was associated with increased severity of general psychopathology, but not with a PTSD diagnosis. In

addition, as described below, atypical P50 gating ratios are observed in many patient populations. Research is needed to determine the significance of impaired auditory gating in PTSD and to examine auditory gating differences between patient groups. In any case, the P50 findings are clearly indicative of abnormal brain activity in response to nontrauma stimuli.

Perhaps the most commonly studied ERP component is the P300, a positive voltage shift in the EEG time-locked to an infrequent or significant event. McFarlane, Weber, & Clark (1993) examined midline ERPs in a three-tone auditory oddball task in controls and patients with PTSD. For the PTSD group, N200, a negative-going ERP component that typically occurs following the recognition of a change in the stimulus series, occurred later. P300 amplitude was smaller and did not distinguish the infrequent tones, whereas controls demonstrated larger P300 to targets than to distractors. McFarlane, Weber and Clark (1993) suggested that patients spent more time on stimulus discrimination, reflected in N200 latency, which leaves fewer resources available for subsequent processing, as evidenced by decreased P300 amplitude.

P300 abnormalities in PTSD have been replicated by some investigators (e.g., Charles et al., 1995; Metzger et al., 1997a; Metzger et al., 1997b), but not others (e.g., Metzger et al., 2002, observed increased target P3b amplitudes in female Vietnam nurse veterans with PTSD). It appears that some differences across studies may be attributable to a more variable P300 in individuals with PTSD (see Neylan et al., 2003). At present, P300 findings suggest the importance of examining measures of variability as well as measures of central tendency, and highlight the need to consider the role of comorbid diagnoses and medication effects when interpreting results.

Difficulty in trauma-related recall is a cardinal feature of PTSD, and several studies have reported impaired performance on tests of verbal and visual memory (e.g., Bremner et al., 1993; Bustamante et al., 2001; Gilbertson et al., 2001). Given the role of the hippocampus in memory processes, researchers have become interested in hippocampal structure and function in PTSD subjects. Interest in the hippocampus also comes from theories about the effect of stress on the hippocampus. Nadel and Jacobs (1998) proposed that some symptoms of PTSD reflect hippocampal damage secondary to stress-related steroid exposure. A number of subsequent authors have endorsed this view, but McNally (2003) argued that having a small hippocampus is a risk factor for, rather than a result of, clinically significant PTSD. Although several studies have observed reduced hippocampal volume in individuals with PTSD (e.g., Bremner et al., 1995; Bremner et al., 2003; Gilbertson et al., 2002; Gurvits et al., 1996; Lindauer et al., 2004; Villarreal et al., 2002a), these findings have not been consistently replicated (e.g., DeBellis et al., 1999; DeBellis et al., 2001; Bonne et al., 2001; Schuff et al., 2001). Aside from reduced hippocampal volume, magnetic resonance spectroscopy (MRS) studies have reported decreased neu-

ronal integrity in hippocampus, as measured by decreased N-acetylaspartate (NAA) levels (e.g., Schuff et al., 2001; Villarreal et al., 2002b).

Although there is clear evidence for structural hippocampal abnormalities in at least a subset of individuals with PTSD, the significance of these abnormalities is uncertain. For example, examining bilaterally reduced hippocampal volume in abused women with PTSD and without PTSD, Bremner et al. (2003) reported that in abused women with PTSD measures of symptoms of dissociation were correlated with smaller left hippocampal volume, and measures of PTSD symptoms were correlated with smaller right hippocampal volume. Bremner et al. (2003) additionally noted that smaller hippocampal volume was not seen in all subjects with a history of childhood abuse, but only in subjects with both a history of abuse and a diagnosis of PTSD. In an earlier study, Gurvits et al. (1996) reported that hippocampal volume is negatively correlated with amount of combat exposure, and suggested that repeated traumatic stress damages the hippocampus. However, in contrast to these studies, examining hippocampal volume in controls, trauma-exposed subjects with PTSD, and trauma-exposed subjects without PTSD, Winter and Irle (2004) found significantly smaller volumes of the right hippocampus in both trauma-exposed groups (severe burn subjects both with and without PTSD). In addition, larger total areas of burned body surface were significantly related to smaller left hippocampal volumes, and the use of analgesic/sedative treatment of the N-methyl-D-aspartic acid (NMDA) antagonist ketamine was significantly related to larger right hippocampal volumes and to stronger PTSD symptoms. Winter and Irle concluded that small hippocampal size may not be associated with PTSD, but instead reflects the result of traumatic stress. In addition, although the application of NMDA antagonists may protect against hippocampal damage induced by traumatic stressors, this treatment strategy increases the patient's risk of developing PTSD symptoms. Additional studies examining trauma subjects with and without PTSD are needed to replicate and interpret these recent findings.

In addition to structural abnormalities, several studies have observed abnormal hippocampal activation (Semple et al., 1993; Bremner et al., 2003; Osuch et al., 2001; Shin et al., 2004; although see Rauch et al., 1996). In a PET study examining hippocampal rCBF during an explicit memory recall task, Shin et al. (2004) took findings of generally elevated hippocampal activity in firefighters with PTSD as indicative of both reduced efficiency of hippocampus during the performance of a memory task or impaired integrity of inhibitory interneurons within the hippocampus. They further observed that symptom severity was positively associated with rCBF in hippocampus and parahippocampal gyrus. These findings are similar to the positive correlation between flashback intensity during symptom provocation and perihippocampal rCBF observed by Osuch et al. (2001).

Although both structural and functional hippocampal abnormalities are consistently observed in subjects with PTSD, research examining the relationship between functional and structural abnormalities is needed, which is a point underscored by Shin et al. (2004). Noting that rCBF abnormalities in the hippocampus might reflect a functional compensation for reduced hippocampal volumes, Shin et al. (2004) hypothesized that hippocampal rCBF changes should correlate with hippocampal volumes and that statistically controlling for hippocampal volumes should eliminate the group differences in rCBF increases (see Roadblocks and Recommendations section for a discussion on methods for controlling for group differences). However, they found neither to be true, and noting a small sample size ($N = 8$ per group) they indicated the need for further research in this area with larger samples.

As with other physiological measures, studies examining the relationship between hippocampal structure and function, state/trait factors, and premorbid risk factors are of interest, especially with regard to etiological theories of PTSD. Whereas one line of research suggests that stress-induced neurotoxicity causes hippocampal damage (glucocorticoids secreted during stress), a separate line of research suggests hippocampal abnormalities predate trauma exposure (see Sapolsky, 2002 for a succinct overview of these findings). Given that hippocampal abnormalities are sometimes observed in other disorders (e.g., depression, Steffens et al., 2000; Frodl et al., 2002), the clinical implications of hippocampal abnormalities in subjects with PTSD have yet to be determined.

Summary. Autonomic measures had been the predominant psychophysiological tool in anxiety research, but it is becoming clear that central nervous system measures provide valuable information about the nature of anxiety. Aside from examining differences in stimulus, paradigm, and data analysis methods, an examination of the relationship of state/trait factors and premorbid risk factors to psychophysiological measures is clearly of interest. Also warranting attention is the high rate of comorbidity in PTSD, including major depression, other anxiety disorders, and substance abuse. Bremner (2003) and Friedman and Yehuda (1995) cautioned against the exclusion of patients with comorbid depression and anxiety from PTSD because excluding subjects with these comorbid disorders would in many cases result in an unrepresentative selection of subjects with PTSD. Additionally, a history of early life stress (such as early parental loss or childhood physical or sexual abuse) can confound some of the psychophysiological findings in PTSD (e.g., Heim & Nemeroff, 2002). Successful investigations of PTSD will need to deal with comorbidity issues. Heller and Nitschke (1998), Miller (in press), Miller, Engels, and Herrington (in press), and Mineka, Watson, and Clark (1998) discussed this issue for anxiety and related disorders more generally.

Mood disorders

Research on mood disorders and research on anxiety disorders share some critical elements (Heller & Nitschke, 1998; Heller et al., 2002). Mood and anxiety are both broad constructs, and diagnostic criteria designed to provide discrete boundaries for each disorder may leave much ambiguity. DSM-IV recognizes several mood disorders, including major depression, dysthymia, bipolar disorder, and several subtypes. Additional distinctions within depression have been utilized, including endogenous/exogenous and agitated/retarded as well as a depressive personality subtype. This range of depressive syndromes can complicate the comparison and interpretation of findings. A second issue is the problem of comorbidity. Depression often co-occurs with anxiety, substance abuse, and other disorders. Isolated or subsyndromal symptoms of depression and anxiety are found in other psychological disorders, and symptoms of other disorders may occur in individuals whose primary disorder is depression or anxiety. Research based on well defined theoretical models and well characterized subject groups can help address these issues, but to date such efforts are too rare to permit much integration. This area is especially in need of the improved delimitation of homogeneous endophenotypes (whether defined categorically or dimensionally) that psychophysiology may foster, as discussed above.

Functional asymmetries in depression. One emphasis that has received increasing attention in psychophysiological research is the relationship between asymmetric activity in specific brain regions, affective factors such as valence, and approach versus defensive withdrawal motivation, and specific aspects of cognition. Recent research examining the central circuitry of depression has identified abnormal activity patterns in the dorsolateral prefrontal cortex (DLPFC) during resting states (for review, see Nitschke et al., 2004). A number of positron emission tomography (PET) studies have reported bilateral DLPFC decreases in blood flow and glucose metabolism (for a recent review see Davidson, 2004). Decreased DLPFC activity has also been observed during task performance. Depressed patients showed less DLPFC activity bilaterally on a complex planning task than nonpsychiatric controls in a PET study measuring blood flow (Elliott et al., 1997).

Other evidence suggests that right DLPFC figures importantly in the negative memory bias accompanying depression. An extensive literature has implicated right PFC mechanisms in withdrawal-related negative emotions and in threat perception. Activity in this region under such circumstances is likely to contribute to a negative memory bias (for reviews, see Davidson, 1998; Heller & Nitschke, 1997; Nitschke & Heller, 2002). Furthermore, numerous electroencephalography (EEG) studies have reported more right than left PFC activity in depression (for reviews, see Davidson & Henriques, 2000; Davidson et al., 2002;

Heller & Nitschke, 1997, 1998). A similar pattern of asymmetry has also been observed in a number of the above-mentioned PET studies showing bilateral DLPFC decreases, in which hypoactivity was more pronounced on the left.

Although these findings indicate an asymmetry in favor of the right PFC in depression, investigation into the brain mechanisms contributing specifically to the negative explicit memory bias in depressed subjects has only recently begun. An ERP study revealed no evidence of a negative memory bias in depressed patients, including no topographical differences for P300 between patients and nonpsychiatric controls during encoding or recognition of negative words or faces (Deldin, Keller, Gergen, & Miller, 2001). Another ERP study examining the slow-wave component for negative adjectives in a delayed-match-to-sample paradigm primarily implicated left parietal irregularities in depressed patients with some right PFC abnormalities observed for correlations with depression severity (Deldin, Deveney, Kim, Casad, & Best, 2001). However, behavioral data indicated that the paradigm was not successful in eliciting an overt negative working memory bias in depressed patients. A fMRI study (Elliott et al., 2002) examined another type of processing bias via an emotional go/no-go task previously shown to result in a bias toward sad stimuli in depressed patients. They reported greater right DLPFC activity for sad stimuli in patients than nonpsychiatric controls. Finally, an earlier blood flow study using PET assessing attentional biases did not report DLPFC abnormalities in depressed patients for a standard Stroop paradigm or an emotional Stroop task (George et al., 1997). Thus, although results from studies examining the brain's instantiation of negative memory biases in depression have thus far been mixed, other research on emotion, depression, and anxiety leads to predictions of right prefrontal engagement.

Psychophysiological studies of memory bias in depression are beginning to make sense of a conflicted literature. Nitschke et al. (2004) measured EEG immediately prior to and during the auditory presentation of a sad narrative in a sample of college students with extreme levels (low and high) of depression and anxiety. Bilateral activity recorded over PFC during a preparatory period immediately preceding the sad narrative was associated with better memory performance in participants reporting low levels of depression but not in those with high levels of depression. This finding is consistent with behavioral studies (for reviews, see Hertel, 1994, 2000) suggesting that depressed individuals do not initiate task-relevant cognitive processes unless concrete strategies are provided. Corroborating other research implicating the right PFC in withdrawal-related negative emotions and threat perception, factors that may play a role in negative cognitive biases (Heller & Nitschke, 1997; Nitschke & Heller, 2002), high depression participants showed an association between right PFC activity when exposed to the sad narrative and improved subsequent recognition of words used in that narrative.

These right PFC findings are highly consistent with prior studies investigating various forms of withdrawal-related negative emotions (Davidson et al., 2002, Davidson et al., 2003; Heller & Nitschke, 1997; Nitschke & Heller, 2002). On the other hand, the bilateral frontal effect supporting Hertel's model was particularly pronounced on the left, as indicated by an analysis on asymmetry scores. Such a pattern would be expected to the extent that initiating cognitive strategies is approach-related (e.g., Davidson et al., 2003) or involves verbal processing. In addition, the analyses for EEG data (regardless of memory performance) replicated previous findings. During preparation for the sad narrative, there was a trend for high-depression subjects to show relatively less left than right frontal activity compared to the low depression subjects (for review, see Davidson et al., 2002).

The associations between brain activity and subsequent memory performance in this study are consistent with two seemingly conflicting literatures, one which documents memory deficits in depression and another which reports better memory performance for negative material. Those studies finding memory deficits in depressed samples either have not used negative stimuli or have not systematically assessed the emotional content of the material tested. These findings provide a neurocognitive account for why memory performance in depression might be impaired in some circumstances and enhanced in others. Furthermore, the confluence of the cognitive-initiative deficit producing memory impairment and the negative memory bias producing selective memory enhancement may result in no apparent memory effects in depressed individuals under certain circumstances.

A more longstanding lateralization literature in depression has developed around EEG alpha as an (inverse) measure of emotion-related regional brain activity. Although controversial with regard to methodology and interpretation (Allen et al., 2004), a considerable number of studies point to important differences in cortical activity as a function of emotion and as a function of depression (Davidson, 2004). Surprisingly, until Herrington et al. (2005) the hemodynamic imaging literature was unable to observe the effects long seen with EEG. This study focused on DLPFC activation during an emotional Stroop task. Whereas the EEG literature has invariably included hemisphere as a factor in the analysis, in the cognitive fMRI literature this has been remarkably rare because the analysis tradition unfortunately has tended not to include brain region as a factor. Davidson (1998) argued that explicit laterality tests are essential in most such cases. Herrington et al. (2005) included hemisphere and obtained a Valence × Hemisphere interaction reflecting a highly significant enhancement of left-DLPFC activity for pleasant stimuli relative to unpleasant stimuli versus a small and nonsignificant enhancement in the homologous right-DLPFC region. Using the same fMRI paradigm, Mohanty et al. (2005) demonstrated differential DLPFC lateralization in response to emotional words as a function of trait

schizotypy. Thus, the fMRI literature is beginning to come into line with the large EEG literature on frontal laterality and emotion. A next step will be studying depression with these methods.

Although less studied than frontal asymmetries, abnormal asymmetries in activity for posterior regions have also been described in depression. Heller (1993) suggested that autonomic activity related to emotion is modulated by right-posterior cortex activity. Reduced right-posterior activity is associated with depressed mood, whereas increased right-posterior activity is associated with anxiety characterized by autonomic hyperarousal. Support came from studies showing that depressives have a selective deficit on right-hemisphere tasks (e.g., Rubinow & Post, 1992; Silberman, Weingartner, & Post, 1983). Depressives have also shown a right-hemisphere deficit in paradigms using lateralized stimulus presentation (Bruder, 1995). This abnormal lateralization has been linked to clinical features of depression, such as subtype and treatment outcome. Furthermore, depressives have been reported to show an attentional bias reflecting underutilization of the posterior right hemisphere (Heller, Etienne, & Miller, 1995; Jaeger, Borod, & Peselow, 1987) on the Chimeric Faces Task, a free-vision facial affect processing test (Levy et al., 1983). Keller, Hicks, and Miller (2000) directly addressed this issue in studies of patients and nonpatients with varying amounts of comorbid depression and anxiety. Two experiments, one using patients and a community control group and another using questionnaire-selected nonpatients with controlled amounts of comorbidity, showed the same pattern of more right-posterior activity in anxiety, less in depression, and a nonadditive combined effect associated with comorbidity.

Right-parietal involvement in depression has also been supported by EEG studies reporting decreased brain activity near right-posterior areas in major depressives during tasks of dichotic listening (Bruder et al., 1995), non-lateralized emotional face presentation (Deldin et al., 2000), and verbal memory (Henriques & Davidson, 1995), though not in language processing (Deldin et al., 2006). Neuropsychological findings and theoretical perspectives of Heller and colleagues (e.g., Heller, Etienne, & Miller, 1995) emphasizing the importance of comorbidity in identifying right posterior involvement have been firmly supported by Bruder's research with clinical populations (Bruder, 1995; Bruder et al., 1997; Bruder et al., 2002; Bruder et al., 1999). Decreased right-posterior activity has been found in individuals with remitted depression (Henriques & Davidson, 1990), which suggests that the relationship reflects trait and not state characteristics of depression. Blood-flow studies have reported similar findings (e.g., Flor-Henry, 1979; Post et al., 1987; Uttdenhoef et al., 1983), but with some exceptions (see Davidson & Tomarken, 1989). Extensive reviews are available from Mayberg and Fossati (*in press*) and Shestyuk and Deldin (*in press*).

Amygdalar abnormalities in depression. Numerous studies have examined the structure and function of the amygdala, although findings in depression have been mixed. Increased amygdala volumes have been observed in first-episode major depression patients (Frodl et al., 2002) and patients with dysthymia (Tebartz van Elst et al., 1999). However, amygdala atrophy has also been associated with chronic depression (Sheline et al., 1999), and it has been suggested that depressed individuals have smaller core amygdala nuclei than never-depressed individuals. Potentially this is due to hypercortisolism, which facilitates excitotoxic effects of glutamate (Sheline et al., 1999). Other studies have not observed altered amygdala volumes in depression (Mervaala et al., 2000; Frodl et al., 2002).

Studies examining blood flow in depression suggest increased activation in limbic and paralimbic areas, such as the amygdala, hippocampus, and basal ganglia (for review, see Mayberg & Fossati, *in press*). In the amygdala, both increased activity during a resting state (e.g., Abercrombie et al., 1998; Drevets et al., 2002) and reduced activity during an experimental task (e.g., Kimbrell et al., 2002; Thomas et al., 2001) have been observed. Depressed patients (both unipolar and bipolar) have also demonstrated increased left amygdala metabolism correlated with depression severity and plasma cortisol levels (Drevets et al., 2002), and elevated amygdala metabolism during remission has also been associated with a risk for relapse (Bremner et al., 1997). Increased resting amygdala metabolism may be specific to primary mood disorders because increased amygdala metabolism has not been observed in anxiety disorders (Drevets, 2003).

Several studies have examined amygdala activation in response to emotionally valenced stimuli. Thomas et al. (2001) found that, although healthy subjects showed increased left amygdala activity in response to fear pictures, this response was blunted in depressed adults. Similarly, Thomas et al. (2001) found a decreased amygdala response in depressed children and an increased response with anxious children. However, other researchers have observed exaggerated left amygdala responses in major depression in response to fearful stimuli (Sheline et al., 2001). Although the available data show some inconsistencies, this relatively new work on cognitive and emotional processing in mood disorders is an exciting area that has potential to integrate theories of depression and psychophysiology.

Summary. For some time, there has been considerable focus on the role of attentional resources or cognitive workload and on whether resource allocation is deficient in depression. Research strongly suggests that the psychological deficits seen in depression reflect reduced initiative and strategic information processing associated with deficient prefrontal activity, especially the left hemisphere. This work remains to be systematically integrated with the extensive literature on asymmetric activity in specific

brain regions, affective valence, and cognitive processing. Recent research examining the central circuitry of depression has identified abnormal activity patterns in DLPFC and in posterior brain regions. Functional and structural abnormalities have also been observed in limbic and paralimbic areas. Across all areas of study, research based on well-defined theoretical models and well-characterized subject groups is needed to clearly interpret findings obtained in studies examining subjects with mood disorders.

Schizophrenia

Across the enormous psychophysiological literature on schizophrenia, findings are varied and an integrated model of pathology in schizophrenia remains elusive. Schizophrenia is thought of as primarily a disorder of cognition, although a variety of other symptoms are frequently present as well. Psychophysiology studies of schizophrenia point to several broad areas of disturbance, including abnormalities in primary auditory processes, attention, working memory, language, and emotional processing. Across psychophysiological methods, no single abnormality has been found to be present in all individuals with schizophrenia and the degree of overlap between patient and control distributions is typically so extensive that only a minority of patients is distinguishable from healthy research participants (Heinrichs, 2004).

The good news for psychophysiology researchers is that effect sizes across the biological methods commonly used to study schizophrenia (e.g., neurochemical, cytoarchitectural, and neurotransmitter receptor densities) indicate that the most powerful and robust patient and control differences pertain to cognitive and psychophysiological aspects of brain function (Heinrichs, 2004). For example, saccadic frequency scores from eye-tracking tests and reduced frontal brain metabolism and blood flow during mental activity produce average effect sizes large enough to describe abnormalities that probably occur in half of the schizophrenia patient population. The review below examines a few of the psychophysiological measures commonly used to study schizophrenia, organized around issues in primary auditory processes and attention.

Primary auditory processes. Numerous neuroimaging studies have reported auditory processing abnormalities in schizophrenia, involving both basic tasks, such as listening to simple tones or clicks without overt performance demands, and more complex tasks. Reviewed below are auditory studies using either MEG source localization methods or spectral analysis techniques.

N100 (EEG) and N100m (MEG) are the most prominent deflections of the auditory event-related potential or field, evolving with a peak latency of about 100 ms after stimulus onset (for a review see Hari, 1990). Examining auditory evoked fields (AEFs) in a nonpatient population, Pantev et al. (1998) observed lateralized latency differences

for the processing of tones with shorter N100m latencies in temporal areas contralateral to the stimulated ear. Similar findings were reported in Picton et al. (1999). These studies replicated findings previously obtained in single-hemisphere MEG studies (Elberling et al., 1980; Mäkelä, 1988; Rogers et al., 1990) as well as whole-cortex MEG studies (Mäkelä et al., 1993; Nakasato et al., 1995). Results were taken to correspond to the anatomical differences of the auditory ascending pathways, which were shorter after the inferior colliculi on the contralateral than on the ipsilateral side (Evans, 1982). Pantev et al. (1998) also observed that the root mean square (rms) value of the measured field strength and the absolute value of the estimated dipole moment were larger for the contralateral hemisphere. These results were interpreted as in line with the fact that most of the fibers of the auditory pathway cross to the contralateral side, where a large cortical response is evoked. Eulitz et al. (1995) observed similar lateralized differences for the processing of phonetic stimuli, and these findings were later replicated (Gootjes et al., 1999).

Extending this line of research to examine basic auditory processes in patients with schizophrenia, hemispheric lateralization has been examined using MEG source localization methods. In the first of a series of studies examining atypical structural and functional laterality, Rockstroh et al. (1998) presented tone stimuli to the right ear in control subjects and in patients with schizophrenia. N100m occurred earlier over the contralateral (left) hemisphere in both controls and patients with schizophrenia, but N100m source strength showed a larger contralateral magnitude only in controls. It was suggested that the symmetry in patients with schizophrenia may reflect a developmental failure in structural brain asymmetry. Rockstroh et al. (2001) extended their investigation to include verbal stimuli (/ba/) as well as tones (1000 Hz) and obtained measures from both unilateral left- and right-ear stimulation. All control subjects showed the expected contralateral predominance of N100m strength, whereas asymmetry was reversed for left-ear tones in 47% of the patient subjects and for right-ear tones in 76% of patient subjects. No group differences were observed using syllable stimuli. Examining the relationship between N100m strength asymmetry scores and patient symptoms, negative correlations indicated that smaller asymmetry scores were associated with more pronounced negative symptoms, longer overall hospitalization, and a higher daily dosage of neuroleptic medication. Examining N100m latency scores, pronounced differences between left and right syllable stimulation were found in patients, and differences were less in control subjects. These results suggest that interhemispheric conduction velocity is similar in control subjects and not in patients with schizophrenia. Rockstroh et al. (2001) concluded that deviation from the normal functional lateralization in schizophrenia appears in a proportion of patients at a basic stage of auditory processing but may be compensated for at higher levels such as the processing of syllables.

In addition to examining temporally discrete components of the auditory event-related potential or field a literature is beginning to study oscillatory phenomena in schizophrenia. The interest in examining time-frequency domain activity arises from the belief that frequency domain information may provide a more accurate measure of neuronal activity. In particular, it is hypothesized that auditory stimuli generate evoked-potentials by reorganizing the phase spectra of the existing ongoing EEG/MEG. Early work by Pantev and his colleagues (Pantev et al., 1991) showed that the overlapping auditory components (e.g., 50 ms and 100 ms) energies belong to different spectral regions and can be separated in the frequency domain. However, in addition to examining the amount of activity in specific frequencies at different times, time-frequency analyses allow for a wide range of additional analyses. Thus, besides the frequency and site of activity, other parameters, such as enhancement, time-locking, phase locking, delay of the oscillation, and prolongation of oscillation can be examined, and are of interest because they are strongly related to brain function.

As previously mentioned, investigators frequently have observed a decreased N100 response in individuals with Sz (e.g., Boutros et al., 2004), and a few studies have employed time-frequency-domain analyses to examine this finding. Winterer et al. (2000) concluded that the decreased N100 amplitude commonly observed in individuals with schizophrenia is the result of an increased amount of EEG background noise and an impaired stimulus-induced phase locking of background EEG. In a related study, Gilmore, Clementz, & Buckley (2004) examined the ability of patient's with schizophrenia to increase N100 amplitude. Noting that N100 amplitude is increased by presenting bursts of steady-state stimuli with frequencies greater than 30 to 40 Hz (suggesting that N100 indexes information integration over time) they hypothesized that although a single transient stimulus conveys insufficient information for efficient processing by patients with schizophrenia, bursts of steady-state stimuli, to a point, would reduce or eliminate patient-control N100 differences. However, they also hypothesized that there is a low ceiling on the ability of patients to handle high-density auditory information and that this would result in a decrease in N1 at high (>40 Hz) burst rates. At 10 Hz patients showed the expected decreased N1 response. The N1 amplitude in controls increased as a function of increased rate of stimulation. At 20 Hz no group differences were observed. However, patients were unable to manage stimulation rates above 20 Hz, and at 40 and 80 Hz low frequency activity decreased. They concluded that patients have a limited capacity for processing high-density auditory information.

The investigation of high frequency activity has been of particular interest as brain activity in the 40 Hz range is thought to be critical for feature binding, allowing functionally and spatially separate brain systems processing distinct stimulus features to cooperate in object per-

ception (Singer, 1993). Abnormality in 40 Hz synchronization could result in a variety of perceptual and cognitive abnormalities, including abnormal perceptions and hallucinations, in schizophrenia. A few studies have examined entrainment of the EEG to trains of clicks presented at constant frequencies (including 40 Hz). In patients with schizophrenia, Kwon et al. (1999) observed a decrease in the ability of auditory neural networks to support synchronous neural activity at 40 Hz, but not at lower click train frequencies (20 and 30 Hz). Hong et al. (2004) observed that the relatives of individuals with schizophrenia-spectrum personality symptoms had reduced power at 40 Hz compared to controls. In addition, although Hong et al. (2004) failed to replicate Kwon et al.'s (1999) findings, they observed that patients taking new-generation antipsychotics had enhanced 40 Hz synchronization compared to patients taking conventional antipsychotics.

Research examining the integrity of the auditory system in schizophrenia is in its infancy. However, given the STG structural abnormalities and auditory functional impairments observed in schizophrenia, research in this area is of great importance. More research is needed examining the relationship between impaired low and high frequency activity and the symptoms and neurocognitive deficits associated with schizophrenia. Particularly promising would be studies exploring interregional synchrony or other types of functional connectivity.

Filtering in schizophrenia. Problems with attention and perception are often noted to be core features of schizophrenia and have been hypothesized to result from defects in filtering or gating of afferent sensory input. In the 1970s and 1980s a large number of studies examined information processing and attentional deficits in schizophrenia subjects. As Braff (1993) noted, "The fundamental focus of these studies and reviews is that schizophrenia patients have critical deficiencies in information processing abilities that are revealed and enhanced when high processing loads, multiple tasks, distraction, or other stressors demand the rapid and efficient processing of information" (p. 56).

Braff (1993) presented a simple framework for understanding information-processing abnormalities in schizophrenia patients. In this framework, attentional and information processing abilities are hypothesized to rely on intact psychophysiological function, normal neurotransmitter and hormonal balance, and an intact neuroanatomic substrate. When these systems are intact and function properly, normal cognition, emotion, and overt function are observed. When these systems are damaged, abnormalities occur manifested in psychiatric symptoms.

Deficient processing in patients with schizophrenia has been hypothesized to result from such factors as excess stimulation as a result of sensory flooding, a smaller pool of resources, an inability to mobilize and allocate resources, or excess resource allocation to task-irrelevant stimuli

(Braff, 1993). Many paradigms have been developed to examine information processing and attention dysfunction in patients with schizophrenia. These include oculomotor function (smooth pursuit eye movement), visual backward masking, continuous performance tasks, latent inhibition, and sensorimotor gating (prepulse inhibition, P50 gating). Poor performance has been observed in patients with schizophrenia on each of these tasks. It is important to note that poor performance is not necessarily slowed performance. In a latent inhibition task, in which the subject is asked to count meaningless syllables while the stimulus of interest (e.g., a 30 ms burst of white noise) is presented concurrently, acute schizophrenia patients identify the target stimuli more rapidly than do control subjects, indicating a failure of inhibitory function. Thus, in this task, normal performance consists of increased levels of inhibition, and the latent inhibition paradigm induces a situation in which failure of inhibition causes "better" performance in patients with schizophrenia.

Across the above tasks, many of the variables under study appear to be fundamental, trait-linked markers for schizophrenia. Antipsychotic medications do not fully normalize these information-processing functions, and many of the observed deficits in schizophrenia patients are not medication-induced artifacts. In addition, subjects at the boundaries of schizophrenia show a pattern of trait-linked information-processing deficits similar to those of schizophrenia patients (Braff, 1993).

It has long been thought that some schizophrenia symptoms, such as hallucinations and delusions of reference, may result from an impaired attentional filter (Kisley, Noecker, & Guinther, 2004; McGhie & Chapman, 1961). The purpose of such a filter is to protect limited-capacity systems from being overloaded with incoming information. An impaired filter could lead to the inability to process optimally the most important information, as well as a tendency to attribute special or inappropriate significance to other information.

Disturbed filtering is frequently examined in schizophrenia using a simple paired-click gating paradigm. In the paired-click paradigm subjects are presented two clicks separated by 500 ms, and the P50 component of the ERP to each click is scored, typically at electrode Cz. In normal subjects suppression of P50 to the second click occurs when the interstimulus interval is less than 1 s. However, in patients with schizophrenia the response to S2 shows less suppression. The larger S2 response in patients is interpreted as a gating deficit. Methodological issues and inconsistencies undermined the early P50 gating literature, including evidence of poor reliability of the P50 ratio measure (Smith, Boutros, & Schwarzkopf, 1994). However, sufficient replications now exist that the deficit can be considered well established. Indeed, recent meta-analyses have found that P50 abnormality is one of the most powerful and reliable neuroscience findings in the schizophrenia literature (Bramon et al., 2004; Heinrichs, 2004).

Uncertainty remains as to relationships of P50 amplitude and P50 suppression to diagnostic subtypes, task demands, and experimental conditions (for review, see Bramon et al., 2004). Issues such as posture of the subject during recording, P50's sensitivity to attentional and stress factors, and selection of valid trials have yet to be resolved. Measurement of P50 can be compromised by the fact that several components (e.g., P30, N40, N100, Nd) occur during or adjacent to P50. Further study of these issues is needed before the nature of P50 suppression and its suitability as a measure of disturbed filtering in schizophrenia-spectrum disorders can be fully determined.

Recently, MEG source localization methods have been used as a means to explore the circuitry of P50 gating and identify the locus of the abnormality in schizophrenia. Huang et al. (2003) showed that bilateral superior temporal gyrus (STG) generators contribute virtually all of the variance in Cz P50. Noting significant between-subject and within-hemisphere differences in the strength, orientation, and latency of the STG generators, Edgar et al. (2003) suggested that a better understanding of the paired-click gating deficit observed schizophrenia could be obtained if activity from the individual 50 ms STG generators was examined rather than the aggregate P50 score at Cz. Thoma et al. (2003) observed a gating deficit for a schizophrenia group in the left- but not right-hemisphere for 50 ms STG activity and also found that left- but not right-hemisphere M50 gating correlated with behavioral measures of sustained attention and working memory. Thoma et al. (2004) reported that, although there were no relationships between EEG P50 sensory gating and positive or negative symptoms, negative symptoms correlated positively with right-hemisphere M50 gating ratio. In contrast, positive symptoms correlated with left M50 gating ratio when a subgroup of patient subjects characterized by particularly good gating and atypical lateralization was removed from the analysis. Together, these studies established the potential of MEG source localization in furthering understanding of dysfunctional sensory gating mechanisms in schizophrenia.

As with the N100/M100m studies, P50/M50 time-frequency domain studies are increasingly common. In a series of studies, Clementz, Blumenfeld, and colleagues used EEG and MEG techniques to examine P50/M50 Low Frequency Responses (LFRs: 1–20 Hz) and Gamma Band Responses (GBR: 20–40 Hz) in patients with schizophrenia. Using multichannel EEG and spatial Principle Component Analysis (PCA) to integrate information over all channels, Clementz and Blumenfeld (2001) observed that groups differed on LFR measures to S1 but not S2. In a similar study examining MEG auditory evoked fields (AEFs), Blumenfeld and Clementz (2001) applied spatial generalized eigenvalue (GEV) decompensation techniques to 148 MEG channels. Controls had larger amplitude LFRs to the first stimulus than did patients. Discussing the results obtained across multiple studies, Blumenfeld and Clementz concluded that controls and patients with

schizophrenia do not differ on initial sensory registration as the patients and controls did not differ on first or second click GBR activity. In addition, they suggested that the abnormally small S1 LFR is inconsistent with a basic stimulus filtering theory for explaining normal-schizophrenia group differences on gating. They speculated that patients have difficulty encoding stimuli after long time delays and that attention effects may be influencing group differences on AER suppression. Results from Johannesen et al. (2005) generally support this claim. Johannesen et al. (2005) observed that both nonparanoid and paranoid schizophrenia patients had a smaller S1 response and spectral analyses revealed smaller S1 and normal S2 responses in schizophrenia across both the GBR and LFR. Poor attention was inversely related to both S1 and S2 values. Given both the smaller LFR and S1 values, they concluded that the low S1 amplitude in schizophrenia reflects a diminished capacity to gate-in relevant signals.

Much more work is needed before the auditory gating abnormalities observed in patients with schizophrenia are fully understood. A greater understanding of the abnormality has been obtained using source localization techniques to study source rather than scalp activity. Whereas previous studies employing time-frequency analyses have provided a way to study activity in particular frequency ranges, recent time-frequency studies have focused on examining the time-frequency profile of the scalp recorded activity. Studies applying time-frequency analyses to the localized STG sources are now needed to more completely investigate normal and abnormal primary and secondary auditory processes. Finally, studies that simultaneously examine activity in different nodes in the auditory system (e.g., prefrontal and perhaps hippocampal areas) are needed to examine the integrity of the entire auditory system.

Selective attention in schizophrenia. According to Braver, Barch, and Cohen (1999), the most consistently reported attentional impairments in schizophrenia involve the exertion of attention in a selective and controlled manner to facilitate processing of task-relevant information and/or to inhibit the processing of task-irrelevant information. Recently, the Stroop task has been used to examine selective attention impairments in patients with schizophrenia. The traditional Stroop (1935) task requires subjects to respond to stimuli that vary in two dimensions, only one of which is task relevant. Thus, it is a means to study the subjects' ability to select or ignore task dimensions and parameters of task interference. Macleod (1991, 1992) provided a comprehensive review of behavioral studies of the Stroop task, and called it the "gold standard" of selective attention phenomena.

Stroop interference is commonly associated with enhanced activity in anterior cingulate cortex (ACC; e.g., Banich et al., 2001). Abnormal ACC activation during Stroop has been frequently observed in schizophrenia, but both the direction (hypoperfusion or hyperperfusion)

and the laterality of the findings have been inconsistent. It has been hypothesized that abnormal ACC activity fosters or reflects deficits in selective attention by disturbing a network of brain areas important in selective attention tasks. Yucel et al. (2002) suggested that schizophrenia is "a disorder of connectivity with specific involvement of the limbic anterior cingulate" (p. 253). Carter et al. (1997), noting that areas other than the ACC showed abnormal activation during the Stroop task, suggested that "patients with schizophrenia fail to modulate cortical activity in distributed networks in a task-appropriate manner" (p. 1677). As Carter et al. (1997) and Yücel et al. (2002) went on to note (see also David, Cosmelli, & Friston, 2004), the development of methods to examine functional connectivity would be a boon to the study of selective attention in schizophrenia, providing investigators with methods to investigate hypotheses about the dynamic operation of the brain.

Aside from abnormalities in ACC, DLPFC has also been implicated in theories of selective attention and schizophrenia. DLPFC appears to play an important role in active maintenance of contextual information (e.g., Braver, Barch, & Cohen, 1999; Banich et al., 2000; Banich et al., 2001), particularly in the face of interference (Miller, Erickson, & Desimone, 1996). It has been proposed that a deficit in the ability to maintain contextual information in patients with schizophrenia involves a disturbance in DLPFC (e.g., Barch et al., 2001). Studies integrating neuropsychological performance with hemodynamic neuroimaging data show that individuals with schizophrenia or at risk for schizophrenia do not activate DLPFC normally when performing a task that places demands on relevant processing resources (e.g., Andreasen et al., 1992; Barch et al., 2001; Gold, Goldberg, & Weinberg, 1992; MacDonald et al., 2003; Mohanty et al., 2004; Weinberger, Berman, & Zec, 1986). This finding has contributed to the concept of 'hypofrontality' in schizophrenia. However, there is increasing evidence that the traditional concept of hypofrontality is incomplete (Ramsey et al., 2002; Weiss et al., 2003). For example, increased task-related activity in either right (Callicott et al., 2000; Callicott et al., 2003; Weiss et al., 2003) or left (Manoach et al., 1999; Manoach et al., 2000; Weiss et al., 2003) DLPFC has been reported in individuals with schizophrenia or at risk for developing it. These apparent inconsistencies might be attributed to many factors, including experimental design and behavioral task complexity, presence of reward (Manoach et al., 2000), and analytic issues such as examining group-averaged data (thus underestimating DLPFC activation due to heterogeneity of location within DLPFC) versus single-subject data (Manoach et al., 2000). In addition, despite considerable evidence demonstrating DLPFC dysfunction in schizophrenia, it remains uncertain whether this dysfunction arises from neural abnormalities primarily in DLPFC or from abnormal dysregulation of DLPFC by other structures (Callicott et al., 2000; Manoach et al., 2000). Again, the development of methods to study

functional brain connectivity is needed to explore these different possibilities.

Summary. Current psychophysiology research on schizophrenia has focused on abnormalities in processing auditory information, filtering deficits, and selective attention impairments. Comparing psychophysiological findings across studies is difficult because of differences in schizophrenia patient subtypes, differences in syndrome-dimensions (e.g., psychomotor poverty, disorganization, and reality distortion), and in medications. Heterogeneous results may also arise from differences in experimental design. In particular, studies that do not employ a within-subjects design may fail to observe between-group differences because they lack the power to detect such changes. In addition, group differences are generally small, making it difficult to observe patient-control differences without large sample sizes. Such reasons are thought to explain the inconsistent findings of slightly enlarged cerebral ventricles and subtle anatomical abnormalities in the region of the anterior hippocampus (Suddath et al., 1990). Overall, study designs that employ adequate Ns, that reduce within-group variability, and that examine medication effects systematically will generally have greater success at identifying subtle electrophysiological changes.

Schizophrenia has long been a focus of psychophysiological research, first emphasizing autonomic, then electrocortical, and most recently hemodynamic measures and MEG. Neuropathology and neuroimaging studies have identified abnormalities in multiple brain regions in schizophrenia, including hippocampus, thalamus, frontal lobes, temporal lobes, and parietal lobes. Given this widespread pathology, it is often hypothesized that the symptoms associated with schizophrenia are the product of distributed abnormalities rather than focal pathology. Several theorists have proposed that functional disconnections between brain regions account for many of the symptoms and impairments in schizophrenia. As researchers continue to examine brain activity in schizophrenia-spectrum disorders, the development of methods to assess communication between multiple brain regions will be of considerable interest.

ROADBLOCKS AND RECOMMENDATIONS

The past decade has seen growing faith in psychophysiology as a means of understanding psychopathology, especially via hemodynamic neuroimaging. A number of challenges must be faced, however.

Problems comparing populations

The study of psychopathology often involves the comparison of groups of individuals in an attempt to understand what is specific to a given population. Such comparisons face a host of problems related to the interpretation of group differences. Because clinical groups typically dif-

fer prior to the experiment, it is difficult to determine whether measured differences are the result of experimental manipulations or to pre-existing differences. Because psychopathology studies cannot rely on random assignment to avoid such differences, alternative approaches must be considered.

Two approaches that appear useful, but are ineffective as general solutions, are matching of samples and analysis of covariance (ANCOVA). Researchers often attempt to match patient and control groups on the basis of pre-experimental scores on various measures, such as intelligence or physiological responsiveness. A central problem with matching samples on one measure is that if the populations from which the samples are drawn do in fact differ on the measure, neither sample is representative of its respective population. Thus, matching subjects on one variable tends to unmatch the groups systematically on other variables (Meehl, 1970, 1971). Furthermore, such matching based on pretesting can foster regression to the mean in the main experimental test (Chapman & Chapman, 1973). These vulnerabilities of the matched-samples strategy have long been known but are frequently overlooked. The implication is not that matching is always unwise but that these vulnerabilities must be taken into account in designing and interpreting between-group studies.

The second approach involves ANCOVA and hopes to remove the effect of differences in scores on one measure from scores on a second measure. Unfortunately, when the question at hand involves group differences, this is not generally a valid use of ANCOVA. Score differences may reflect real differences between groups. It has long been established that no statistical technique can "correct" for a real difference between groups (Benjamin, 1967; Chapman & Chapman, 1973; Fleiss & Tanur, 1973; Miller & Chapman, 2001). Indeed, "correcting" for such a difference is not even an appropriate goal. When a potential covariate is related to the grouping variable, removing variance associated with the covariate necessarily means that the (residual) grouping variable is altered. ANCOVA is properly employed to remove noise variance, but not systematic variance. Studies of psychopathology that examine group differences are typically inappropriate for candidates for ANCOVA (for extended discussion, see Miller & Chapman, 2001).

There are better ways to compare groups that deal with preexisting differences. One way is to employ multiple measures of performance on the same task. Measures might be carefully selected in order to tap distinct subsets of the mental operations involved in task performance. Evaluation of the pattern of results obtained from the different measures may isolate specific operations which are affected or unaffected by psychopathology. Psychophysiological approaches are particularly well suited for this type of approach because they can often provide multiple measures of aspects of task performance (Coles, 1989).

A second generally sound approach involves the use of the same or similar measures across several tasks in order to determine to what extent a deficit on one task may exceed a deficit on another task. Measures may be considered similar based on their being matched on administration format, difficulty, and reliability. Even when one group of subjects scores below another across all tasks measured, the difference on one task may be substantially larger than the difference on another task. Such a pattern would suggest that the larger deficit involves mental processes that are especially deficient in one group (Chapman & Chapman, 1973). However, it can be difficult to identify or develop tasks and measures that are equated in terms of difficulty and reliability across groups. Differences in difficulty or reliability can produce artifactual findings that misrepresent the importance of a specific deficit. Davidson et al. (1990) and Hanlon et al. (in press) are rare examples of a psychophysiological study that handled them explicitly.

A third approach to address pre-existing differences is to manipulate task difficulty such that each group performs an equally difficult task. A common implementation of this approach is to adjust task difficulty until each group attains accuracy scores approximating 50% (Chapman & Chapman, 1989). A more sophisticated and flexible version of this approach is to employ a task in which each group's performance is equally distant from 50% (Miller, Chapman, Chapman, & Collins, 1995). However, the difficulty of tasks of interest is not always readily adjustable.

A fourth approach to address pre-existing differences is related to ANCOVA, but does not require that the groups be equal on the covariate. Rather than treating the apparently tangential variable on which the groups differ as a covariate, the analysis incorporates it and attempt to understand its substantive role. Procedurally, this can be accomplished in a standard hierarchical regression analysis by treating the variable simply as another predictor of interest, especially if its interaction with other variables of interest is included in the analysis. Leutner and Rammsayer (1995) discussed this approach in a personality/self-report context, but their examples generalize well to psychopathology and psychophysiology.

A final approach attempts to sidestep the problem of group differences by using groups that exhibit some characteristics of psychopathology, but are sufficiently well functioning that their performance is substantially equal to the functioning of the controls. One way to accomplish this is to study individuals at risk for developing psychopathology but fully functional (Miller, 1995). Such at-risk individuals may include relatives of patients, demographically similar individuals, or individuals with subthreshold or few symptoms. Because onset of psychopathology is presumably determined by numerous factors, it is not necessary for at-risk individuals to develop full-blown psychopathology for data from them to be useful. They provide the opportunity to study processes that are important in psychopathology while avoiding many of

the complications that result from studying manifest psychopathology.

Problems studying affected populations

The benefits of working with at-risk samples notwithstanding, much of the work has to be carried out with fully affected samples. A common challenge in such studies is differentiating the effects of psychotropic medications (Blanchard & Neale, 1992). Conflicting findings and limited data have made it difficult to draw firm conclusions about the effects of medications on various physiological measures. Self-medication (including tobacco, alcohol, and illicit drugs) can cause similar problems. Another challenge is the ability to provide informed consent for participation in clinical research. Individuals with psychopathology will vary in their ability to understand the research protocol, its risks, and its implications. This topic is receiving increasing attention and more systematic empirical research, including increased priority at NIH.

Despite difficulties in working with psychiatric populations, there are ways to address many of these problems. Although medication is often not under the control of the research team, nor is random assignment normally possible, researchers can obtain information about the medication of the participants and employ this information when analyzing the data. Research-specific diagnostic screening is often necessary to ensure adequate characterization of patients because treatment and research staff may use diagnoses for different purposes. Careful screening procedures may also address such problems of substance abuse and comorbidity (see discussion below).

Yet another challenge in studying psychopathology is identifying appropriate control or comparison groups. Patient groups may offer a population that is perhaps comparably medicated and hospitalized. Nonpsychiatric groups provide a basis for comparison to nonpsychopathology research, but can be surprisingly difficult to find given the high rate of subthreshold and undiagnosed disorders in the general population. Researchers need to choose comparison groups based on their experimental questions, but an underutilized strategy is to involve multiple control groups of which none may be ideal but in aggregate can address a number of issues (Miller & Chapman, 2001).

An alternative to studying diagnosed patients is studying nonpatients at risk for developing diagnosable psychopathology or already showing certain symptoms. As noted above, there are well-established advantages to using at-risk groups to examine psychopathology. First, the use of at-risk groups generally avoids problems associated with patient status such as medication effects, informed consent, and tolerance for research protocols. Second, if a deficit in a particular mental function is fundamental to the development of a disorder, then indications of that deficit will often be manifest prior to the actual onset of the disorder. Third, premorbid studies allow researchers to identify

possible compensatory mechanisms that at-risk individuals could employ to delay or avoid the onset of more severe psychopathology. Information gained from such studies of at-risk individuals would be useful for understanding the process of the disorder as well as developing preventive or ameliorative interventions.

Problems of heterogeneity

The heterogeneity of symptom patterns allowed in DSM-IV can be problematic for psychopathology research. Within-group variance can be considerable for both the clinical manifestations that drive diagnosis and the psychophysiological phenomena one tries to identify. It is particularly important to consider the prevalence and theoretical significance of particular physiological symptoms in order to select appropriate psychophysiological measures. Because traditional diagnostic categories rely heavily on verbal and behavioral symptoms, they typically fail to consider the role of physiological symptoms or non-symptomatic physiological manifestations of relevant processes. It is quite striking that the operationalization of diagnoses in DSM-IV includes virtually no physiological criteria (not to be confused with self-reports of physiological symptoms), despite the increasing claims for biological factors in psychopathology. Starting points for psychophysiological research are often not obvious. However, though little utilized, the option of defining abnormality in terms of a specific physiological phenomenon may be a very promising strategy as a means of reducing diagnostic heterogeneity.

Problems of comorbidity

Another problem that complicates psychopathological research is comorbidity of different mental disorders in the same individual (Cuthbert, *in press*; Heller & Nitschke, 1998; Mineka, Watson, & Clark, 1998). Because each diagnosis is associated with different clusters of verbal, physiological, and behavioral symptoms, comorbidity becomes particularly problematic when co-occurring disorders have divergent effects on the same measure. For example, if depression and anxiety have divergent effects on EEG alpha suppression, then the co-occurrence of these disorders will confound interpretation of this physiological variable. This problem is particularly challenging when an individual meets criteria for one diagnosis and is sub-threshold for another diagnosis.

Investigators have a choice of describing psychopathology in terms of a diagnosis (e.g., schizophrenia), an observed symptom (e.g., disorganized speech, depressed mood, or exaggerated startle response), or an inferred mental process (e.g., impaired working memory, hallucinations). Although genetic and other biological phenomena are a growing focus of research on psychopathology, they do not themselves constitute psychopathology. The investigator's choice depends on many considerations, including

the level of resolution needed to answer the research question (Cacioppo & Berntson, 1992), which is in turn dependent on (too often only implicit) value judgments about what is most important or most promising. Psychophysiological methods have often been applied haphazardly, which has caused the literature to be spread rather thinly, with relatively little conclusive evidence.

Problems comparing neuroimaging methods

For researchers interested in studying psychopathology, neuroimaging approaches can be especially enticing, which is evidenced by the rapid growth of this literature in recent years. Electromagnetic measures offer a noninvasive method for monitoring physiological activity with excellent temporal resolution and in most cases provides direct assessment of aggregate neural activity. In many cases EEG is relatively limited in the spatial resolution that it can provide, although aggressive research programs are underway that are improving spatial localization (e.g., Baillet, Mosher, & Leahy, 2001; Dale & Halgren, 2001; Gräve de Peralta et al., 2004; Hoechstetter et al., 2004; Huang et al., 1998; Huang et al., 2004, under review; Michel et al., 2004; Scherg & Berg, 1996). MEG is noninvasive, provides excellent temporal resolution, and is often better suited for studying neural events in that they are not distorted by conductivity differences between bone and other tissue separating the sensor from neuronal activity (Hämäläinen et al., 1993; Lewine & Orrison, 1995). Hemodynamic methods such as fMRI and PET, based on blood flow, blood oxygenation, etc., offer less direct information about the location and timing of neural events. Hemodynamic methods are also far more expensive and less widely available than electrophysiological measures. However, in many circumstances fMRI offers spatial resolution equal to that of MEG for most of cortex and superior for deeper structures, yet under some circumstances MEG can reach deep structures such as hippocampus (Hanlon et al., 2003).

Not widely appreciated is the recent revolution in EEG and MEG research methods and, as a consequence, the rich potential of combining them with MRI (e.g., Ahlfors et al., 1999; Dale et al., 2000; Dale & Halgren, 2001; Korvenoja et al., 1999). A widespread misperception of EEG (and to a lesser degree MEG) as substantially inferior to fMRI in spatial localization is based on a failure to appreciate the respective histories of these methods. EEG evolved long prior to the availability of subject-specific brain anatomy information such as is now increasingly available via structural MRI (sMRI). Furthermore, for most of the long history of EEG the norm was to record from no more than a few widely spaced electrodes. Low electrode density, poor coverage of the entire head, and absence of subject-specific anatomical information precluded generally acceptable source localization. Although much valuable research on cognition does not require dense-array recordings or source localization, such methods are becoming common.

In contrast, fMRI is in its infancy. Much of its literature is primitive by comparison to EEG. For example, what in the fMRI literature is often called an “event-related design” is not a feature of the experimental design but a data-analysis strategy. The event-related design was introduced into the fMRI literature with much fanfare and much-deserved impact, but has been routine in event-related brain potential (ERP) studies of EEG phenomena for 35 years. It must be appreciated that new methods are almost invariably primitive and not immediately infused with expertise available in more developed traditions. Thus, fMRI methods are improving rapidly. Furthermore, it should be anticipated that, as a relatively new method, fMRI will see profound improvements in the near term in directions not presently obvious.

More germane to the issue of the relative spatial localization ability of EEG and fMRI is that the horserace has often been set up inappropriately. Taken very literally, essentially no one conducts fMRI research. Virtually every study examines a combination of fMRI with sMRI. Even superficial familiarity with fMRI data analysis would make one reluctant to place much faith in inferences about localization obtained from fMRI data in the absence of carefully coregistered sMRI data. A separate but very practical consideration is that the marginal cost of obtaining sMRI data given fMRI data is trivial, whereas in general the marginal cost of obtaining sMRI data given EEG data is quite high. Given that inclusion of sMRI is essentially universal in fMRI studies, but that the vast majority of EEG studies (even those with dense-array electrode montages) do not have sMRI information available, any comparison of fMRI (with sMRI) and EEG (without sMRI) is uninformative and even systematically misleading.

As a result, the common perception of EEG (and MEG) as inherently unsatisfactory for spatial localization of functional activity is unfounded. On the contrary, a number of demonstrations of successful spatial localization have been available for some time, most impressively when sMRI data are brought to bear (e.g., Sanders, Lewine, & Orrison, 1996). It should also be noted that, in many research contexts, localization within a few millimeters is of little interest or consequence. Rather, the source localization solutions are valuable primarily as a systematic means of reducing the dimensionality of the data. Particularly of value in studies of psychopathology, the structure of the solution (e.g., number of generators, hemispheric symmetry of generators, and the relative time courses of their activity) may be more important than anatomic specificity.

Much work remains to be done, and will be done, to advance electromagnetic and hemodynamic methods. One can anticipate that spatial localization will continue to improve for electromagnetic methods and that temporal localization will continue to improve for hemodynamic methods. Yet each will retain certain advantages. A pressing need is for research that identifies the linkages and diverges of these two classes of methods.

An even newer development is optical neuroimaging (see papers in special section of *Psychophysiology*; Gratton et al., 2003). It shows promise as a means to bridge the gap between hemodynamic and electromagnetic neuroimaging. To date, it appears to have been used just once in psychopathology research (Matsuo et al., 2003).

A growing consensus in the psychophysiology/cognitive neuroscience community is that the various established and emerging electromagnetic, hemodynamic, and optical measures are mutually complementary and individually essential. Some of the most exciting work since the original draft of this chapter (Keller et al., 2000) integrates multiple psychophysiological measures in this way. Psychophysiological approaches that combine several measures can provide a rich view of biological systems associated with psychopathology. Particularly promising is the ability of psychophysiology to define the endophenotype in psychopathology, the manifestation of a disorder via anomalies not observable by diagnostic interview or observation of overt behavior. This may prove to be crucial, for example, for identification of affected individuals in genetic linkage studies (Iacono, 1998).

Suggestions for future psychophysiological research on psychopathology

This chapter has argued that findings that are particularly meaningful share a common feature: the integration of good psychological with good physiological theory. Unfortunately, the modal report is simply one more empirical demonstration that individuals with psychopathology differ from controls. The field should ask more of itself.

Perhaps the greatest current challenge facing psychophysiological research on psychopathology is the development of tools to evaluate functional connectivity among brain regions. This need is arguably greater than the considerable and ongoing improvements in spatial localization underway in EEG and MEG research. As David et al. (2004) recently noted, functional connectivity analysis strategies are growing but in most cases are new and diverse, “making research in this area exciting but quite confusing” (p. 659). Broad progress in this domain will challenge researchers in psychophysiology and in psychology more generally to upgrade their quantitative skills (Miller, Elbert, Sutton, & Heller, in press).

This chapter has also emphasized the importance of a number of issues that arise in psychopathology research and are crucial, though not specific, to psychophysiological measurement. Thorough, reliable diagnostic screening is essential for clear characterization of subject samples. Careful strategies for addressing and interpreting group differences on tangential variables are critical. Consideration of diagnostic comorbidity as well as delineation and evaluation of relevant symptom or diagnostic subtypes is necessary.

Psychophysiology has a tradition of innovation and as a result an increasingly powerful set of tools that provide

valuable information in understanding psychopathology. A number of considerations have been outlined here that influence the utility, significance, and impact of psychophysiological research on psychopathology. Research in this area will be most beneficial when strong theories of the fundamental psychological disturbance are integrated with solid theories of related physiological processes.

Detection of Deception

WILLIAM G. IACONO

INTRODUCTION

Relying on their listening and observational skills, people can detect liars with about 54% accuracy, which is only slightly better than chance (DePaulo et al., 2003). Given the ease with which we are deceived and the often high cost of being taken in by a liar, it is little wonder that security and law enforcement agencies, corporations striving to maintain a competitive edge, and private individuals concerned about the trustworthiness of friends and relatives would like to have an accurate “lie detector.” However, there is no foolproof technique for detecting lies or liars, although efforts to develop and improve procedures to do so have been around since Harvard psychologist William Marston (1917) introduced his systolic blood pressure test for detecting lying in the early part of the last century.

In this chapter, I will provide an overview of psychophysiological techniques used to detect deception, how well they work, and a critical appraisal of the science underlying these methods. Besides highlighting issues of continuing importance, my focus will be on recent developments, especially those spanning the time elapsing since the second edition of this *Handbook* was published in 2000. Readers wishing for a broader account of the development of deception detection techniques are urged to consult the second edition (Iacono, 2000).

APPLICATIONS

Lie detection techniques have been developed to detect two types of liars: criminals and untrustworthy employees. Forensic procedures are primarily used by law enforcement to detect criminals. These techniques are often referred to as specific incident tests because the examiner is attempting to resolve a known criminal incident under investigation. In contrast, screening procedures are typically employed by government and private agencies to detect security risks. For these procedures, it is not known whether a particular incident has taken place, so the questions deal with the likelihood that the examinee has engaged in past behaviors that would make that indi-

vidual a security risk. Forensic and security screening tests measure autonomic nervous system reactions to questions put to the examinee. Modern field polygraphs are computer based, and are accompanied by proprietary software that scores test outcomes to yield a probability estimate of a subject’s truthfulness. However, as sophisticated as these devices have become, they are designed to monitor the same types of physiological reactions recorded by field polygraphs of the 1940s (electrodermal, blood pressure, and respiratory responses), and hand scoring of charts remains the preferred method of reaching a verdict.

Forensic applications

Control question technique (CQT)

The so-called control question test and its many variants are by far the procedures most widely used by law enforcement. A typical test contains 10 questions that are repeated two or more times in somewhat different order each time. All variants of the CQT include two types of questions, designated control and relevant, which are used to evaluate the outcome. For a typical CQT, there are three pairs of such questions (six questions total; the other four questions are not scored). Relevant questions deal with involvement in the specific incident under investigation (e.g., “Did you rob the bank?”). Control questions deal with assumed transgressions that everyone taking the test is likely to have committed (e.g., “Did you ever take something from a person who trusted you?”). Examinees are led to believe that it is important to tell the truth about both the control and relevant questions. The polygraph operator tells the examinees that the subject is expected to be able to answer all the questions truthfully with a “no.” In this way, the examiner implies that failing a control question would lead to a failed test outcome, which is a psychological manipulation that is intended to make it appear as though control questions are as important as the relevant questions.

The CQT is scored by comparing the magnitude of responses to these two types of questions. Guilty individuals are assumed to be unconcerned by their answers to the control questions, and thus are expected to give

substantially larger responses to the lies elicited by the relevant queries. Innocent people are presumed to not care about the accusation embedded in the relevant question. Instead, CQT theory requires that they be more concerned about the transgression tapped by the control question, which causes it to elicit stronger physiological responses than relevant questions. Proponents of the CQT argue accuracy rates exceeding 90%. For instance, the American Polygraph Association (2005) asserts that its review of polygraph studies involving almost 2,200 real life examinations points to an average accuracy of 98%. Psychologists trained in psychophysiology have also argued an average of 98% accuracy for field examiners (Honts, Raskin, & Kircher, 2002; see Table 29.5 and accompanying text).

Criticisms of the CQT focus on the likelihood that guilty and innocent examinees respond as predicted often enough to ensure the claimed high accuracy. Innocent examinees who have a lot at stake, especially if they have misgivings about validity, may be more reactive to their denial of the false but important accusation contained in the relevant question than by their possibly truthful but presumed lie to whatever misdeed is covered by the control question. Innocent people taking a CQT are not likely to attach the same consequences to "failing" control and relevant questions despite the polygraph operators' efforts to convince them otherwise. In other words, the control question does not provide a true scientific control for the emotional impact of being asked the accusatory relevant question. To blunt this criticism, in 1999 the American Polygraph Association elected to abandon the use of the term "control question." Now proponents of polygraphy refer to the CQT as the *comparison* question technique (Raskin & Honts, 2002), arguing in effect that it does not matter whether the question provides a true scientific control because the (claimed) high accuracy of the CQT speaks to the appropriateness of the control question irrespective of its theoretical rationale.

Although there are various reasons why guilty individuals may respond more to relevant questions (Iacono & Lykken, 2002), prime among them concerns the likelihood that they can learn simple countermeasures (e.g., carrying out mental arithmetic exercises) to boost their response to control questions enough to overwhelm reactions to relevant questions. Various readily accessed sources explain CQT methods and countermeasure techniques (e.g., www.polygraph.com, www.antipolygraph.org), and studies have shown that guilty mock crime participants provided with this type of information (in the form of a half hour tutorial) can defeat the CQT while going undetected by skilled examiners (Honts, Hodes, & Raskin, 1985; Honts, Raskin, & Kircher, 1994).

Directed lie technique (DLT)

The DLT differs from the CQT in one respect: The "probable lie" control questions of the CQT are replaced with "directed lies." In effect, the polygraph examiner develops a set of questions with the examinee that both individu-

als agree elicit lies (e.g., "Have you ever made even one mistake?"). Subjects are told to think of a specific instance of a lie covered by the directed lie question. Those taking the DLT are told that the purpose of the question is to determine what a lie response looks like. In this way, the DLT attempts to remedy the shortcomings associated with the CQT assumption that control questions elicit actual lies and real concern when in fact they may not.

The DLT has stimulated little research while generating the same criticisms as the CQT. The DLT has the additional shortcoming of making transparent the purpose of the directed lie, thereby facilitating the application of countermeasures.

Guilty knowledge test (GKT)

The GKT (also referred to as the concealed information test or CIT) has been developed and promoted by Lykken as a scientifically based alternative to the CQT (Lykken, 1959, 1981). The GKT is a psychophysiological examination designed to uncover whether a suspect possesses crime-specific knowledge that the perpetrator of a crime, but not uninvolved individuals, would be expected to have. Questions take the form of multiple-choice items. However, rather than the examinee choosing the correct alternative to each question, physiological reactions to each alternative are monitored to see if the guilty knowledge alternative elicits a stronger reaction than the others. For instance, a suspect might be asked: "If you committed this bank robbery, then you would know how much cash you took. Was it about \$3000...\$7000...\$11000...\$13000? You would also know what you wrote on your holdup note. Was it Don't sound the alarm?; Do as I say and you won't get hurt?; This is a robbery? Listen closely I have a gun pointed at you? An innocent suspect taking such a test would respond randomly to the various options, but the recognition of correct alternatives by the perpetrator would elicit stronger physiological reactions to the guilty knowledge options by likely reflecting an orienting response to the concealed information (Verschueren et al., 2004). The orienting response, a phasic autonomic reaction first identified by Pavlov and studied extensively by Sokolov (Sokolov, 1963), arises when a person is first presented with a discrete stimulus. The orienting response reflects the degree to which the stimulus has significance, in this case, the degree to which it reflects incriminating knowledge. With repeated presentations, eventually a stimulus loses its significance, and the orienting response and its associated autonomic accompaniments habituate. For this reason, GKT question lists are typically presented only once as habituation eventually diminishes the ability to differentiate responses between the meaningful guilty knowledge and meaningless alternative options (Iacono, Boisvenu, & Fleming, 1984).

A properly administered GKT with a sufficient number of items has almost no chance of producing a false positive outcome. Unfortunately, there is no similar built-in mechanism to protect against false negative outcomes. Anyone

can develop a GKT that even a perpetrator would pass by choosing material for items that is obscure or easily forgotten. Indeed, the major challenge facing widespread acceptance of the GKT in forensic settings is the lack of research concerning how to develop good items that are likely to be recalled by criminals. Most laboratory GKT studies require participants to commit to memory relevant crime details, and then administer the GKT immediately after the mock crime, ensuring minimal forgetting. When crimes are made more realistic and a delay is introduced between crime commission and GKT administration detection accuracy drops with GKT questions involving peripheral crime details (e.g., the contents of a wall hanging in the room where the crime takes place) less effective than those dealing with features more central to the crime (Carmel et al., 2003). Hence, the method followed to develop items is a key aspect of the evaluation of any GKT administration. Unfortunately, it is not always apparent what constitutes a good item, but premeditated crimes that are well thought out and sex crimes that are executed following a distinct ritual would be examples of crimes that may be productively addressed with the GKT.

Although these problems undermine the confidence that can be placed in passed GKTs, similar problems do not exist for failed GKTs. For instance, for a 10 item GKT each with five alternatives, an innocent person has one chance in ten million of responding most strongly to all the guilty alternatives (Lykken, 1998, p. 302). Depending how the threshold is set for what constitutes a failure, a carefully administered but failed GKT can be highly incriminating (Iacono, 1985; Iacono, 2000; Iacono et al., 1984; Lykken, 1981). Thus, compared to the CQT which is biased against innocent individuals and, therefore, apt to be prejudicial when failed, the GKT is likely to have probative value when failed.

Despite the apparent strengths of the GKT, the complexity of the procedure coupled with the belief of the polygraph profession that the simpler-to-administer CQT is nearly infallible has led to its being largely ignored by practitioners. Although the GKT is used extensively in Japan (Hira & Furumitsu, 2002; Nakayama, 2002; Suzuki, Nakayama, & Furedy, 2004), virtually all forensic polygraph tests administered in the U.S., Canada, and Israel, are CQTs.

Security screening

Most polygraph tests are administered by the U.S. federal government, and most of these tests are for security screening. There are about two-dozen federal agencies using polygraph procedures, and their use has escalated over the last decade as concerns about security and terrorism have heightened. These tests are used to screen prospective employees, such as FBI and CIA agents, as part of the hiring evaluation process. They are also used to check whether current employees, such as those responsible for

protecting government secrets and national safety, warrant their security clearances.

Because those undergoing screening procedures are not known to have committed any wrongdoing, for these tests, the relevant questions resemble CQT control questions as they cover possible past misdeeds over the lifetime of the examinee. Hence, ambiguity surrounds what constitutes an appropriate "control" question on a screening test. This introduces greater subjectivity in how these tests are constructed and interpreted. The evidence available from various government reports indicates that examiners giving these tests alter the threshold for diagnosing deception depending on the expected base rate of deception in the population they are testing as well as the perceived consequences of false positive outcomes (Barland, Honts, & Barger, 1989; Honts, 1991; Iacono & Lykken, 2002). That is, when testing rigorously screened and currently employed individuals with high-level security clearances, few of whom are apt to be spies and all of whom may be difficult to replace given their esoteric training and expertise, only a tiny fraction (1–2%) are deemed to fail a polygraph test. But when screening employee prospects, who exceed the number of available positions and have not undergone expensive training, a third or more are likely to fail.

An issue that is unique to screening government employees is the cumulative likelihood of failing a test over the employee's lifetime. The tests are administered repeatedly, with government programs advocating the retesting of employees both aperiodically and periodically at intervals spanning 3–5 years. Little attention has been paid to the likelihood of these tests eventually generating a false positive outcome for an employee with a career spanning decades who may have to take the test a half dozen or more times.

Relevant/irrelevant technique (RIT)

Although there are many different screening test formats, these procedures are descendants of the relevant/irrelevant technique (RIT), a forerunner of the CQT that was commonly used in criminal investigations. In the original RIT, relevant questions like those on the CQT were intermixed with irrelevant questions (e.g., "Do you now live in Minneapolis?"). Consistently stronger reaction to relevant questions is considered presumptive evidence of guilt.

Even staunch proponents of polygraphy acknowledge the inadequacy of irrelevant questions as legitimate controls. Thus, modern screening tests include such questions largely to provide a type of psychological refuge from the stream of relevant questions covering topics like drug use, alcoholism, work habits, trustworthiness, and rule compliance. After presenting multiple questions tapping each of these themes, examiners attempt to identify question categories (e.g., concerning drug use) that elicit stronger reactions than other content areas (Ferguson, 1966). Having identified a topic that appears to elicit strong responses, the examiner probes the examinee for an explanation. This explanation may in turn provoke the development of

additional questions and the running of more charts to test the truthfulness of the clarification. Examinees adept at impression management and capable of “explaining away” their reactions (e.g., “I was bothered by your questions about irresponsible drinking because my alcoholic father died of cirrhosis last year.”) may be those most likely to pass these tests (Thurber, 1981).

The premises on which screening techniques are based are no more sound than those of the CQT. Heightened reactions to certain types of questions can occur for reasons other than deceptiveness, and there is no reason why these reactions should dissipate once an explanation for them is presented to a polygraph examiner. At one time, these tests were used routinely by private corporations to screen the integrity of their employees. A Congressionally mandated study carried out in the 1980s raised serious concerns about these tests (Saxe, Dougherty, & Cross, 1985), which led to their being banned under the Employee Polygraph Protection Act (Public Law 100–347). Ironically, Congress exempted government agencies from this law, and subsequent to its passage expanded polygraph testing programs (Krapohl, 2002).

Test for espionage and sabotage (TES)

U.S. national security agencies have recently introduced the Test for Espionage and Sabotage (TES). The TES is typically administered periodically to government employees with top-secret security clearances as a response to concerns that some of these individuals may be spies. Questions such as “Have you committed espionage?” are compared to directed lie control questions (e.g., “Did you ever violate a traffic law?”). The TES can be scored using the same procedures followed for the CQT and DLT and is vulnerable to the same criticisms.

EVALUATION

Before considering how well these procedures work, it is important to highlight several points critical to their evaluation.

Research has focused on forensic applications

Very little research has addressed the accuracy of security screening tests. Only the GKT and CQT have received extensive research attention, and the CQT is by far the most studied polygraph procedure.

Polygraph tests are investigative tools

Field examiners using polygraph tests and the government agencies that sponsor them have been largely unconcerned about what scholars conclude regarding polygraph accuracy. True for decades, this is no less true today, because it is the perceived utility of polygraph testing that sustains its use in the face of stiff criticism regarding accuracy.

Good polygraph examiners are expert interrogators skilled at using the polygraph as a tool to extract admissions of wrongdoing as well as outright confessions. Confronted by an examiner who uses the polygraph to justify skepticism over an examinee’s account of the facts, many examinees will divulge information in an attempt to get the examiner to back down. Government agents are happy to collect this information, much of which could either not be obtained in any other way or would be prohibitively expensive to obtain through other investigative means. In security screening, this information might include acknowledging procedure violations or eliciting suspicions about other employees who then become the focus of investigation. In criminal investigations, suspects may correct inaccuracies in their statements, confess to other wrongdoings, or confess to the matter under investigation. A common forensic application of polygraph tests is a sex crime where there is skimpy physical evidence and the case is reduced to the credibility of those involved. In the hands of a skilled examiner, one of the involved parties may “come clean,” not only solving the case, but avoiding the expense and uncertain outcome of a protracted trial.

Despite the widespread acceptance of polygraph testing utility, empirical data indicating how often admissions and confessions lead to investigative breakthroughs is unavailable. This is especially so in national security investigations where it has been noted that no spy has ever been identified as a result of a polygraph test, while false negatives, such as the failure to catch notorious CIA spy Aldrich Ames despite repeated polygraph tests, are known (Iacono & Lykken, 2002). Having such data would be especially useful given the accumulating evidence that individuals often make false admissions during stressful interrogations (Kassin, 2005; Kassin & Gudjonsson, 2004). In particular, data are needed to show how often a confession is corroborated (e.g., by the confession leading to the uncovering of other investigation-relevant information).

Legal status of polygraph testing

By federal law, government agencies and certain private corporations where security is important are allowed to evaluate employees using screening tests. New Mexico is the only state allowing routine admittance of polygraph test results in criminal cases, although about half the states allow the admission of stipulated tests, i.e., those that the prosecution and defense agree will be admissible in advance of test administration. Otherwise, polygraph test results seldom find their way into state or federal courts (Faigman et al., 2002).

Scientific opinion

Psychologists and psychophysicists have been surveyed repeatedly regarding their opinions of polygraph testing, in part because the consensus opinion of the scientific community has been used by courts as one of the criteria

to consider in determining whether the results of a technique are acceptable as scientific evidence. The most favorable surveys (Amato, 1993; Gallup, 1984), both polling members of the Society for Psychophysiological Research (SPR), have found that approximately 60% indicated that a polygraph test is “a useful diagnostic tool when considered with other available information.” However, these surveys did not ask directly about accuracy; diagnostic usefulness could be equated as easily with utility as with accuracy. They also did not distinguish among types of polygraph tests. Thus, these surveys left it unclear to what degree they refer to the CQT as opposed to, for instance, the GKT, which most scientists view as on a more solid footing than the CQT. David Lykken and I (Iacono & Lykken, 1997) carried out surveys of members of both SPR and the American Psychological Association, and were careful to make clear when questions addressed the CQT, DLT, or GKT. The opinions of members of both groups were quite similar, and indicated strong skepticism about the CQT and DLT but not about the GKT. For instance, these scientists did not believe the CQT: (a) is based on sound theory, (b) could be as accurate as polygraph professionals claim, (c) should be used in court, (d) is standardized, (e) is objective, or (f) is immune to countermeasures.

What is needed to evaluate accuracy

A second reason why polygraph testing continues despite persisting accuracy concerns is that it has proved impossible to provide anything approaching a definitive validity test. Although the nature of social science research seldom provides for definitive conclusions, there are only two meaningful outcomes for a polygraph test, and those taking it are either truthful or lying. Hence, many of the measurement and criterion problems that complicate psychological study in general are not applicable to polygraph validity studies. So why, then, has the validity question remained intractable?

Laboratory studies

The simplest way to ensure criterion validity is to conduct a mock crime study where participants are assigned to guilty or innocent groups. The criterion (guilt or innocence) can be unambiguously established by ensuring that subjects follow the experimenter’s programmed instructions, and criterion validity can be estimated by the degree to which programmed guilty subjects fail and innocent subjects pass their polygraph tests. The generally acknowledged problem using this approach to evaluate validity is that it is unrealistic. In real life, those undergoing polygraph exams face serious consequences if they fail, and are living under the veil of a serious accusation. Under these circumstances the emotional impact of the relevant questions is likely to be heightened, as is the motivation to beat the test. In the laboratory situation, innocent subjects have little to fear if they are diagnosed “guilty.” When tested with the CQT, they are more apt than in real life to find the privacy invading control questions emotionally troubling. This outcome

is likely because control questions are potentially more psychologically bothersome than relevant questions that deal with a “crime” carried out only to satisfy study requirements. Moreover, a recent study from scientists at the Department of Defense Polygraph Institute attempted to evaluate the generalizability of the data from laboratory mock crime investigations by comparing the physiological responses obtained from mock crime and real life cases (Pollina et al., 2004). The results indicated that electrodermal, cardiovascular, and respiratory responses were more pronounced in field polygraph applications. Following Sokolov’s orienting theory (Sokolov, 1963), the authors interpreted these findings as possibly reflecting defensive responses motivated by fear during field polygraph tests, and orienting responses reflecting “fascination with the process and a desire to ‘win the game’” (p. 1104) in laboratory situations.

For the GKT, a major limitation of laboratory investigations relates to item development. Mock crime studies are typically set up to ensure both that subjects pay attention to crime details and that the examiner knows what the relevant details are. In real life, neither of these circumstances is likely. Laboratory studies are useful for examining factors that may moderate outcomes, such as personality characteristics or drug effects, but there is no way to tell how well their hit rates generalize to real-life settings.

Field studies

Field studies effectively address the realism issue because they are designed to evaluate accuracy in real-life criminal cases that have involved polygraph tests. However, criterion validity presents a problem. Confessions have become the accepted standard for establishing ground truth because they unambiguously identify the guilty and clear the innocent when a suspect in a multisuspect case confesses. Having established ground truth, polygraph charts can be blindly scored to see how closely the polygraph verdicts match the confession criterion. However, confessions are almost always obtained by the original examiner who, working in the field, has concluded the psychophysiological record is indicative of deception. When this occurs, the confession is not independent of the outcome of the polygraph test, and the charts that ultimately are chosen for study are only likely to be those where the original examiner was correct. As I have illustrated elsewhere (Iacono, 1991), under these circumstances, a test with no better than chance accuracy can be made to look virtually infallible.

The problems inherent to the use of confessions to establish ground truth are highlighted in Figure 29.1. Cases where guilty individuals appear truthful on their polygraph charts will not lead to confessions because the examiner, who believes the suspect to be innocent, will not seek a confession (see Figure 29.1, flowchart A). Likewise, cases where the original examiner erroneously scored the charts deceptive would not be selected for field study because the innocent victims of such an outcome would not be

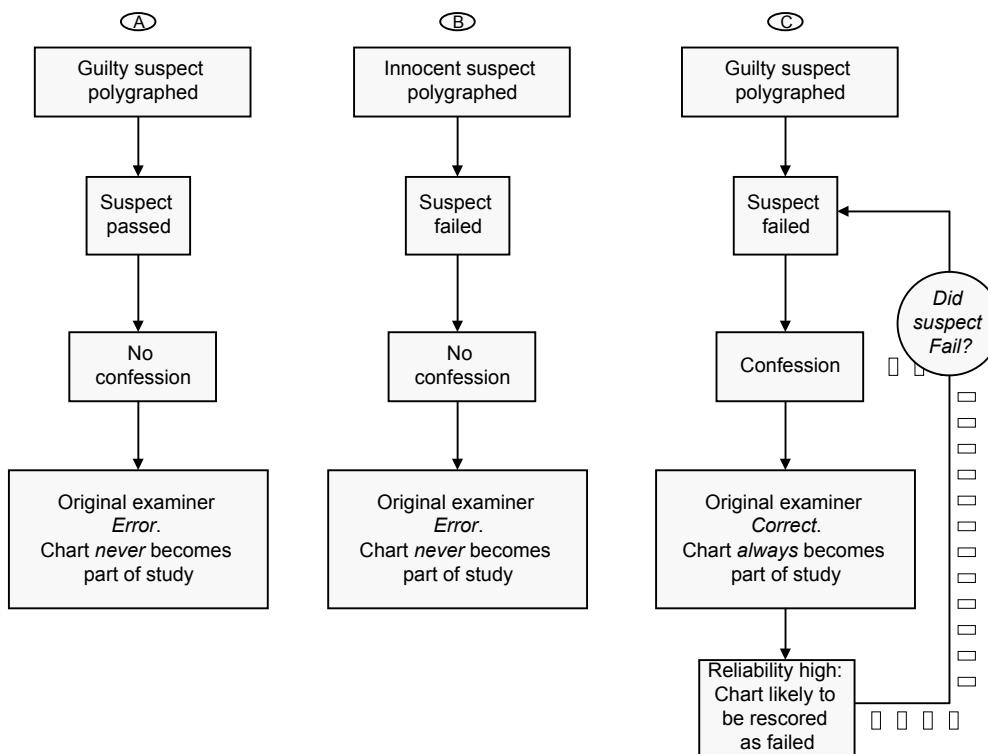

Figure 29.1. Flowcharts indicating how cases are selected for field studies of polygraph validity when confessions are used to verify ground truth. In these studies, the original examiner establishes ground truth if it is possible to obtain a confession of guilt from a suspect who fails a polygraph. Flowchart A indicates that guilty suspects whom the examiner passes will not be asked to confess, and their false negative chart thus does not become part of the validity study. Flowchart B illustrates that innocent suspects who fail also do not become part of such a study because their false positive result does not yield a confession. Only cases represented in Flowchart C become part of field validity studies. This flowchart illustrates the circularity of a case selection method that forces biased selection of only cases that the original examiner scored correctly, which results in a re-scored deceptive chart that almost always matches the confession criterion. Not represented is how confirmed innocent cases become part of such a study. When flowchart C applies to multiple suspect cases, charts from individuals who pass a polygraph are included because they are confirmed as innocent by the confession of the guilty party.

expected to confess (see Figure 29.1, flowchart B). Hence, studies that select cases using a confession to confirm ground truth systematically eliminate all of the original examiner's false positive and false negative errors. The only cases included for study are those where the original examiner was correct (see Figure 29.1, flowchart C). In these cases, a guilty individual must both fail the polygraph and confess. When this occurs, the selected charts are rescored and then compared to ground truth (i.e., the confession). Because chart scoring is highly reliable, blindly rescoreing the charts can be expected to result in the same failed polygraph verdict that led to the confession in the first place. As a consequence, field studies overestimate accuracy.

The solution to these problems with laboratory and confession-based field studies is to carry out a field study where the criterion for ground truth is independent of test outcome. Christopher Patrick and I (Patrick & Iacono, 1991) conducted such a study with the Royal Canadian Mounted Police (RCMP). We identified cases where individuals had undergone a polygraph test and a confession was obtained not by the polygraph operator, but as part of

the ongoing detective work accompanying the case. When these independently obtained confessions were compared to the blindly rescored polygraph charts, the hit rate for innocent examinees was 57%. Unfortunately, the corresponding hit rate could not be determined for guilty examinees. This difficulty establishing independent evidence of ground truth for the guilty reflected the fact that the confessions obtained, while frequently clearing the innocent, seldom also originated with a guilty person who had taken a polygraph test.

Reviews of the deception detection literature

Reviews of CQT studies carried out by those who themselves administer polygraph tests have concluded that the CQT is highly accurate (Honts, Raskin, & Kircher, 2002; Raskin & Honts, 2002). Reviews of the same CQT investigations carried out by those not affiliated with the polygraph profession have concluded these claims are indefensible (Ben-Shakar, 2002; Fiedler, Schmod, & Stahl, 2002; Iacono & Lykken, 2002; Oskol & O'Donohue, 2003). Although polygraph proponents are generally skeptical that the GKT

offers any advantage over the CQT, reviews of the GKT by those outside of the polygraph profession have pointed to the under-realized value of this technique (Ben-Shakar & Elaad, 2003; Ben-Shakhar, Bar-Hillel, & Kremnitzer, 2002; Iacono & Lykken, 2002). The most recent and comprehensive review of this literature was published as a book by the National Research Council (NRC) of the National Academy of Sciences (2003). Given the extensiveness of this report and the prestige of its authors, I will highlight in some detail the circumstances surrounding this review as well as its main conclusions.

As part of the National Defense Authorization Act of 2000, Public Law 106–65 required scientists at nuclear weapons laboratories (such as New Mexico's Sandia and Los Alamos Laboratories) to submit to security screening tests to maintain their top-secret clearances. This law was passed following concerns that one of the scientists at the Los Alamos laboratory (Wen Ho Lee) was spying for the Chinese – a charge that was never proved (see Greenberg, 2002). Confronted with the prospect that they would have to undergo these security tests, a panel of Sandia's senior weapons scientists and engineers conducted their own evaluation of the polygraph literature (Sandia's Senior Scientists & Engineers, 1999). These scientists often provide evaluations of technical issues of concern to weapons lab management. They concluded that there were no adequate studies to support screening, and that it was impossible to predict what error rates might be expected. They also expressed concern that the implementation of this program might reduce the likelihood that talented scientists would choose a career at these labs if they knew their employment future depended on polygraph test outcomes. Against this backdrop, as part of the National Defense Authorization Act for 2002, Congress instructed the U.S. Department of Energy (DOE), which oversees the labs, to evaluate their use of lie detectors. DOE in turn asked the National Academy to examine the validity of polygraph testing.

The NRC panel was composed of 14 distinguished scholars with diverse backgrounds in psychophysiology, psychology, statistics, law, and medicine. Aided by a scientific support staff, this panel conducted the most far-reaching and thorough evaluation of polygraph testing ever undertaken. Their work spanned almost two years and included public hearings, visits to polygraph facilities, and access to unpublished government reports, including classified material. Although security screening was a primary concern of the panel, because there is little available research on this topic, most of the research the panel had to evaluate was derived from specific incident polygraph testing (disproportionately CQT studies), so their conclusions apply to polygraph testing broadly. The following key NRC findings address the scientific basis of polygraph testing.

Regarding polygraph theory. The NRC panel noted that the theoretical rationale for CQT polygraph testing is quite weak. Little is known about the psychological states or spe-

cific factors purported to cause differential responses to control and relevant questions. By contrast, the theoretical basis of the GKT has been developed and linked to orienting response theory. The NRC panel concluded that “in short, the bulk of polygraph research . . . can be accurately characterized as atheoretical” (p. 94).

Regarding polygraph research. Research on polygraph testing was characterized as similarly weak. The studies themselves were found to be of generally low quality. Taken in the aggregate, there was little evidence of accumulated knowledge that had strengthened the scientific underpinnings of polygraph testing.

Regarding laboratory studies. The panel characterized existing validity studies as having serious limitations, and noted that laboratory studies fail to reflect critical aspects of field polygraph testing, especially because they do not mirror the real-life consequences of failing a polygraph. The panel concluded that laboratory studies “are likely to overestimate accuracy in field practice, but by an unknown amount” (p. 210).

Regarding field studies. The panel commented that “virtually all of the observational field studies have been focused on specific incidents and have been plagued by measurement biases that favor overestimation of accuracy, such as examiner contamination, as well as biases created by the lack of a clear and independent measure of truth” (p. 214). This led them to conclude that “the available field studies are also likely to overestimate the accuracy achieved in actual practice” (p. 210).

Regarding accuracy. The panel was clearly dubious of the accuracy claims of the polygraph profession: “What is remarkable, given the large body of relevant research, is that claims about the accuracy of the polygraph made today parallel those made throughout the history of the polygraph: practitioners have always claimed extremely high levels of accuracy, and these claims have rarely been reflected in empirical research (p. 107) . . . almost a century of research in scientific psychology and physiology provides little basis for the expectation that a polygraph test could have extremely high accuracy” (p. 212). Accuracy cannot be established because “the evidence does not allow any precise quantitative estimate of polygraph accuracy or provide confidence that accuracy is stable across personality types, sociodemographic groups, psychological and medical conditions, examiner and examinee expectancies, or ways of administering the test and selecting questions” (p. 214).

Summary. Despite this clear indictment of polygraph testing, this report has had little effect on the practice of polygraphy even in the DOE laboratories (Malakoff, 2003). Possible reasons for this include the fact that the report did not challenge strongly claims regarding utility. Rather, the

authors concluded that polygraph tests might be useful when they “elicit admissions and confessions, deter undesired activity, and instill public confidence” (p. 214). As noted previously, belief in the utility of polygraph testing has always been used to justify its use in the face of scientific criticism. In addition, the NRC noted that no alternative method for detecting deception appears to outperform the polygraph even for security screening. Given the current salience of concerns over security, there is little incentive to drop or substantially modify polygraph practice.

Finally, despite the panel’s lack of confidence in the quality of the existing polygraph research, the panel identified 57 specific incident studies (combining both CQT and GKT formats) that met “minimal criteria” (p. 107) for inclusion in a signal detection analysis. This analysis was based on receiver operating curves (ROC) calculated for each of the 57 studies. The area under the ROC curve yields an “accuracy index” (designated A). The ROC analysis demonstrated high variability across studies in the value of A by yielding a median value $A = .86$. A does not translate directly into hit rate estimates, such as those provided in other reviews of this literature, primarily because the ROC analysis takes into account inconclusive outcomes as well as differences across studies in the rules followed to identify passed and failed tests. Because none of the 57 investigations generated ROC curves indicating less than chance or near perfect accuracy, the panel concluded that for those untrained in countermeasures, “specific incident polygraph tests for event-specific investigations can discriminate lying from truth telling at rates well above chance, though well below perfection” (p. 214). This ambiguous statement is not seen as inconsistent with proponents’ claims that the CQT may have better than 90% accuracy. Of course, it is also not inconsistent with critic’s claims that accuracy is substantially lower.

RECENT ADVANCES

In this section, I will review deception detection research that relies on measures other than autonomic measures to infer deceptive behavior. Some of this research was covered by the NRC report, so my focus will be to briefly highlight progress in this area with an eye toward future developments. Without exception, this area of investigation fails to grapple successfully with the many problems that have plagued lie detection research for the last half-century. This research is laboratory based and fails to tackle seriously the problem associated with the low levels of jeopardy experienced by laboratory subjects.

Computer voice stress analyzer (CVSA)

Voice stress analysis has been around for over 30 years, and was evaluated (and largely dismissed as invalid) based on research in the 1970s and 1980s (Lykken, 1998). However, it has experienced a renaissance with heightened U.S. concerns about terrorism and the purchase of CVSA equip-

ment by many police departments across the country (see the National Institute of Truth Verification web page at www.cvsa1.com/product.php). Basically, the CVSA revival has involved packaging old voice stress technology with a computer and marketing the package as an unobtrusive method to catch liars. The theoretical foundation for voice stress analysis is weak because it is based on the unsubstantiated, although perhaps plausible, notion that the human voice produces inaudible microtremors associated with lying that can be analyzed from a voice recording. The assumptions on which voice stress is based are similar to those on which conventional lie detection is founded, and require the ability to discriminate between stress associated with lying from stress associated with any other human emotion that might be associated with accusations, denials, and other forms of highly charged speech. However, there is little evidence that voice stress analyzers do an adequate job of reliably assessing voice stress (Brenner, Branscomb, & Schwartz, 1979; Horvath, 1978; Lynch & Henry, 1979; Waln & Downey, 1987), let alone its causes. The NRC panel reviewed five unpublished government studies of the CVSA conducted between 1994 and 2000, and found no evidence that it worked much better than chance (NRC, 2003).

Thermal imaging

This technology made a big splash when a paper published in *Nature* was covered by the media as a possible method to screen airline passengers who might have terroristic intent (Pavlidis, Eberhardt, & Levine, 2002). Like the CVSA, thermal imaging can be carried out unobtrusively, without attaching sensors to the subject. Thermography relies on a high-speed motion picture camera sensitive to changes in facial blood flow. In a mock-crime study, Pavlidis, Eberhardt, and Levine (2002) correctly identified 6/8 guilty and 11/12 innocent participants based on thermal characteristics of blood flow around the eyes. Although the original report of this research resembled more a news article than a scientific paper, a more detailed presentation of the methodology has since become available (Pavlidis & Levine, 2002). Nevertheless, much more work would be required to determine whether facial temperature monitoring has potential as a lie detection procedure.

P300 event related potential GKT

Most GKT research has been based on the recording of autonomic reactions, especially skin conductance. In the 1980s (for reviews, see Allen & Iacono, 2001; Iacono & Patrick, 2005; Rosenfeld, 2002), this technique was adapted to an oddball event-related potential (ERP) paradigm designed to elicit P300 ERPs. Many hundreds of studies have demonstrated that the P300 response is sensitive to the probability of stimulus occurrence and relevance. Because the guilty knowledge alternatives of GKT multiple-choice questions are both uncommon (compared

to the nonguilty knowledge foils) and highly relevant to the guilty, there is a strong *prima facie* basis to expect the GKT paradigm to lend itself well to ERP adaptations.

Unlike the traditional autonomic GKT, an ERP extension of the GKT is now being pushed for forensic applications. Larry Farwell (see www.brainwavescience.com) has patented aspects of this technology and marketed it under the trademark “Brain Fingerprinting.” He has also applied it in legal appeals of convicted felons who have maintained their innocence, most notably in the case of Terry Harrington, an Iowan convicted of murder, who passed Farwell’s test and ultimately won his appeal. The publicity surrounding this case led to a review of this technique by the General Accounting Office (GAO, 2001). Farwell has started a company devoted to developing forensic and medical applications of “brain fingerprinting,” making it possible that this technique will grow in significance in the near future. Farwell’s procedure involves analysis of the P300 waveform and another aspect of the ERP termed the memory and encoding related multifaceted electroencephalographic response, or MERMER (Farwell & Smith, 2001). The MERMER appears to include P300 and other aspects of the ERP, but exactly what constitutes the MERMER is considered proprietary. Consequently, the criteria used to identify it are unspecified in the one publication that describes it (Farwell & Smith, 2001).

P300-GKts can be tailored to include validity-enhancing novel elements not typically part of a conventional GKT that allow each subject to serve as his or her own control. In P300 adaptations of the GKT, three types of stimuli may be presented to a suspect on a computer monitor. “Target” stimuli reflect information that is known to all examinees. In a bank robbery, this might be generally available information about the robbery (e.g., the name of the bank). “Probe” stimuli reflect guilty knowledge (e.g., the phrasing of the holdup note). Targets and probes are presented relatively infrequently such that each has the potential to elicit a P300 response. “Irrelevant” stimuli are similar to alternatives on a conventional GKT that serve as foils (e.g., other bank names, made-up phrasing). Because these stimuli have no special meaning and they are abundant, they are not expected to elicit a strong P300 response. All examinees are expected to show a pronounced P300 wave to targets and a diminished wave to irrelevants. If an examinee did not show this result, the particular test administration would be invalid. For the innocent, probes and irrelevants are equivalent in their (lack of) significance, so the probes would not be expected to generate a P300 response. For the guilty, the probe and target both have relevance, so the probe should elicit a P300 response that makes the probe ERP more like the target ERP than the irrelevant ERP. Hundreds of probe, target, and irrelevant stimuli can be presented, yielding reliable representations of the brain response to these stimuli, and their resulting ERPs averaged. By statistically computing the degree to which the average probe ERP resembles the average target versus the irrelevant ERPs, it is possible to determine whether the

examinee possesses guilty knowledge. The statistical comparison can be conducted such that strong resemblance of the probe ERP to either the target or the irrelevants is required for a verdict to be issued; otherwise, the outcome is inconclusive.

A conventional GKT could in principle be developed following the ERP-GKT format. Doing so requires overcoming the sensitivity of autonomic nervous system measures like electrodermal reactivity to order and habituation effects, which could become pronounced in an extended GKT with many questions and additional item alternatives to cover targets (Iacono, Boisvenu, & Fleming, 1984). Groundwork for overcoming these problems has been laid by Lim et al. (Lim et al., 1999) who showed that skin conductance responses could be effectively recorded to targets using an oddball paradigm with 287 stimuli (40 targets) presented every 1.3 seconds. In addition, Ben-Shakar and colleagues (Ben-Shakar, Gronau, & Elaad, 1999) have shown that the introduction of a target stimulus into a conventional GKT may reduce the likelihood of false positive outcomes.

An additional enhancement of this procedure is the requirement that the subject respond manually to each stimulus presentation and that a target presentation requires a different key response than all nontargets. This requirement forces subjects to attend to the stimuli, and makes it possible to deem invalid any test administration associated with unusually slow reaction times or frequent target errors. A test like this can be presented with the simple instruction to press a “yes” key every time a crime relevant detail is presented and a “no” key for all crime irrelevant details. For a guilty person who recognizes probes as crime relevant, the natural tendency to press “yes” to the recognition of crime relevant stimuli must be suppressed before responding with the “no” key, thus lengthening reaction times to probe stimuli. Analysis of reaction time data has the potential to usefully complement the P300 analysis. Whether reaction time alone may itself lead to highly accurate classification of guilty and innocent test takers remains to be determined (Allen & Iacono, 1992; Gronau, Ben-Shakhar, & Cohen, 2005; Seymour et al., 2000). Like the autonomically based GKT, P300 adaptations have generally produced high hit rates, including studies showing perfect classification accuracy for both innocent and guilty subjects when inconclusive outcomes were removed from the analyses (Allen & Iacono, 1997; Farwell & Donchin, 1991; Farwell & Smith, 2001).

While aggregating results across studies is often a useful way to evaluate the effectiveness of a technique, the important question to ask is how well the procedure works when optimally applied? This question has been asked in a meta-analysis of the conventional GKT, and has led to both the identification of validity enhancing features and a substantial boost in the GKT’s estimated accuracy (Ben-Shakhar & Elaad, 2003). However, this question also needs to be addressed when considering the effectiveness of event related potential GKts. A P300-based GKT study could be

carried out without the inclusion of a target condition, the need to respond manually to each stimulus presentation, or the inclusion of decision-making rules that allow for inconclusive outcomes. Omitting one or more of these features, as many studies have, would make the test more like a traditional GKT, but may not optimize classification accuracy.

For both types of GKT, it is probably better to use the equivalent of multiple-choice alternatives that are easily perceived as different in order to minimize response generalization across similar stimuli. A GKT item that lists as murder weapon options "hammer-ice pick-rope-poison" is more likely to register a distinct recognition response than one that lists types of hammers. Likewise, a test with multiple items may generally be more effective than one with only a few items (assuming the items have equivalent psychometric properties). Although this was shown in a meta-analysis of the autonomic GKT literature (Ben-Shakhar & Elaad, 2003), questions have been raised about its appropriateness in P300-GKTs because of the added complexity of this type of GKT (Rosenfeld et al., 2004). Tests should be reviewed with a prospective subject to determine if any of the items or alternatives have personal significance that could elicit a recognition response even if the individual was not involved in the crime. A plumber who works with ball peen hammers should not be asked a question that includes this type of hammer as one of the multiple choice alternatives.

In the previous edition of this *Handbook*, I posited that P300 adaptations of the GKT might be difficult to beat. This speculation was premised on the supposition that introducing countermeasures would lengthen ERP latencies and manual reaction times, introduce more variability into these measures, and possibly produce atypical manual response errors. These results might be expected as the guilty individual strains to introduce an effective manipulation into a procedure that depends on millisecond timing to ensure the validity of an individual test. Hence, the important question is not whether ERPs and associated behavioral data can be altered by countermeasures, but whether countermeasures can be used easily without being detected or generating an inconclusive result.

Using a mental countermeasure in which participants carried out a serial subtraction task, Sasaki and colleagues (Sasaki, Hira, & Matsuda, 2002) found little evidence of countermeasure effectiveness. A more thorough evaluation of countermeasure effects was recently published by Rosenfeld and colleagues (Rosenfeld et al., 2004). This ambitious study had many components making it difficult to summarize thoroughly, so the interested reader should consult the original paper.

These investigators taught mock-crime guilty subjects to use countermeasures to appear innocent on a P300-GKT. The countermeasures involved pressing a finger against a leg, wiggling a toe, and imagining being slapped following the appearance of irrelevant stimuli. Because it used small samples (group size averaged 11 subjects), it was

not possible to reach firm conclusions for many interesting hypotheses (e.g., the classification hit rate difference between guilty and countermeasure subjects was not statistically significant). Nevertheless, the study provided evidence indicating that countermeasures could be effective for some subjects. ERPs were altered in a way that compromised accurate classification of those using countermeasures, and the reaction time data of some of these individuals appeared relatively unaffected by their use.

However, this study had a number of features that did not allow for a thorough evaluation of the likelihood that countermeasures would be both effective and go undetected. No inconclusive category was included. To the extent that a probe ERP resembled an irrelevant ERP more than a target ERP, the subject was classified as nondeceptive without considering the magnitude of the similarity between the probe and irrelevant stimuli or the magnitude of the differences in similarity between the ERP pairings. The use of countermeasures directed at irrelevant stimuli is likely to blur distinction between these stimuli and both targets and probes. To the extent all three types of stimuli produce similar P300 responses, this should lead to a test administration being dismissed as invalid; *no test should be accepted as valid if the irrelevant and target stimuli cannot be easily differentiated*. This problem was noted by the authors in one of their analyses when they commented that "all three stimulus types generated a small P300, probably because all were meaningful. The reduced size is probably due to the loss of unique oddball probability for probe and target" (p. 214).

Manual response data could have also been used more effectively either to identify guilty subjects or to render evaluations inconclusive. Guilty subjects, especially in the countermeasure group, were significantly more likely to give a "yes" response to probe stimuli. This information was dismissed as of no value because the rates of such error were low. However, there is no reason for any innocent person to respond disproportionately with "yes" responses to probe stimuli, so such a pattern should at least cast doubt on the validity of the test administration if not be used to indict participants as guilty. Although as many as 9 of the 11 subjects in the countermeasure group were deemed to beat the test in certain ERP analyses, only three subjects in this group produced manual reaction times to probe and irrelevant stimuli that were as fast as those of even the slowest innocent subjects. Again, such discrepant behavioral data should at least cast doubt on the validity of the ERP analyses. Finally, questions can be raised about the salience of the probes used in this study, even for guilty subjects, because they did not elicit responses as large as the targets. This led to these subjects being erroneously classified 46% of the time when using Farwell's method which has yielded high accuracy with guilty subjects in three different studies (Allen & Iacono, 1992; Farwell & Donchin, 1991; Farwell & Smith, 2001) even when counting inconclusive outcomes in these three studies as errors. Coincidentally, this error rate matched that of Rosenfeld

et al.'s countermeasure group when analyzed using the same method. Despite these qualifications, the report of Rosenfeld et al. (2004) is important because it is the first to explore how countermeasures might affect this type of GKT, and it suggests that those using this methodology cannot be confident that it is immune to countermeasure effects.

In this regard, it is also useful to consider enhancements that might improve the accuracy of P300-GKTs in the face of countermeasures. In this study, subjects used one hand to manipulate both the "yes" and "no" response buttons while the other hand was used for leg self-stimulation. Subjects could be given pushbuttons for each hand, a modification that would probably eliminate this countermeasure and provide reaction time data that is more sensitive to the expected delays caused by the effortful use of countermeasures. If sufficient numbers of subjects were examined using a standardized version of the P300-GKT, behavioral and ERP norms could be developed that might be used profitably to identify outliers whose test results could be treated with skepticism.

Physical countermeasures can be detected through electromyographic (EMG) recordings when used with conventional polygraph tests (Honts et al., 1994), but the field instrumentation used by polygraphers does not lend itself to adding sensors that might detect them. Although movement sensors that can be attached to examinee chairs are available for monitoring countermeasure attempts, they are seldom used by field polygraphers. A similar problem does not exist for ERP-GKTs, which depend on multichannel laboratory instruments. These devices can easily be adapted to record EMG from muscles anywhere on the body. In addition, extra scalp electrodes positioned over the sensorimotor cortex have the potential to detect repeated muscle manipulations such as the finger and toe countermeasure movements used in Rosenfeld et al. (2004).

Finally, it is noteworthy that countermeasures only affect the confidence that can be placed in passed tests. As noted previously, the great value of these procedures in forensic applications may eventually lie with the incriminating nature of a failed test.

Other electrocortical research

Other brain electrocortical measures besides P300 also have been used to study deception. Unfortunately, each of these methods has been examined in a single report, thus rendering difficult an evaluation of their potential.

Taking advantage of the N400 ERP's sensitivity to semantic incongruity, Boaz et al. (Boaz, Perry, Raney, Fieschler, & Shuman, 1991) employed a GKT design to determine how subjects responded to crime relevant phrases that terminated with endings that were either true or false. Although the average observed hit rate exceeded 70%, this technique does not appear to offer any advantage over the P300-GKT, which yields higher accuracy.

More recently, Fang and associates (Fang, Liu, & Shen, 2003) evaluated the utility of the contingent negative variation (CNV) for detecting deception. Their design required subjects to evaluate whether pictures of faces presented to them were novel or familiar. Compared to trials on which subjects responded truthfully, CNV was augmented when participants were preparing to lie. Taking a slightly different tack, Lo et al. (Lo, Fook-Chong, & Tan, 2003) used transcranial magnetic stimulation to examine motor control mechanisms potentially associated with lying. Their participants either silently lied or told the truth when asked 80 different questions. The amplitude of motor evoked potentials (MEP) to magnetic pulses presented before and after each question was significantly greater after a question associated with lying. MEP amplitudes were no different when responding truthfully to questions. In addition, MEPs preceding a question that elicited a lie were elevated. These results suggest that cortical excitability is increased both following a lie and in anticipation of deceiving. Because neither Fang et al. nor Lo et al. estimated hit rates using these methods, their results cannot be compared easily to those of other ERP investigations.

Johnson and colleagues (Johnson, Barnhardt, & Zhu, 2003, 2004) have moved beyond evaluating applications to isolate brain processes that underlie deception. Using multichannel EEG recording, they have introduced tasks that are designed to separate the different psychological processes involved in lying. Their results suggest that lying is associated with medial frontal negativities reflecting anterior cingulate (ACC) processes. These processes are related to the response conflict associated with having to inhibit the prepotent truthful response prior to lying. A second process, associated with parietal cortex late positivity, appears to be related to recollection and episodic memory of past truthfulness, which reflects a guilty knowledge effect.

Brain mechanisms

Deception detection research has been driven largely by applied considerations. The result has been a collection of box scores indicating how well physiological measures differentiate lying from truth telling in one paradigm or another. As Furedy et al. (Furedy, Davis, & Gurevich, 1988) have noted, research on deception detection has done little to shed light on underlying processes, in part because lie detection methods, even if they work, provide few clues as to why they might work. This problem is well illustrated with the CQT because differential responding to control and relevant questions may stem from any of the many psychological attributes, which vary across these two question types. They confound cognitive and emotional processes. They do not differ in the likelihood that they elicit lies, nor do they differ along the same dimensions for guilty and innocent examinees. CQT theory presumes that both questions elicit lies for the guilty, but the relevant question elicits a more significant lie. For the innocent, only the

control question is expected to elicit a lie, but this is merely plausible and not known to be the case. Fear of detection, guilt, cognitive processes associated with both the intent to lie and the act of lying, and social behavior associated with lying all confound the ability to interpret the psychological significance of responses to control and relevant questions. To varying extents, similar problems exist with other deception detection formats. Until research moves substantially beyond evaluating applications, we will miss the opportunity for insightful discoveries that have potential to inform the development of improved deception detection techniques.

Recently, a number of investigators have begun to move beyond empirical evaluation to isolate brain structure and processes that underlie deception. As noted above, Johnson et al. (Johnson, Barnhardt, & Zhu, 2003, 2004) have extended EEG research along these lines. In a structural imaging study, Yang et al. (2005) found differences in prefrontal white and grey matter when pathological liars were compared to antisocial and normal controls. Other investigators, taking advantage of recent developments in functional magnetic resonance imaging (fMRI), have also investigated processes and brain regions involved with deception. In the first of these studies (Spence et al., 2001), subjects were presented with autobiographical questions to which they responded manually with a "yes" or "no" button press. Every question was answered once truthfully and once with a lie. The task was characterized as requiring the suppression of the prepotent response (the truth) in favor of its alternative, a lie. Consistent activation of the bilateral ventrolateral prefrontal cortex was observed. The authors noted that their design did not allow them to differentiate between two possible interpretations for the brain activation, one associated with answering with a lie and the other associated with the withholding of the truth in order to lie.

Langleben et al. (2002) employed a GKT in which subjects tried to conceal their possession of a playing card as different cards were presented to them. The guilty knowledge card and the cards serving as foils were presented along with the question "Do you have this card?" To ensure that subjects paid attention and did not simply answer every question with an automatic "no," occasionally the question "Is this the 10 of spades?" appeared together with the 10 of spades (to which they responded "yes"). The key finding involved activation of the ACC, but not the dorsolateral prefrontal cortex (DLPFC) during lying. Because other studies have shown that ACC activation is proportional to the degree of response conflict and inversely related to DLPFC activation, the results suggested that a conflict with the prepotent response (truth) and eventually its inhibition took place. Activation of right frontal motor and premotor and adjacent anterior parietal cortex was also observed and attributed to the increased demand for motor control involved in directing the left hand to the appropriate response button. Although this GKT paradigm seems fairly straightforward, even this simple manipulation con-

founded lying to the guilty knowledge card with recognition memory, as this was apparently the only card presented to subjects before they entered the scanner. This illustrates the difficulty conducting these types of experiments in a way that leads to unambiguous conclusions, which is a problem that looms even larger in some of the other imaging-deception studies.

Adopting a different approach, Lee et al. (2002) evaluated brain activation when subjects lied to feign memory impairment in what were referred to as two "forced choice" tasks designed to assess short and longterm memory impairment. The first task required them to decide whether two three-digit numbers presented about two seconds apart were the same or different. The second task asked an autobiographical question followed two seconds later by an answer. The brain activation from these two memory tests was contrasted with that of each subject when doing the same task answering all the questions truthfully. Participants were given a description of the nature of the memory tests they were about to take, and told "your goal is to fake well, do it with skill, and avoid detection." Presumably participants understood that this meant they should not answer every single question with a lie. Doing so would make them detectable because their response pattern would suggest a significant departure from the chance responding that those with memory impairment would be expected to display. Subjects were, however, left on their own to decide how to respond when given the two different memory tasks. Results common to both tasks revealed bilateral prefrontal (including DLPFC), frontal, parietal, and caudate activation. From this, the authors concluded that feigned memory impairment involves a prefrontal-parietal-caudate circuit reflecting memory processes (frontal), calculations regarding how often to respond with a lie versus the truth so as to look impaired but escape detection (parietal), and the inhibition of typical responding coupled with performance monitoring (caudate).

Two types of lies were examined by Ganis et al. (Ganis et al., 2003). One involved answering questions about a prepared but made-up autobiographical account of a vacation or work experience. These lies were thus rehearsed and elaborate. The other lies were spontaneously created in the scanner and dealt with single facts about these same experiences (rather than the coherent set of rehearsed, integrated facts characteristic of the prepared lies). Brain responses to the two types of lies were compared to each other as well as to those associated with truthful answers to questions that were designed to stimulate the two types of lies. Rehearsed, elaborate lies were more likely to activate right frontal cortex than spontaneous, isolated lies, whereas the latter evoked more ACC and posterior visual cortex responses than the well-prepared lies. Compared with truth telling, both types of lies activated prefrontal cortex and the parahippocampal gyrus, right precuneus, and left cerebellum. Hence, different patterns of brain activation were associated with different types of lies.

These activations were interpreted as likely to reflect cognitive processes involving semantic and episodic knowledge, visual imagery, working memory, and response conflict.

In the only imaging research on deception to involve a constructive replication, Kozel and colleagues (Kozel, Padgett, & George, 2004; Kozel et al., 2004) contrasted truthful and false answers to questions concerning under which objects money was hidden. Somewhat different protocols were followed in each study, but prior to scanning, subjects searched a room to determine under which objects \$50 was concealed. They then viewed pictures and indicated whether the money was under the pictured object. As most of the pictured objects did not have money under them, this procedure was like a GKT. Because participants had been exposed to all the objects in advance, memory was not confounded with lying. Each study included pictures that required a truthful response as well as pictures that required a lie. Results indicated that for lying, there was more activation in the right ACC; right inferior, middle, and orbitofrontal cortex; and left middle temporal areas. Given that fear of detection is likely to be present when one lies, of special interest were possible amygdala effects. In one of the studies (Kozel et al., 2004), a specific effort was made to test for amygdala activation, but the result was negative. In the other report (Kozel, Padgett, & George, 2004), a special effort was made to determine whether data from each individual subject could be analyzed to detect lying on a person by person basis. Consistent activation patterns were not evident.

Two recent studies have extended fMRI technology to the identification of individual lies and liars. Langleben et al. (2005) extended the GKT paradigm of Langleben et al. (2002) and obtained a classification accuracy of 78% in their ability to discriminate lie from truth. Kozel et al. (2005) had subjects participate in a mock theft where either a ring or a watch was stolen. During the fMRI recording, participants denied stealing both items, thus lying about their involvement with one of them. Truthful and deceptive responses were differentiated from each other with accuracies ranging from 90–93%. Based on the results of these laboratory studies, patents have been filed and two startup companies have been formed (see www.cephoscorp.com and www.noliemri.com) with the intent of offering fMRI-based lie detection services.

This collection of imaging studies is illuminating in several important respects. Thus far, the research has not been programmatic and a diversity of deception protocols has been used, and render difficult any interpretation of the inconsistencies in brain activation evident across studies. These investigations did little to take advantage of the accumulated knowledge regarding the methodological pitfalls associated with the last 50 years of deception detection research. None of the investigations was designed well enough to tease apart the many processes involved in lying. Instead, patterns of brain activation were generally interpreted post hoc as consistent with the likely role of various cognitive processes (and the unlikely role

of other processes, like emotion, that was not considered seriously in the simple, constrained paradigms employed). Although the prefrontal cortex and ACC emerged as activated regions in most of the studies, on balance, this collection of investigations has thus far provided little insight into the neural circuitry underlying lying.

Although fMRI technology is now being advertised as ready for field applications, the use of these techniques in real-life situations requires a much more substantial research foundation, one that comes to grips with the many methodological problems that have been identified in attempts to validate the CQT and GKT. These studies used fairly simple paradigms, yet a diversity of brain activation patterns was observed. None of the investigations included anything approaching the circumstances one would encounter in a real-life application. Had they done so, there is a good chance the results would be even more complex because emotion would play a more prominent role in brain activation, which is likely true even for the GKT (Suzuki, Nakayama, & Furedy, 2004). It is not unreasonable to imagine brain activation associated with lying to vary according to the type of crime (or criminal). For instance, how reasonable would it be to expect a sex offender's brain activation during a lie to resemble that of a burglar's or of someone making a false accusation? This is an empirical question, and many such issues would have to be resolved to advance an fMRI-based lie detector.

fMRI holds obvious promise over autonomic measures, in part because it taps more directly brain processes involved in lying. In theory, a pattern of brain activation that is uniquely associated with lying could exist; no such pattern is ever likely to be found for autonomic measures. Because the research conducted to date is quite preliminary, it is unrealistic to expect great headway to this point in time. For now, perhaps basic science fMRI research focused on elucidating the neural and cognitive mechanisms associated with deceit has the greatest potential to contribute to the eventual development of an improved lie detector regardless of the technology ultimately used.

CONCLUSION

Professional polygraph testing has gone through many changes over the last 20 years, which have been advertised as improvements by the polygraph profession. These changes have included renaming the CQT, substituting the measurement of skin conductance for resistance, switching to computerized recording and scoring, better examiner training, more attention to standardization, and elimination of the most widespread abuses of polygraphy associated with employee screening by private corporations. Nevertheless, the forensic and screening tests used today are on no surer scientific footing than they were at their inception. This state of affairs persists because no matter what remedies are introduced to improve the output of polygraph tests, the psychological premises on which they are based remain weak. There is no way to know how

a given person, whether guilty or innocent, will respond to the different types of questions on these tests or why they respond as they do. Countermeasures remain a serious threat. Research on polygraph testing has failed to grapple successfully with the vexing methodological issues that have plagued it since evaluative research was begun in earnest 40 years ago. How a polygraph test is conducted and the outcome obtained remains highly dependent on who gives it. It remains an investigative tool that assists information gathering. Simply put, it is unscientific (Iacono, 2001), and there is no simple way to adjust current practices to change this fact.

The GKT, by contrast, has a reasonable scientific foundation. Innovations in GKT methodology, especially P300-based modifications, have at least the potential to lead to improved applications. However, these techniques beg for research designed to identify what constitutes good material for developing GKT items. In particular, what are criminals likely to pay attention to and remember that is related to the crime they commit? Until this question is seriously tackled, law enforcement is unlikely to embrace GKT techniques because of concern over false negatives. While laboratory research can help refine the GKT, ultimately field studies or investigations with excellent external validity need to be conducted to place the development of GKT items on a solid footing.

Most detection deception research has focused on applications in the absence of any sound theoretical foundation regarding the psychological and neurobiological underpinnings of lying. Recent psychophysiological and fMRI studies have begun to fill this void, but clearly much remains to be done. In the absence of any significant breakthroughs, it is unlikely that forensic and security screening applications of lie detection can be improved or that these techniques will give way to better methods with proven validity.

Neuroergonomics: Application of Neuroscience to Human Factors

ARTHUR F. KRAMER AND RAJA PARASURAMAN

The main goal of this chapter is to illustrate how human neuroscience techniques, as well as scientific theories that integrate behavioral and neuroscientific levels of description, can be used to address problems and concerns in the field of human factors and ergonomics. In order to accomplish this goal we begin with a brief discussion of the field of human factors and describe a limited but important subset of current questions and issues. Next we describe some of the criteria that must be met for human neuroscience measures to serve a useful function in assisting human factors researchers and practitioners to enhance the functionality, efficiency, and safety of current and future human-machine systems. We then provide a brief history of the role of neuroscience methods and theories as applied to the field of human factors. This is followed by a description of some recent developments in methods and a discussion of their potential application to questions of relevance to human factors. We then briefly describe a few illustrative examples of human factors issues that have been addressed with a series of converging operations, which include neuroscience measures and models. These topics include: the study of mental workload and multitask processing, the examination of individual differences in performance and information processing strategies, and the use of neuroscience techniques and theory to develop brain-computer interfaces. This discussion is followed by a brief conclusions and future directions section.

I. A BRIEF INTRODUCTION TO HUMAN FACTORS

Human factors has been defined as the study of human capabilities and limitations that affect the design of human-machine systems (Wickens, 2000). However, the field of human factors extends beyond the theoretical and empirical study of human behavior and cognition in

complex systems to the formulation of guidelines, principles, and models that can be used to design systems that accommodate human users and operators (Meister, 1989). In other words, human factors is neither a domain that resides solely in the laboratory nor one that focuses exclusively on the engineering of new (or the retrofitting of old) human-machine systems. That is, the field of human factors endeavors to provide a bridge between (1) the study of human behavior and cognition in laboratory and other relatively well-controlled, specified simulated environments, and (2) the design and evaluation of human-machine systems. These systems range from (purportedly) simple consumer products such as TVs, VCRs, PDAs, and cell phones to complex systems such as automobiles, aircraft, process control plants, medical equipment and systems, and the World Wide Web.

Over the years, the core topics of interest within the human factors community have changed with the development of technology. Specifically, the change has occurred in technologies that have reduced the need for humans to serve as manual laborers and controllers, and has shifted the role of humans to that of system managers and supervisors. Although such developments in technology have generally been advantageous for the humans who have participated in the operation of complex systems and products, there have also been a number of costs associated with the transition of humans from the role of manual controller to that of supervisor, who is occasionally a more active participant, especially when an unexpected problem occurs in semi-automated and automated systems.

For example, one recurrent problem has been referred to as automation-induced complacency. This occurs when human operators are expected to perform a series of manual tasks while also monitoring automated systems. Under such conditions monitoring performance often decreases precipitously rather quickly, often within 30 minutes. However, such performance decrements occur less often when the human operator's only task is to monitor the automated systems (Parasuraman, Molloy, & Singh, 1993). Thus, if human operators are expected to perform multiple

The preparation of this chapter was supported by grants from the Office of Naval Research, the Defense Advanced Research Projects Agency, and the National Institute on Aging.

tasks, some of which require active intervention and manual control, then the monitoring of automated systems may suffer. Of course, one solution to such a problem might be to automate the manual tasks and thereby unburden the operator from the dual tasks of manual control and supervisory management. However, such a change is often technically impractical and may also overwhelm the human operator with excessive monitoring demands. Even when highly automated systems are a practical alternative, operators have been shown to overestimate the reliability of the automated systems and succumb to automation-induced complacency even in the absence of manual control demands (Riley, 1994).

Another problem associated with highly automated systems has been referred to as out-of-the-loop unfamiliarity or, more generally, as a lack of situation awareness (Endsley 1994; Wickens 1992). This occurs when human operators must suddenly, and often without warning, get back into the control loop and perform manual control duties, detect and diagnose problems with automated systems, or both. In such cases the human operators are slower and more error-prone in carrying out these duties than if they had been an active participant in the operation of the system rather than a passive system monitor (Metzger & Parasuraman, 2001). Important questions regarding this problem include how to keep the operator continuously aware of the state of important systems and how best to monitor (human) operator readiness to take over important duties should automation fail (Scerbo, 1994).

There is still another set of important issues that arises in the context of complex semi-automated and automated systems. How should the overwhelming amounts of multimodal information be presented to human operators, and how should we assess whether mission-critical information has been adequately extracted and retained by the operators? These general issues include questions of a sensory and perceptual nature. Is critical information sufficiently distinct from background information? Is critical information displayed long enough for operators to note and extract task-critical components? There are also important cognitive concerns. Is the information presented to the operator in a format that is consistent with his or her mental representation of the system? Do the working memory requirements exceed operator capacity? Given the rapid development of virtual and augmented reality technology for operator training and system control, the sensory, perceptual, and cognitive issues associated with information presentation and multimodal integration have become more than an academic exercise. These issues are now on the verge of becoming a serious bottleneck for the effective use of this technology.

The issues raised here (and many others) have been and continue to be addressed through the application of a variety of traditional human factors methodologies. For

example, the questions of whether and when to automate system functions have been addressed with several different methods, including (1) the use of both engineering and psychologically-inspired models of human performance and cognition to predict the situations in which human performance is likely to degrade, (2) the continuous assessment of human performance via measurement of overt actions and responses, and (3) the use of self-report procedures and questionnaires such as the NASA-TLX workload scale and a variety of different scales that assess attentiveness or error-proneness. Indeed, the model-based and assessment-based procedures have also been combined into a hybrid approach to enhance the efficiency of adaptively automated systems (Byrne & Parasuraman, 1996). Similar techniques have been employed to evaluate new display concepts and to ensure the information is presented in formats consistent with the perceptual capabilities and cognitive representations of human operators (Stanny et al., 2004).

II. ROLE OF NEUROSCIENCE IN HUMAN FACTORS

Traditionally, human factors and ergonomics have not paid much attention to neuroscience or to the results of studies concerning brain mechanisms underlying human perceptual, cognitive, affective, and motor processes. This relative neglect of human brain function is understandable given that this discipline had its roots in a psychology of the 1940s, which was firmly in the behaviorist camp. The rise of cognitive psychology in the 1960s influenced the field, but while the cognitive approach is a major feature of modern human factors, neuroscience is ignored for the most part. Currently, however, our understanding of human cognitive functions has been considerably enriched by neuroscience research. It is, therefore, natural to seek applications of this knowledge to problems of cognition in relation to technology and work. This intersection of neuroscience and human factors (ergonomics) has been termed neuroergonomics (Parasuraman, 2003).

Given that there are a multitude of techniques available to address human factors problems and issues, one must ask what novel and important role neuroergonomics might play in human factors research and application. Certainly, to the extent that information gained through neuroscience measurement is redundant with that obtained from other measures and models employed by the human factors community, neuroergonomics measures will be unlikely to gain wide acceptance. This is likely to be the case for a number of the human neuroscience measures when compared with the subjective rating and performance-based measurement techniques traditionally employed by human factors practitioners and researchers, in light of the relatively high cost and substantial amount of expertise required for collecting, analyzing, and interpreting neuroergonomic measures when compared with the subjective rating and performance-based measurement

techniques traditionally employed by human factors practitioners and researchers.

Thus, for neuroergonomic measurement techniques to gain acceptance in the human factors research and applications community, these measures must:

1. prove to be more valid and/or reliable indices of relevant psychological (or, in some cases, physiological) constructs than traditional behavioral and subjective measures; or
2. enable the measurement of psychological constructs that are difficult or impossible to measure with traditional measures; or
3. enable the measurement of relevant psychological or physiological constructs in situations where other types of measures are unavailable or difficult to obtain.

Indeed, there is evidence (to be discussed shortly) that each of these three criteria has been or can be met within a human factors context with measures obtained via models inspired by neuroscience.

Another important consideration is the temporal sensitivity of neuroergonomic measures. In many human factors contexts – for example, the evaluation of new display concepts, the examination of the effects of different environmental conditions (e.g., differences in ambient temperature, humidity, or lighting) on human performance and information processing, the evaluation of training proficiency, and the assessment of fitness for duty – data can be collected and then analyzed and interpreted offline (i.e., at a later time that can, depending on circumstances, range from minutes to days). In such situations, enough time and effort can often be allocated to ensure adequate signal-to-noise ratios and to deal adequately with potential artifacts in the neuroscience data. On the other hand, there are also a number of human factors contexts that demand almost instantaneous data processing and interpretation. For example, given the increasing trend toward adaptive automation in systems, such as aircraft and process control, it has become important to develop measures that can both describe and predict changes in psychological constructs in or near real-time such as mental workload, alertness, and information processing strategies. Such information could then serve, in addition to inferences about human information processing capacities extracted from dynamic models of the interaction between humans, tasks, and environment, as input to algorithms that determine the dynamic task allocation policy between humans and automated systems. Of course, such situations pose technical problems for neuroergonomic measures that are not encountered in offline contexts such as rapid data collection, processing, artifact rejection, and interpretation. Additionally, the bandwidth of some systems (e.g., high-performance aircraft) may be high enough to preclude collecting sufficient amounts of (at least some types of) neuroer-

gonomic data to ensure adequate reliability or signal-to-noise ratios.

One additional issue that merits some discussion is the applicability of neuroergonomic measurement techniques to extralaboratory environments. Most human neuroscience research has focused on explicating the functional significance of different measures and components with relatively simple tasks in well-controlled laboratory environments. Even so, a great deal of effort has been expended on the elimination of potential artifacts (e.g., from ambient electrical fields, contamination from other physiological signals that may mask the signal of interest, individual differences in baselines, or a measure's morphology or topography). When such artifacts are difficult or impossible to eliminate during data recording, the focus has been on adjusting the physiological measures in order to minimize the impact of artifacts on data interpretation. Given the diversity and magnitude of the artifacts encountered in such well-controlled settings, is it a reasonable expectation to collect valid and reliable neuroergonomics data in less well-controlled environments such as high-fidelity (and sometimes motion-based) simulators or operational environments? Although collecting neuroscience data in such environments clearly provides a considerable technical challenge, there have been a number of promising developments in the design of miniaturized recording equipment that can withstand the rigors of operational environments (Berka et al., 2004; Hoover & Muth, 2004; Miller, 1995; Sterman & Mann, 1995). There have also been developments in pattern recognition and signal analysis techniques that enhance the detection, recognition, and processing of a number of physiological signals in noise (Bostanov, 2004; Wolpaw et al., 2002), as well as development of automated artifact rejection procedures (Berka et al., 2004; Du, Leong, & Gevins 1994). For example, Gevins et al. (1995; see also Berka et al., 2004) reported the development of a "smart helmet" system in flight helmets, which incorporates a combination of 32 EEG and EOG electrodes along with miniaturized preamplifiers. Barring technological roadblocks, such developments should continue to increase the potential for recording psychophysiological signals in a number of complex environments.

In summary, each of the issues discussed so far needs to be carefully considered when human neuroscience theory and measures are to be used in addressing human factors issues. Indeed, it is likely that some measures will be appropriate for only a subset of situations in which human factors issues are examined, for example, Positron Emission Tomography (PET) and functional Magnetic Resonance Imaging, (fMRI), whereas other measures may be more widely applicable. At the same time, neuroscience theory may be used to inform human factors issues, even though no neural measures are used (Parasuraman, 2003). In an effort to make some of these considerations more concrete, we now turn to a critical review of current applications of psychophysiological measurement issues in the human factors field.

III. NEUROERGONOMICS AND HUMAN FACTORS: A BRIEF HISTORY

Human factors developed as a unique discipline in response to human performance questions that arose around the time of World War II. For the first time, systems such as military aircraft, ships, and ground vehicles were becoming sufficiently complex that more numerous (and sometimes catastrophic) errors were observed, even though the systems were functioning as designed from a mechanical standpoint. That is, human operators either could not execute their assigned functions as expected or they did not have sufficient training to do so. As a consequence of these system problems and the well-founded suspicion that systems were not being designed to ensure adequate human performance, experimental psychologists were called upon to evaluate the human-machine interface and training regimes, to diagnose problems, predict problems not yet observed, and suggest system improvements and training modifications to ensure safe and efficient system operation (Fitts & Jones, 1947; Mackworth, 1948).

It is interesting to note that psychophysiological measures, principally measures of gaze direction, played an important role in the examination of human performance in complex systems during the early years of human factors. Fitts and colleagues (Fitts, Jones, & Milton, 1950; Jones, Milton, & Fitts, 1950) used measures of gaze direction, gaze duration, and the sequence of eye movements to examine the information extraction strategies employed by novice and experienced aircraft pilots during instrument flight. Data acquired from these studies were used to reconfigure instrument panels to optimize the speed and accuracy with which pilots could locate and extract flight-relevant information. Eye scan measures continue to be used today, in conjunction with measures of pilot and automobile driver performance, to assess strategies for extracting information as well as mental workload and skill acquisition in a variety of different transportation systems (Bellenkes et al., 1997; McCarley et al., 2004; Strayer, Drews, & Johnston, 2003).

The use of other neuroscience and psychophysiological measures to examine issues of interest to the human factors community soon followed the pioneering research of Fitts and co-workers. For example, Sem-Jacobsen and colleagues (Sem-Jacobsen 1959, 1961; Sem-Jacobsen & Sem-Jacobsen 1963) recorded electroencephalographic (EEG) activity from pilots as they flew missions of varying difficulty during simulated and actual flight in an effort to examine the utility of this psychophysiological measure for assessing the deleterious effects of high-G environments and mental and emotional workload. It was also speculated that psychophysiological measures, in particular measures of the EEG, would prove useful for the selection and evaluation of pilots for high-performance aircraft and for adaptively automated systems (see also Gomer, 1981). Although Sem-Jacobsen's visions for applications have not yet been realized, our review of the current literature will indi-

cate that at least some of these applications soon will be realized.

Finally, measures of heart rate and heart rate variability have long been used to provide a continuous record of the cardio-respiratory function and mental workload of operators in complex simulated and real-world systems. Heart rate measures have been recorded as aircraft pilots execute a number of maneuvers in simulated and actual aircraft such as landing (Ruffel-Smith, 1967), refueling during long-haul flights (Brown et al., 1969), performing steep descents (Roscoe, 1975), and flying combat missions (Roman, Older, & Jones, 1967). Such measures continue to be used today, often in the context of other psychophysiological measures and along with a more sophisticated appreciation for the underlying physiology.

In summary, although the application of neuroscience techniques to issues of human factors has a relatively recent history, these measures have provided useful insights into human performance and cognition in and outside of the laboratory. In the [following section](#) of the chapter we provide a brief discussion of neuroscience techniques, of a relatively recent vintage, that have not yet been widely applied to human factors questions and issues, but have the potential to provide important insights into human performance in and outside of the laboratory.

IV. A BRIEF DISCUSSION OF SOME RECENT DEVELOPMENTS IN HUMAN NEUROSCIENCE TECHNIQUES OF RELEVANCE FOR HUMAN FACTORS

Electroencephalographic activity and event-related brain potentials. As briefly discussed above (and in more detail in the Applications sections below), event-related brain potentials (ERP) and EEG activity have served as the main central nervous systems measures in Human Factors research to date. These techniques provide a measure of the electrical fields of simultaneously active neurons that are recorded at the scalp. EEG data is analyzed in the frequency domain and entails the derivation of differences in power across different individuals or experimental conditions in frequency bands that have been empirically related to perceptual, cognitive, and motor constructs. On the other hand, the ERP is a transient series of voltage oscillations in the brain, which can be recorded from the scalp in response to discrete stimuli and responses. Specific ERP components, usually defined in terms of polarity and minimum latency with respect to a discrete stimulus or response, have been found to reflect a number of distinct perceptual, cognitive, and motor processes and prove useful in decomposing the processing requirements of complex tasks (Fabiani, Gratton, & Coles, 2000).

An important advantage of EEG measures is that they can be recorded in the absence of discrete stimuli or responses that make them useful in situations in which an operator is monitoring slowly changing displays that require little intervention. Indeed, as a result of this characteristic EEG measures have been employed as an index of

vigilance in a variety of different simulated and real-world settings encountered in human factors research including flying (Gundel, Drescher, & Turowski, 2000), driving (Miller, 1995), and performance of rotating shift work in power plants (Gillberg et al., 2003). Additionally, EEG measures have served as the basis for online alertness predictors (Makeig, Elliot, & Postal, 1994). However, although EEG measures can be employed to provide a somewhat precise temporal index of changes in alertness and attention, ERPs can be used to decompose, in a temporally precise manner, the information processing activities that transpire between the time stimuli impinge on sensory receptors until an individual produces an action, whether it is an eye movement, vocalization, or skilled movement of the hands or feet. Another important advantage of ERPs is that for a number of ERP components the brain regions from which a component is generated are known. This knowledge enables the researcher to capitalize on the extensive neuropsychological literature that maps particular cognitive functions to neuroanatomical circuits.

However, as is the case with all of the measures discussed in this chapter, there are also constraints and potential difficulties in using EEG and ERP measures in different situations. Given problems with motion artifacts and electrical noise it is preferable to record EEG and ERPs from individuals who are not ambulatory. This clearly reduces the number of situations in which these can be utilized. In any event, there are still ample professions and settings or from which ERP and EEG recording is possible (e.g., pilots, drivers, office workers, process control operators, etc). However, as discussed above the increasingly rapid development of noise detection and signal processing algorithms will continue to increase the feasibility of recording EEG and ERP measures in a wider range of simulated and real-world environments (e.g., Berka et al., 2004). ERPs, unlike EEG, require a discrete stimulus or response. Therefore, some situations are not easily amenable to ERP recording, for instance, situations in which it is difficult to record ERPs from discrete stimuli or responses in a closed system (e.g., a system in which it is difficult to acquire precise timing of new stimuli and responses) or when it is unfeasible to introduce signals from which ERPs can be recorded (e.g., in a secondary task). Finally, ERP and EEG recording, analysis and interpretation require relatively substantial training both in terms of the recording procedures as well as in the relevant psychological and physiological literatures.

Positron emission tomography and function magnetic resonance imaging. The field of cognitive neuroscience has benefited tremendously from the utilization of relatively noninvasive *in vivo* neuroimaging techniques. However, given the constraints of these techniques and the fact that thus far the focus has been on elucidating patterns of brain activation in relatively simple tasks in an effort to isolate specific cognitive processes, the field of human factors has yet to reap substantial benefits.

Both PET and fMRI utilize biophysiological correlates of neural activity to infer the involvement of cortical regions in a given task. One of the clear advantages of PET is the ability to translate detected signals into biologically meaningful units (e.g., glucose metabolism or regional cerebral blood flow; e.g., Brickman et al., 2003). In contrast, the signal changes detected by fMRI methods vary along arbitrary units that do not directly translate into an absolute metric of biological function. Another advantage of PET is the ability for researchers to design isotope-tagged molecules that bind to specific biologically relevant elements, such as dopamine receptors. This allows one to map out brain function and other important individual differences in brain chemistry that can potentially be linked to gene expression (see the Applications section for further discussion of molecular genetic studies of individual differences). Perhaps the most obvious disadvantage of PET is that the participants must be injected with or inhale a radioactive substance, whereas fMRI uses the native contrast of naturally occurring biological processes to infer function. fMRI also has the advantage of improved temporal resolution, which allows the researchers to resolve inferred neural activity from rapidly presented stimuli (e.g., Burock et al., 1998) or even self-paced events (e.g., Maccotta, Zacks & Buckner, 2001) on a trial-by-trial basis. This allows the researcher to separate and compare, for example, correct responses from errors (Hester, Fassbender, & Garavan, 2004), remembered versus forgotten events or objects (Morcom et al., 2003), or intermixed conditions of varying difficulty (Olson et al., 2004). In contrast, given the slow evolution of the signal changes, PET studies must utilize blocked designs, where the participant responds to repeated trials of a given type. This precludes the use of more standard cognitive experimental designs in which trials of each type are often intermixed and balanced for order of presentation. Additionally, it is not possible to resolve neural activity to individual trials (e.g., errors), and the neural activity from all trials within the block becomes averaged together. Furthermore, compared to electrophysiological and optical methods (see Optical Imaging section below), both fMRI and PET cannot easily resolve activity within a trial because of the intrinsically slow course of hemodynamic and metabolic phenomena that follow neuronal activity. Nonetheless, PET and fMRI studies have contributed substantially to our understanding of cortical and cognitive function.

As mentioned above, the great majority of studies that have employed PET and fMRI have done so in relatively simple tasks in an effort to isolate specific perceptual, cognitive, motor, and affective processes. However, even the investigation of patterns of brain activation in relatively simple tasks has provided insights that are potentially relevant to performance outside of the laboratory. For example, the use of fMRI and PET to investigate executive control processes, which include planning, scheduling, working memory, resolving conflicts between stimuli and responses, and multi-tasking, has provided insights

which enable both the testing of theories of relevance to the design of displays and information presentation strategies (e.g., Jiang, Saxe, & Kanwisher, 2004; Smith & Jonides, 1999) as well as the understanding of the nature of individual differences in performance (Scarmeas et al., 2003). Investigators have also begun to use PET and fMRI measures to address other issues of relevance to human factors. For example, Chee and Choo (2004) examined changes in performance and fMRI activation in both short-term and working memory tasks before and after 24 hours of sleep deprivation. They found a pattern of both deactivations and, presumably, compensatory activations following sleep loss that were predictive of changes in memory performance. Whether such changes can be used to predict performance deficits in specific individuals, which enable the implementation of effective countermeasures, is an interesting and important question for future research. Finally, a number of investigators have begun to tackle the examination of changes in brain activation in components of complex real-world tasks such as the inspection of static and dynamic real-world scenes (Bartels & Zeki, 2003; Huettel, Guzeldere, & McCarthy, 2001) and automobile driving (Calhoun et al., 2002). While the constraints of PET and fMRI recording will likely preclude the recording of data in extra-laboratory environments, the continued development of Virtual Reality systems and technology will enable investigators to bring high fidelity simulations of real-world tasks into the laboratory by capitalizing on the benefits of these neuroimaging techniques for exploring the interface between brain and mind.

Optical imaging of brain activity. Noninvasive optical imaging represents a relatively recent addition to the neuroimaging tools available for human research. It has been known for over 50 years that the activity of neurons are associated with changes in optical as well as chemical and electrical properties (Hill & Keynes, 1949). Since this time optical properties of brain cells have been examined in cell cultures and within intact brains (Villringer & Chance, 1997), either from recordings on the exposed cortex or with indwelling optical sensors.

However, more recently a class of optical techniques has been developed that enable the noninvasive measurement of functional activity of the brain. These techniques capitalize on the absorption and scattering properties of near-infrared light (between 700 and 1000 nm) in biological tissue. Light within this range can penetrate and diffuse several cm into tissue because water and other substances present in tissue do not absorb much of the light within this part of the spectrum. Indeed an optical measurement approach referred to as photon migration has enabled the reliable and non-invasive recording of functional brain activity in humans to depths of approximately 2.5 cm (Gratton et al., 2003). This optical measurement procedure is based on the assessment of the intensity or delay of photons as they travel from a source to a detector along a mathematically well-described path in the brain.

The photon migration technique, which is based on the measurement of the delay in photons between a source and detector (generally referred to as the time-resolved optical method), has a number of distinct advantages including the ability to separately quantify the scattering and absorption coefficients in the tissue through which the photons travel and provides good spatial resolution similar to that obtained with fMRI.

The use of the photon migration technique has enabled the measurement of a number of different signals: (1) relatively slow signals which enable the quantification of changes in oxy- and deoxy-hemoglobin in selective regions of the cortex (Villinger & Chance, 1997), and (2) faster stimulus or response locked signals, referred to as the event-related optical signal (EROS), that reflect neuronal activity (Gratton & Fabiani, 2001). As in fMRI, the slower signals provide an index of changes in hemodynamic activity that may differ over experimental conditions and individuals. However, unlike fMRI, the slower signals have the advantage of providing separate estimates of oxy- and deoxy-hemoglobin. The faster signal is quite similar, in many ways, to the ERP with the additional advantage of superior spatial resolution. Thus, the measurement of optical activity can enable the concurrent collection of hemodynamic and neuronal activity, which capitalizes on the relative strengths of both of these neuroimaging techniques.

However, as with any measurement procedure there are also several disadvantages, some of which can likely be overcome with the development of new signal analysis techniques, software, and hardware that are associated with optical imaging. For example, unlike fMRI, spatial resolution is limited to approximately 2.5 cm from the scalp. It is also the case that, at present, the fast neuronally based optical signal has a relatively low signal-to-noise ratio. This requires the collection of a substantial amount of data, more so than for ERPs, to reliably resolve optical components. However, there have been a number of recent proposals, which include new data filters and hardware, that have the potential to substantially improve signal to noise ratio (Mackin, Gratton, & Fabiani, 2003).

Early studies of both the slow hemodynamic and fast neuronal optical signals focused on validating these measures against ERP, PET, and fMRI indices of different sensory and motor processes. That is, these early studies demonstrated the selective recording of optical parameters in motor (Gratton et al., 1995), somatosensory (Steinbrink et al., 2000), visual (Gratton, Goddman-Wood, & Fabiani, 2001), and auditory (Rinne et al., 1999) cortices with appropriate task stimulation.

More recent studies have gone beyond establishing the reliability and validity of optical measures and have begun to utilize them to address important theoretical and practical issues for which they are well suited. For example, DeSoto et al. (2001) examined whether conflict between two different dimensions of a stimulus can result in the simultaneous activation of multiple motor responses.

Previous studies using the lateralized readiness potential (LRP) of the ERP, a component that provides an index of motor activation, have already been used to track motor activation during the performance of a variety of different tasks (e.g., Osman & Moore, 1993). However, because the LRP is a measure of the differential activation between the left and right motor cortices, it cannot provide information about their simultaneous activation. Given the appropriate placement of sensors, activation of multiple responses in different hemispheres can be measured with optical imaging. Using EROS, DeSoto and colleagues measured activation in a Stroop experiment in which subjects either were to pay attention to the meaning or the spatial position of words such as above and below. When the responses to these two dimensions (i.e., one task relevant and one task irrelevant dimension on each trial) conflicted evidence of activation of motor responses was obtained for both the dimensions. Such data suggests, in agreement with parallel but inconsistent with serial models of information processing, that priming of multiple responses can indeed occur concurrently. The ability to simultaneously measure the activation of multiple responses could be, in principle, invaluable in future brain-computer interfaces (see discussion below).

In summary, while noninvasive optical imaging of human brain activity is still in its infancy, the research conducted to date suggests great promise for this technique given its ability to tap both hemodynamic and neuronal activity, thereby capitalizing on both good spatial and temporal resolution without the physical constraints of other neuroimaging measures (e.g., PET and fMRI). Clearly additional research is necessary to successfully address the signal-to-noise issue, but given the rapid development of new signal processing techniques and multiple channel optical recording devices this would appear to be a solvable problem in the near future.

Assessing brain structure. The topic of brain structure or anatomy might seem out of place in a chapter on the application of neuroscience techniques to the field of Human Factors. However, it has recently become acknowledged, in the scientific literature, that human brain structure can, and indeed does, change as a function of a variety of experiences. It has also become increasingly clear that individual differences in anatomy, often measured as differences in cortical volume, density, or both can be related to performance on a variety of perceptual and cognitive tasks. Therefore, it is conceivable that in the near future that the nonintrusive measurement of brain structure might be a useful converging measure of both individual differences in components of neural circuits that support performance and a reflection in the efficacy of training induced cortical plasticity.

Both hand tracing and automated segmentation techniques have been used for a number of years to characterize change in brain volume in regionally specific fashion, during development and aging, and to relate changes

in volume to selective aspects of cognition. For example, hand-traced estimates of prefrontal gray matter volume in cross-sectional samples significantly predict age-correlated reductions in performance on frontally mediated executive tasks such as the Wisconsin Card Sorting Test (Gunning-Dixon & Raz, 2003) and verbal working memory (Head et al., 2002). Another set of studies linked the hippocampal volume of older adults to their long-term memory performance (across several weeks) and even accounted for the effects of age on memory (Walhovd, et al., 2004).

However, perhaps more exciting, are a couple of recent studies that have used automated segmentation techniques to track within individual changes in human brain structure over time in response to environmental interventions. Draganski et al. (2004) examined change in the cortical volume of 24 young adults, half of whom were taught to juggle over a three-month period. Compared to the non-training controls, those individuals who were taught to juggle displayed bilateral increases in the volume of the medial-temporal region of cortex, which is a brain region responsible, in part, for the processing of motion. Interestingly, when the study participants were scanned again three months after training (in which no further juggling practice was received), there were slight reductions in the volume of medial-temporal cortex. Colcombe et al. (submitted) used automated segmentation techniques to assess longitudinal changes in the brain structure of older adults who were randomly assigned to participate in either a six-month cardiovascular fitness-training program or a nonexercise control group. They found that older adults who participated in the exercise group showed a significant increase in gray matter volume in regions of the frontal and superior temporal lobe than the control group. And exercising older adults showed a significant increase in the volume of the anterior white matter tracts that allow the frontal lobes of the brain to communicate. Thus, these two studies, when viewed together, suggest that an analysis of high resolution MRI data has the potential to reflect changes in anatomy that may be related to human performance in and outside the laboratory. However, it should be noted that the limitations of the automated segmentation techniques do not allow one to infer precisely what mechanism(s) results in these changes (e.g., increase in cell body size, increased dendritic connections, increased capillary bed volume, and increased glial size or number, etc.). Clearly, more research is needed, including animal studies and human magnetic imaging spectroscopy, to further delineate the nature of the volume changes.

Transcranial doppler sonography. Ultrasound techniques have long been used for various medical applications, including fetal heart rate monitoring and assessment of blood flow in the carotid arteries in stroke patients. More recently, Transcranial Doppler Sonography (TCD) has been used in neuropsychological research to measure dynamic changes in cerebral blood perfusion that occur during the

performance of a wide variety of mental tasks (Duschek & Schandry, 2003; Stroobant & Vingerhoets, 2001). Accordingly, there has also been recent interest in using TCD in the examination of issues relevant to human factors and ergonomics (Tripp & Warm, *in press*; Wilson, Finomore, & Estepp, 2003; Zinni & Parasuraman, 2004).

TCD offers the advantages over PET and fMRI of low cost, does not require participants to be immobile, and good temporal resolution (Aaslid, 1986). The TCD technique capitalizes on the well-known Doppler effect, which refers to the modulation of the frequency of optical or acoustic waves between a source and a receiver that are moving relative to one another. TCD uses a transducer mounted on the participant's head that directs ultrasound waves toward an artery within the brain. A Doppler shift in frequency occurs when the ultrasound waves are reflected back by red blood cells moving through the cerebral arteries, and the sign of the shift depends on whether the blood is flowing away from or towards the transducer. Blood flow velocity can then be measured in the middle (MCA), anterior (ACA), or the posterior cerebral arteries (PCA). The MCA carries over 75% of the blood flow within each cerebral hemisphere and, hence, is usually the artery that is imaged in the majority of TCD studies.

Assessments of the reliability of TCD have focused both on baseline and activation-related values of blood flow. Several investigations have reported moderate to high reliability ($>.7$) for baseline blood flow values (Baumgartner et al., 1994). With respect to task-induced blood flow changes Knecht et al. (1998) reported a test-retest reliability coefficient of .9 for blood flow in a linguistic (word-fluency) task. Stroobant and Vingerhoets (2001) also reported moderate to high reliability values for several verbal and visuospatial tasks. The validity of TCD blood flow changes has been compared to those obtained with PET and fMRI. Most studies report high correlations between techniques with respect to overall blood flow changes in each cerebral hemisphere (Duschek & Schandry, 2003). Knake et al. (2003) also reported a correlation between TCD-based assessment of hemispheric laterality for language and the Wada test, which is generally considered the gold standard.

Gaze contingent displays

Although the measurement of eye movements, and more specifically saccades have long been used as a technique to elucidate information extraction strategies from visual displays, for example, the pioneering research of Fitts and colleagues, which used eye movements to understand instrument scanning by pilots (Fitts, Jones, & Milton 1950; Jones, Milton, & Fitts 1950.) new saccade measurement procedures have further enhanced the utility of eye movements in both basic and applied research.

The moving window technique, first developed to examine peripheral information utilization in reading (McConkie & Rayner, 1975), has proven useful in the study of visual search and, in particular, in the study of the

size of the visual field from which individuals can effectively extract information within a fixation (referred to as the perceptual span). This technique entails providing a window, centered around fixation, in which information is presented normally (i.e., how it would be perceived in the absence of a viewing window). Information outside of the window is either removed or degraded. The critical aspect of the technique is the manipulation of the size of the eye-movement contingent window and the comparison of search performance with different window sizes to search to performance with normal, unobstructed viewing (see Reingold et al., 2003, for a recent detailed review of this technique). Visual span is defined in terms of the window size that yields search performance equivalent to that obtained via normal viewing.

Bertera and Rayner (2000) used the moving window technique to examine average visual span size in the search of cluttered displays. They found that window sizes of five degrees and larger yielded search performance equivalent to that obtained through normal viewing. Based on the number, size, and separation of letter stimuli used in their study they estimated that individuals were able to extract between three and six items within each fixation. Loschky and McConkie (2002) found that by manipulating the size of the high resolution window centered on fixation they could actually speed search among the items in the window, but at a cost for inspecting objects outside of the high resolution window. Pomplun, Reingold, and Shen (2001) examined the impact of processing load, both within the search task and from other tasks, on visual span using the moving window technique. They discovered that both the difficulty of the search task as well as the introduction of and increase in difficulty of an auditory secondary task decreased the effective visual span. Such a result is interesting in that it suggests that nonvisual processing can detrimentally impact our ability to efficiently extract information from a visual display.
