A variation of the moving window technique that is referred to as the gaze contingent technique has been used to examine the memory representations that underlie visual search. In the version of the contingent search paradigm developed by McCarley and colleagues (2003; see also Boot et al., 2004), a subject is initially presented with a fixation cross and one search item on a computer display. At this point, there is only one possible search item to examine. During the initial saccade to the first search item, a second search item is presented. By presenting new search items during saccades, saccadic suppression prevents the new items from acting as abrupt onsets and capturing attention. If the fixated item is the target the individual is to respond with the appropriate keypress and the trial is terminated. If the fixated item is a distractor search continues until the target is found or all of the items have been presented.

After the first saccade, the subject still has only one potential saccade target. As the subject makes the next saccade, a new item is added to the display and the first item

remains on the screen. From this point on, three items will always be present in the display: the currently fixated item and two potential saccade targets. One of the potential saccade targets is always a *new* item that has not yet been identified, and the other is an *old* item that has already been examined (the *decoy*). Decoys always reappear in the same location and same orientation as originally presented, and except for the third event, where there is only one previously examined item, decoys are randomly chosen from the list of examined items.

Critical to this paradigm is that the subject is forced to choose between making a saccade to a new item or a decoy. If visual search is guided by a memory that is perfect, then a new item will always be chosen. If there is no memory, or memory has failed, the subject will chose to make a saccade to a decoy half the time. McCarley and colleagues (2003) examined how long memory lasts during visual search by looking at the probability that a decoy was reexamined based on the number of intervening fixations since the decoy was first examined (*lag*). Memory for the last two previously fixated items is quite good with most of the saccades going to the new item. However, with additional lags, performance eventually reaches chance levels (generally by the 4th or 5th lag), providing an estimate of the size of the memory buffer that supports memory for previously visited locations in search. Followup studies with this gaze contingent paradigm have revealed that (1) the memory representations that underlie visual search are largely implicit (Boot et al., 2004), (2) background layout and landmarks boost memory for previously inspected locations (Peterson et al., 2004), and (3) substantial individual differences exist in the size of the memory buffer that supports efficient visual search (Becic, Kramer, & Boot, *in press*). It is important to note, however, that thus far this technique has been used with relatively simple visual search displays in well-controlled laboratory settings. Clearly, an important question for the future is whether this gaze contingent technique can be “scaled-up” and perhaps also combined with other eye movement monitoring and neuroimaging techniques to enable the assessment of the role of memory in search and information extraction in more realistic and varied environments. For example, Belopolsky and Kramer (in preparation) have recently combined eye movement and ERP recording techniques to examine the nature of error processing when the eyes are misdirected away from an intended goal.

V. APPLICATION AREAS

A. Workload/multi-task processing

Assessment of mental workload continues to be an important topic in human factors research and practice. This is primarily because the design of an efficient human-machine system does not simply involve assessing operator performance, but also evaluating how well operators can meet the workload demands imposed on them

by the system. A major question that must be addressed in any human-machine system is whether the human operators are overloaded and can meet additional unexpected demands if they arise during system operations. Behavioral measures such as accuracy and speed of response to probe events have been widely used to assess mental workload, but measures of brain function offer some unique advantages that can be exploited in particular applications (Kramer & Weber 2000; Parasuraman, 2003). Such measures can also be linked to emerging cognitive neuroscience knowledge, thereby, allowing for the development of neuroergonomic theories of mental workload.

There are many approaches to the study of mental workload and a variety of definitions (Wickens & Hollands, 2000). From a neuroergonomic perspective, mental workload can be considered to be a composite set of brain/mind states that modulate human performance of perceptual, cognitive, and motor tasks (Parasuraman & Caggiano, 2002). Workload can be driven exogenously (“bottom-up”) by environmental sources (task load) or endogenously (or “top-down”) by the voluntary application of attentional resources (Wickens, 1984). Both sources of workload are presumably reflected in changes in regional patterns of brain activation. The challenge for neuroergonomic research is to be able to characterize these patterns in a theoretically meaningful way.

Cerebral blood flow measures of mental workload and dual-task interference. Although mental workload has been viewed in a number of different ways, the notion that it can be linked to the brain has a long history. The British physiologist Charles Sherrington first demonstrated the close relationship between neuronal activity, the energy demands of the associated cellular processes, and regional cerebral blood flow (Roy & Sherrington, 1890). His pioneering work suggested that, in principle, increased neuronal activity associated with mental processing could be assessed by measuring the blood flow responses of the brain. The development of noninvasive techniques for measuring cerebral blood flow in humans, such as TCD, PET, and fMRI, has paved the way for testing his suggestion.

Several TCD studies have shown that cerebral blood flow increases in response to the requirement to engage in mental activities. In general, an increase in cerebral blood flow from a baseline condition to one requiring cognitive processing can be demonstrated reliably (Stroobant & Vingerhoets, 2001). To be useful as a measure of mental workload, however, TCD measures of blood flow need to be linked to manipulations of task difficulty. Despite the large literature on TCD and neuropsychological task performance, only a few such studies have been carried out.

Serrati et al. (2000) examined changes in blood flow in a mental rotation task. They found that the increase in blood flow from baseline to task performance was greater for more difficult mental rotations. Wilson, Finomore, and Estepp (2003) also found that blood flow associated with

performance of the Multi-Attribute Task Battery, a simple flight simulation task, varied with task difficulty. However, Zinni and Parasuraman (2004) could not find reliable changes in cerebral blood flow with within-task changes in difficulty in a working memory task and in a tracking task. More such studies involving parametric variations in difficulty must be conducted before the use of TCD can be validated to assess mental workload. However, the major drawback of TCD is that it cannot provide any information on localization of blood flow changes associated with cognitive processing within a hemisphere. Accordingly, understanding the brain systems of mental workload requires other neuroimaging methods with better spatial localization capability, such as PET and fMRI.

Studies of mental workload often compare performance on two concurrent tasks (dual-task) to single-task performance. A major issue is whether dual-task decrements result from activation of a distinct, resource-consumptive, multitask coordination module or whether they result from interference in functionally independent modules or resource pools (Wickens, 2002). Can neuroimaging studies localize such a general-purpose module or provide evidence for multiple resource pools? D'Esposito et al. (1995) reported that the dorsolateral prefrontal cortex was activated preferentially during the performance of concurrent tasks compared to single-task performance. However, subsequent studies have not provided consistent support for the overadditivity of activation in this brain region, and have had some failures in replicating the original finding (Adcock et al., 2000; Bunge et al., 2000). One problem may be that these studies used dual tasks with interspersed blank-time intervals (to enable fMRI analysis), so that task switching rather than dual tasking might have occurred. Dreher and Grafman (2003) examined patterns of activation in prefrontal cortex in a comparison of dual-task (concurrently performing two tasks) and task-switching (alternatively performing each of the two tasks alone) conditions. They reported that dual-task processing selectively activated the anterior cingulate region of the medial frontal cortex, whereas task switching activated the dorsolateral prefrontal cortex.

Another group of studies have used the psychological refractory period (PRP) paradigm, which allows for the partitioning of dual-task interference to discrete processing stages (Pashler, 1994). Herath et al. (2001) found that the superior frontal gyrus and the intraparietal sulcus were activated to a greater extent in the PRP task compared to single task conditions. Moreover, they found that activation in the right inferior frontal gyrus was positively associated with individual differences in the degree of dual-task interference. The results of this and other PRP studies (e.g., Schubert & Szameitat, 2003) indicate that, consistent with behavioral studies, the source of dual-task interference in the PRP paradigm lies primarily in the response selection and response execution stages. However, Jiang (2004) compared the standard PRP task to conditions in which the two overlapping tasks were either both presented in the

periphery or one was presented centrally and the other peripherally. The first condition imposed a greater competitive demand on spatial attention than the second condition or the standard PRP task (for which both tasks were presented centrally). The right inferior frontal gyrus was differentially activated when the overlapping tasks were presented peripherally, which indicates that in addition to response selection, competition for spatial attention also limits dual-task performance.

These studies indicate that dual-task performance is associated with the activation of prefrontal cortex, which is consistent with the general view that this brain region is critically involved in executive control processes. Such control processes are likely to be involved in dual-task performance and in other conditions, for instance, resolving conflict between competing responses. There is also some evidence that regions of the inferior and middle frontal gyrus may be specifically implicated in dual-task performance, at least in the PRP paradigm, but additional work with other dual-task pairings, including continuous (as opposed to discrete) and more complex tasks, needs to be conducted to assess the generality of this finding.

Event-related brain potentials. The neuroimaging studies discussed previously have been informative with regard to the identification of a global hemispheric measure of mental workload, as well as the possible localization of brain systems underlying dual-task performance. However, in general, such studies have not been informative with respect to the temporal locus of dual-task interference. This is a natural consequence of the limited temporal resolution of fMRI. (but see Jiang, 2004). Event-related potentials offer good temporal resolution in assessing neural activity. Accordingly, it is instructive to examine ERP studies of dual-task performance.

Most such ERP studies have examined the P3 or P300 component, which was first described by Sutton et al. (1965). P300 is characterized by a slow positive wave with a mean latency following stimulus onset of about 300 ms, depending on stimulus complexity, probability, and other factors (Polich, 1987). The P300 is thought to reflect post-perceptual or postcategorical processes prior to response selection and execution stages. For example, increasing the difficulty of identifying the target stimulus increases the latency of P300 (Kutas, McCarthy, & Donchin, 1977), whereas increasing the difficulty of response selection does not (Magliero et al., 1984). This has led to the view that the latency of the P300 provides a relatively pure measure of perceptual processing and categorization time that is independent of response selection and execution stages (Kutas, McCarthy, & Donchin, 1977).

It has also been proposed that the amplitude of P300 is proportional to the amount of central processing resources allocated to the P300 eliciting stimulus (Johnson, 1986). Thus, any diversion of processing resources away from target discrimination in a dual-task situation will lead to a reduction in P300 amplitude. Isreal et al. (1980) showed

that the amplitude of P300 decreased when a primary task, tone counting, was combined with a secondary task of visual tracking. However, increases in the difficulty of the tracking task (by increasing the bandwidth of the forcing function) did not lead to a further reduction in P300 amplitude. This pattern of findings was taken to support the view that the P300 reflects processing resources associated with perceptual processing and stimulus categorization, but not response-related processes, which was manipulated in the tracking task.

These and other related studies (Kramer, Wickens, & Donchin, 1983, 1985) have clearly established that P300 amplitude provides a reliable index of resource allocation related to perceptual and cognitive processing in dual-task situations. Similar results have been obtained when P300 has been used in conjunction with performance in flight simulators (Kramer, Sirevaag, & Braune, 1987; Sirevaag et al., 1993). P300, therefore, provides a reliable and valid index of mental workload, to the extent that perceptual and cognitive aspects of information processing are major contributors to workload in a given performance setting. Response-related contributions to workload, however, are not reflected in P300 amplitude.

A more recent human factors study exploited these characteristics of P300 to assess cognitive workload during simulated driving (Baldwin, Freeman, & Coyne, 2004). P300 in a visual, color-discrimination task was recorded while participants engaged in driving conditions of normal and reduced visibility (fog). P300 amplitude, but not discrimination accuracy or reaction time (RT), was reduced when participants drove in fog compared to driving with normal visibility. However, P300 did not vary significantly with changes in traffic density, while RT measures were sensitive to this manipulation of driving difficulty. Baldwin, Freeman, and Coyne (2004) concluded that neither neural nor behavioral measures alone are sufficient for assessing cognitive workload during different driving scenarios, but that multiple measures may be needed.

A unique feature of the P300 is that it is simultaneously sensitive to the allocation of attentional resources (P300 amplitude) and to the timing of stimulus identification and categorization processes (P300 latency). These features allow not only for assessing the workload associated with dual- or multitask performance, but also for identifying the sources that contribute to workload and dual-task interference. These features were further elegantly exploited in a dual-task study by Luck (1998) using the PRP paradigm. The typical finding in this paradigm is that RT to the second target is substantially delayed when the interval between the two targets is short. Luck (1998) identified the source of this interference by recording the P300 to the second target stimulus, which was either the letter X or the letter O, with one of the letters being presented only 25% of the time (the odd ball). Whereas RT was significantly increased when the interval between the two stimuli was short, P300 latency was only slightly increased. This suggested that the primary source of dual-task interference was the

response selection stage, which affected RT but not P300 latency.

Despite the large body of evidence confirming the sensitivity of P300 to perceptual and cognitive workload, the issue of whether P300 can be used to track dynamic variation in workload, in real-time or near real-time, has not been fully resolved. On the one hand, P300 is a relatively large ERP component, so that its measurement on single (or a few) trials is easier than for other ERP components. However, the question remains whether P300 amplitude computed on the basis of just a few trials can reliably discriminate between different levels of cognitive workload. Humphrey and Kramer (1994) provided important information relevant to this issue. They had participants perform two complex, continuous tasks, a gauge-monitoring and mental arithmetic, and recorded ERPs to discrete events from each task. The difficulty of each was manipulated to create low and high workload conditions. The amplitude of the ERP, which was averaged over many samples, was sensitive to increased processing demands in each task. Humphrey and Kramer then used a stepwise discriminant analysis to ascertain how the number of ERP samples underlying P300 affected accuracy of classification of the low and high workload conditions. They found that classification accuracy increased monotonically with the number of ERP samples, but that high accuracy (~90%) could be achieved with relatively few samples (5–10). Such a small number of samples can be collected relatively quickly, say in about 25–50 seconds, assuming a 20% oddball target frequency and a one-second interstimulus interval. These results are encouraging with respect to the use of single-trial P300 for dynamic assessment of workload.

The early N1 component of the ERP, which has a peak latency of about 100 ms in audition and about 160 ms in vision (Naataanen, 1992), has also been shown to be resource sensitive. Parasuraman (1985) had participants perform a visual and an auditory discrimination concurrently, and systematically varied the priority to be placed on one task relative to the other, from 0% to 100%. The amplitudes of the visual N160 and the auditory N100 components varied directly and in a graded manner with task priority. The auditory N100 component is known to consist of both an exogenous N100 component and an endogenous Nd component that is modulated by attention (Naataanen, 1992). It is of interest to note that the Nd component is also resource sensitive. Singhal, Doerfling, and Fowler (2002) had participants perform a dichotic listening task while engaged in a simulated flight task of varying levels of difficulty. The amplitudes of both Nd and P300 were reduced at the highest level of difficulty.

In conclusion, the sensitivity of ERPs to temporal aspects of neural activation has been put to good use in dissecting sources of dual-task interference. Furthermore, as illustrated by the research of Humphrey and Kramer (1994), there has also been some success in using ERP components as near real-time measures of mental

workload. Furthermore, flight and driving simulation studies have shown the added value that ERPs can provide in assessment of workload in complex tasks. However, additional work is needed with single-trial ERPs to further validate the use of ERPs for real-time workload assessments.

B. Brain-computer interfaces

If EEG and ERP signals can be obtained reliably in real-time in order to assess and, perhaps, modulate operator mental workload, then it is a logical to ask about other applications of these signals. Another neuroergonomic application involves using such brain signals to directly control devices, an area of research and development that has come to be known as brain-computer interfaces (BCI). The basic idea behind BCIs is to use brain signals to control external devices without the need for motor output, which would be advantageous for individuals who either have only limited motor control or, as in the case of "locked-in" patients with amyotrophic lateral sclerosis (ALS), virtually no motor control.

The idea of BCIs follows naturally from the work on "biocybernetics" in the 1980s pioneered by Donchin and others (Donchin, 1980; Gomer, 1981). The goal of biocybernetics was to use EEG and ERPs as an additional communication channel for use in human-machine interaction. Similarly, BCI researchers hope to provide those with limited communication abilities additional means of communicating with and interacting with the world. Farwell and Donchin (1988) characterized the BCI as a "mental prosthesis" which could assist individuals with little or no motor function. The BCI allows a user to interact with the environment without engaging in any muscular activity, for example, without the need for hand, eye, foot, or mouth movement. Instead, the user is trained to engage in a specific type of mental activity that is associated with a unique brain electrical "signature." The resulting brain potentials are recorded, processed and classified in such a way as to provide a control signal in real-time for an external device. A reliable BCI requires considerable technical development and "tailoring" a system to a specific individual. Effective use of BCIs may also require extensive training on the part of the user. BCI applications have used a variety of different measures of brain electrical activity. Invasive methods include recording of field potentials and multi-unit neuronal activity from implanted electrodes. Success has been reported in controlling robotic arms with both intracortical electrode grids (Nicolelis, 2003) and subdural electrode strips (Levine et al., 2000). Such invasive recording techniques have superior signal to noise ratio but are obviously limited to use in animals or patients with no motor functions in whom electrode implantation is clinically justified.

Noninvasive BCIs have used a variety of brain signals derived from scalp EEG recordings. These include quantified EEG from different frequency bands, such as beta and mu waves (Pfurtscheller & Neuper, 2001). BCIs

based on ERPs have included P300 (Donchin, Spencer, & Wijesinghe, 2000), steady state evoked potentials (McFarland, Sarnacki, & Wolpaw, 2003), and contingent negative variation and other slow potentials (Birbaumer et al., 1999). The BCIs based on these signals have been used to operate voice synthesizers, control cursor movements on a computer display, and move robotic arms. Pfurtscheller and Neuper (2001), for example, have created a "virtual keyboard" based on EEG mu rhythms that can be operated by the user, following extensive training, by imagining movements.

Currently many of the noninvasive BCIs suffer from poor signal-to-noise ratio (compared to the invasive BCIs) and slow throughput. Extensive training is also required, and the need for periodic recalibration can be a hindrance to routine usage. However, researchers in the area think that further technical refinements will allow for faster interaction times and reduced training. They also envisage promising new applications in areas such as control of virtual reality and multimedia systems (Pfurtscheller, Scherer, & Neuper, *in press*).

C. Individual differences: genetics, selection, and training

The importance of methods for assessing and quantifying individual differences in human performance has long been recognized in human factors (Matthews, Davies, & Stammers, 2000). Traditionally, individual differences have been assessed using the psychometric approach in which questionnaire measures of intelligence, personality, specific cognitive abilities, and other individual attributes have been linked to measures of task or job performance. More recently, alternative approaches to characterizing individual differences have begun to emerge. Some involve the neuroimaging techniques such as fMRI, ERPs, and EEG that we have discussed previously in this chapter. The most recent of these new approaches to the study of individual differences involves the application of molecular genetic methods, a trend that is a direct result of the stunning success of the Human Genome Project.

It is widely understood that both genetic and environmental factors contribute to individual differences in cognitive ability. In the past, identifying the genetic component required comparing identical and fraternal twins for a particular ability or trait, a paradigm that has been widely used in behavioral genetics research for over a century. For example, such studies have shown convincingly that general intelligence, or *g*, is highly heritable, and that the degree of heritability for *g* and for other psychological traits can be quantified (Plomin & Crabbe, 2000). However, this approach cannot identify the particular genes involved in intelligence or the cognitive components of *g*. Recent advances in molecular genetics now allow a different, complementary approach to behavioral genetics: *allelic association*. This method has been recently applied to the study of individual differences in cognition in healthy individuals

and reveals evidence of modulation of cognitive task performance by specific genes (Diamond et al., 2004; Fan et al., 2003; Greenwood et al., 2000; Parasuraman et al., 2005).

Molecular genetics of human performance: A framework.

Parasuraman and Greenwood (2004) have outlined a framework for examining the molecular genetics of cognition that combines cognitive neuroscience with the cognitive, or information-processing, approach. The framework involves several steps, beginning with the identification of *candidate* genes – genes deemed likely to influence a given cognitive ability or trait because of the functional role of protein product of the gene in the brain. The vast majority (>99%) of individual DNA sequences in the human genome do not differ between individuals. The remainder, which still amount to several million sequences, is of primary interest to those investigating individual differences in normal cognition.

DNA sequences involve combinations of four nucleotides (bases): adenine (A), cytosine (C), guanine (G), and thymine (T). Some of the DNA base pairs (bp) occur in different forms or *alleles*. Many types of allelic variation result from the substitution of one nucleotide for another, which is known as a single nucleotide polymorphism (SNP). For example, a particular gene may have variants involving a T to C substitution at a particular location within the gene sequence. Accordingly, the bp at that location may be TT (no substitution), TC (one of the T bases replaced), or CC (both T bases replaced). TT, TC, and CC define the three different alleles of the SNP. Variation can also occur because some small parts of the DNA sequence are repeated more or less often in different individuals. SNPs and other allelic variations are estimated to occur at a rate of about 1 every 1000 bp in unrelated individuals. There are several web sites that list currently known human SNPs, and the databases being updated regularly. Because they are so numerous, some constraint on a search through the SNP databases is necessary. In the Parasuraman and Greenwood (2004) framework, SNPs are selected if they are likely to influence neurotransmitter activity and are expressed in brain regions that are known (e.g., from neuroimaging studies) to be involved in networks that control a particular cognitive function. For example, visual attention, lesion, and electrophysiological studies in animals (Everitt & Robbins, 1997) and neuroimaging and pharmacological studies in humans (Posner & Petersen, 1990) indicate the key role of acetylcholine in posterior parietal cortex in the control of spatial attention. Hence, SNPs that can be linked to cholinergic pathways that include parietal cortex would represent candidate genes for examining individual differences in spatial attention. Similarly, dopaminergic (Sawaguchi & Goldman-Rakic, 1991) and noradrenergic (Arnsten, 1998) pathways converging in prefrontal cortex have been implicated in the control of working memory (Jiang et al., 2000), which suggest that SNPs linked to

dopamine or norepinephrine would be good candidates for assaying individual differences in this cognitive function.

The limitations of the combined allelic association/cognitive neuroscience approach to the genetics of cognition should also be considered. No component of human performance, no matter how microscopic, is likely to be modified by only one gene, and the interpretation of individual differences in a particular cognitive function will ultimately involve specification of the role of many genes as well as environmental factors (Plomin & Crabbe, 2000). It is also important that SNPs or other candidate genes are chosen in a theory-based manner for their functional significance for cognition, so as to minimize the probability of type I error. Nevertheless, several investigators have been able to demonstrate single gene-cognition links using this basic approach.

Genetics of spatial attention and working memory.

A recent study of spatial attention and working memory by Parasuraman et al. (2005) illustrates this approach. These authors examined a SNP in the dopamine hydroxylase (DBH) gene, which involves a G to A substitution at a specific location (444, exon 2; G444A) within chromosome 9. DBH is a functional polymorphism – the A allele is associated with lower levels of the enzyme dopamine beta hydroxylase in blood and in spinal fluid, and the G allele with higher levels (Cubells et al., 1998). A group of healthy adults were genotyped for the G444A polymorphism of the DBH gene and tested on tasks of working memory and visuospatial attention. The genotyping resulted in three sub-groups, the GG, GA, and AA genotypes. The working memory task involved maintaining a representation of up to three target locations over a period of time, and at the end of the task of memory for the location(s) was tested with a probe. Working memory accuracy declined as the number of locations to be remembered increased from one to two to three. Accuracy was equivalent for all three genotypes at the lowest memory load, but increased with higher gene dose of the G allele, particularly for the highest (3 target) load. Memory accuracy for the group with the GG allele (G gene dose = 2) was significantly greater than that for both the AG (G gene dose = 1) and AA alleles (G gene dose = 0).

A simple visuospatial attention task involving cued letter discrimination with little or no working memory component was also administered to the same group of participants. Individual differences in performance of this task were not significantly related to allelic variation in the DBH gene. Furthermore, working memory accuracy at the highest memory load was not correlated with performance on the attention task. In sum, these findings point to a reliable association between the DBH gene and working memory performance. Increasing gene dose of the G allele of the DBH was associated with better working memory performance. This effect was most apparent when the number of target locations to be retained was high. Thus, the association between the DBH gene and working memory was

particularly marked under conditions that most taxed the working memory system.

Parasuraman et al. (2005) also examined a cholinergic receptor gene, CHRNA4, and found that it was significantly associated with performance on the spatial attention task, but not with the same working memory task that was associated with the DBH gene. These findings are consistent with a double dissociation between the effects of CHRNA4 and DBH on spatial attention and working memory. In addition, another study that used a cued visual search task confirmed the association between CHRNA4 and spatial attention (Greenwood, Fossella, & Parasuraman, *in press*).

These results, and those of other groups (Diamond et al., 2004; Egan et al., 2001) using similar approaches, are indicative of the progress that is being made on establishing a molecular basis for normal individual variation in cognitive functions. It is also encouraging that the effect sizes in cognitive studies have been moderate to large (Parasuraman et al., 2005), in contrast to genetic studies of disease in which, they are often very low (Ioannidis et al., 2001). In future research, cognitive phenotypes will need to be supplemented by those derived from electrophysiological and neuroimaging measures (e.g., Fan et al., 2003). PET studies using neurotransmitter ligands may also permit new genetic associations to be discovered. All these methods will lead to better understanding of sources of individual differences in cognition.

Implications for selection and training. Reliable quantification of individual differences in cognitive function will have obvious implications for selection of operators for high-workload demanding occupations. The molecular genetic approach to cognition does not have immediate applications to personnel selection, but further programmatic research on more complex cognitive tasks will undoubtedly lead to progress in such an endeavor. The postgenomic era has clearly demonstrated that inheritance of a particular genotype only sets a range for the phenotypic expression of that genotype with the exact point within that range being determined by other genetic and environmental factors. What genomic analysis allows is for a much more precise specification of that range for any phenotype, and for linking phenotypic variation to specific genetic polymorphisms. To the extent that selection for a particular skill or job can be linked to a desired range of cognitive ability, molecular genetic analysis will have implications for selection for high-performance skills.

Molecular genetic research on cognition can be complemented by additional work on the influence of environmental factors on brain plasticity and cognitive performance. It has become increasingly clear that genetic studies, far from downplaying the importance of environmental factors for the development of adult cognitive skills, have pointed to new ways in which environmental variables can be identified and their effects on behavior quantified. Moreover, gene-environment interactions may be nonlinear, so that genetic effects need to be examined

over a wide range of environmental factors. For example, the effects of environmental factors on the development of intelligence in children may be substantial in low socioeconomic groups compared to that in middle and upper class children, even given the high heritability of intelligence (Turkheimer et al., 2003). Thus, additional gene-environment interaction studies are needed for a complete understanding of individual differences in cognition.

Recent studies on the effects of training on neural activation provide some exciting pointers for future work in this area. For example, Scalf et al., (2005) found that performance on multiple tasks activated some of the same prefrontal cortex regions involved in executive control that were reviewed earlier. More importantly, Scalf et al. (2005) examined how cognitive training improved attentional capacity and whether such training altered neural activation patterns. They found that training-related alterations in activation in brain regions that were sensitive to the effects of cognitive load. Relative to a control group, the training group showed decreased sensitivity to cognitive load (effect of a secondary task on the functional field of view in a primary task) in inferior frontal gyrus. Recall that this brain region has been shown to be differentially activated during dual-task performance (e.g., Jiang, 2004). This important finding regarding brain plasticity suggests that cognitive training improved the computational efficiency of this brain region under attentional demanding conditions. Scalf et al. also found similar task-related deactivations in a number of different task paradigms, indicating that cognitive training improved the efficiency of neural systems that were involved in the performance of each task. The improved efficiency is most probably the result of increased selectivity and specificity of the neural populations recruited to support task performance. It may be profitable in future research to combine the neuroimaging and genetic studies that have been discussed in this chapter with training/brain plasticity studies to examine the interactions of selection and training on brain function and performance. Selection and training have traditionally been considered together in human factors research and practice (e.g., Sanders & McCormick, 1983), but rarely in terms of a common biological framework. The examination of cortical activation in relation to molecular genetics and plasticity provides such a framework.

VI. CONCLUSIONS AND FUTURE DIRECTIONS

In this chapter we have provided a brief synopsis of several current issues in the field of human factors that have benefited from the theoretically based application of neuroergonomic techniques. In discussing each of these potential application areas, we have endeavored, whenever possible, to describe studies in which neuroergonomic measures have been used to address issues of concern to the human factors community in complex tasks, simulated environments, or, to a lesser extent, operational environments. Indeed, if neuroergonomics is to make a lasting

contribution to the field of human factors, it is important that we "transition" our measurement techniques from the relatively sterile yet well-controlled environment of the laboratory to the much richer but less controlled, simulated (including the increasingly richer virtual reality environments), and operational settings. Clearly, as evidenced by our critical review of the literature, such transitions are beginning to take place, at least, in selective research domains such as the characterization of skill development in driving and flying and in the development of brain-computer interfaces for handicapped individuals and for other potential uses.

In each of the research and application domains that we discussed – the assessment of mental workload and multitask performance and processing, assessment of individual differences through converging operations from the fields of neuroscience and molecular genetics, and the development of brain-computer interfaces – there have been demonstrations of successful applications of neuroergonomic techniques. In these cases, neuroergonomic measurement has either (1) provided converging support, along with performance and subjective measures, of important changes in information processing strategies, attention, or memory; or (2) provided insights that were not available with other measures, for example, by indicating changes in resource allocation and attentional strategies with implications for multitask performance, revealing the role and nature of memory representations that support visual search, and providing an index of attention or motor processes in individuals who are unable to communicate through traditional channels. Clearly, given the continued development of semi-automated and automated systems in which human operators monitor rather than actively control system functions, there will be numerous additional opportunities for the use of neuroergonomic measures and theories to provide insights into the covert processes of the mind.

However, in each of the research domains that we have discussed, there remain a number of important challenges for neuroergonomic measurement. These challenges include:

- 1.** the development and further refinement of signal extraction, pattern recognition, and artifact rejection and compensation algorithms that can be employed in relatively noisy environments and in situations in which the available data is relatively sparse;
- 2.** the continued development of neurophysiological and psychological models of processes of relevance to human performance and information processing of interest to the human factors community;
- 3.** the mapping of important psychological and neurophysiological constructs to neuroergonomic measures and models; and
- 4.** the continued development of converging measures from cognitive psychology, ergonomics, industrial engi-

neering, and other fields that can, when used together, provide a rich and relatively comprehensive view of human performance and cognition in a variety of different environments and tasks.

Indeed, there appears to be activity on each of these fronts and in particular on the integration of neuroergonomics, neuroscience, cognition, and emotion in the development of both micro- and macromodels of human psychological function, both inside and outside the laboratory.

Psychophysiological Contributions to Behavioral Medicine and Psychosomatics

ANDREW STEPTOE

INTRODUCTION

Behavioral medicine first emerged in the 1970s as interest developed in the application of behavioral treatments, such as biofeedback and relaxation training, to alleviate physical health problems, and the role of learning in physical disease etiology. Later, behavioral medicine expanded to become defined as the interdisciplinary field concerned with the development and integration of social, behavioral, and biomedical science, the knowledge and techniques relevant to health and illness, and the application of this knowledge to prevention, diagnosis, treatment, and rehabilitation (Slater, Steptoe, Weickgenant, & Dimsdale, 2003). Psychosomatics has a longer history and originated in the middle decades of the twentieth century as an application of psychodynamic psychotherapy to physical illness. Researchers and therapists in the psychosomatic tradition primarily focused on a small number of psychosomatic conditions such as hypertension (high blood pressure), peptic ulcer, rheumatoid arthritis, and bronchial asthma.

Behavioral and psychosomatic medicine were once polar opposites, the first concerned with behavior and the relevance of experimental psychological concepts such as operant conditioning to illness, and the second concentrating on intrapsychic and interpersonal influences. However, there has long been reconciliation such that the research described in behavioral medicine and psychosomatic conferences and journals is virtually interchangeable. The field has also moved beyond the small group of illnesses prioritized by psychosomatic medicine to a broader concept in which psychosocial and social factors are deemed to be relevant across the entire spectrum of physical illnesses. Modern research and practice views psychosocial factors as part of the broader biomedical and behavioral risk profile for disease, and operates to a variable extent in different cases, which depends on individual characteristics and on the disorder being investigated (Steptoe, 1998).

Other contributions to the *Handbook* have described many of the psychophysiological processes relevant to behavioral medicine and psychosomatics, including spe-

cific autonomic, neuroendocrine and immunological pathways, emotional influences on physiology, and stress and illness. The purpose of this chapter is to outline how this psychophysiological knowledge is applied in behavioral medicine and psychosomatics and focuses on two broad issues. First is the application of psychophysiology to understanding the etiology of physical illnesses such as coronary heart disease, hypertension, infectious illness, immune-related diseases, and musculoskeletal disorders. This is the field in which psychophysiological methods have deepened our understanding of physical disease development and maintenance. The second general issue is the application of psychophysiology to the management of physical illnesses, and the evaluation of treatment effects. Additionally, I will explain how psychophysiology provides a powerful set of tools for research and clinical practice in behavioral medicine and psychosomatics. Researchers in this field have developed particular approaches to psychophysiology that differ to some extent from those that are commonly used in experimental research. The chapter, therefore, begins with a summary of methodological issues relevant to the application of psychophysiology to behavioral medicine and psychosomatics.

METHODS OF STUDYING PSYCHOPHYSIOLOGICAL PROCESSES

Much of nonpsychiatric clinical medicine involves the measurement of biological functions. As psychophysiology has expanded beyond traditional measures such as heart rate and electrodermal activity to include hormonal, immunological, and even molecular variables, the dividing line between where clinical measurement ends and psychophysiology begins has become increasingly opaque. It is, however, important to recognize that in behavioral medicine and psychosomatics, the psychophysiological measures studied fall into three categories (Steptoe, 2005):

1. Biological indicators of disease states, such as blood pressure in hypertension, blood glucose in diabetes, or

airways resistance in bronchial asthma. These measures are direct measures of the physiological dysfunctions constituting the disease state, are used in research on the role of psychophysiological processes in the etiology of disease, and in evaluating the impact of psychosocial interventions.

2. Biological markers of processes involved in the etiology of disease. Examples include measures of vascular endothelial function and fibrinogen in coronary heart disease, the concentration of circulating lymphocyte subsets in HIV/AIDS, and the measurement of gut hormones in obesity. The biological parameters assessed in such studies are more distal to disease states than those assessed in category 1, but nevertheless provide objective information concerning the impact of psychophysiological factors on precursors of disease, which underlie pathological dysfunctions, and on treatment effects.

3. Nonspecific biological markers of activation or resistance to disease that are influenced by stress and other psychosocial factors. Psychophysiological measures in this category include heart rate, blood pressure, electrodermal activity, stress hormones such as cortisol and catecholamines, circulating lymphocyte numbers and activity, and concentrations of inflammatory cytokines and immunoglobulins. These variables are not assessed as markers of specific disease states, but as more general indicators of biological activation and host resistance.

These distinctions are important because the implications of responses in these categories of measure can be quite different.

Strategies of psychophysiological measurement

Psychophysiology is traditionally a laboratory-based science involving measurement of physiological function under carefully controlled conditions and the application of experimental research designs, such as the random allocation of participants to different experimental conditions or the comparison of biological responses to different patterns of behavioral stimulation. Psychophysiological applications in behavioral medicine and psychosomatics are broader, frequently moving outside the laboratory to clinical situations in which environmental conditions are less tightly controlled.

Within the laboratory, the major method of investigation is psychophysiological or mental stress testing. This involves monitoring biological responses to standardized psychological or social stimuli, often comparing groups such as people with and without a specific illness or people at low and high risk for a particular condition. A wide range of behavioral challenges is employed including cognitive and problem solving tasks, simulated public speaking, upsetting films, and interpersonal conflict tasks. Although most tasks involve cognitive processing, experimental conditions are commonly selected for their stress-

fulness and not because they mobilize particular cognitive processes.

A psychophysiological stress testing session typically involves a period of rest so that baseline levels of physiological function can be established. Many studies now include blood sampling as well as traditional psychophysiological measures, so baseline periods may be prolonged in order to allow the impact of the blood taking or cannulation to dissipate before exposure to challenges that may last anywhere from five minutes to three hours. Further biological measures are obtained during the challenge period and for some time afterwards, depending on the dynamics of the measure under investigation. For example, blood pressure and heart rate respond within minutes of onset of behavioral tasks, while cortisol in saliva and blood may not peak for 30 minutes, and inflammatory cytokines such as interleukin (IL) 6 continue to rise for at least two hours.

The value of psychophysiological stress testing is that responses to psychosocial stimuli can be monitored under environmentally controlled conditions, which reduces many of the sources of bias and individual difference that might otherwise be present. Experimental designs can be used with randomization to different conditions (such as low and high stress controllability), and sophisticated biological measures are possible. There are two major limitations to this type of study. The first is that the stimuli used are often arbitrary and divorced from everyday life. After all, few people spend much of their lives carrying out mirror tracing, though this is a popular research task. Studies using more ecologically valid challenges such as interpersonal conflict tasks remain in the minority. Second, the stimuli used are brief and only acute biological responses are recorded. Chronic challenges may elicit different response patterns because of habituation and adaptation. The generalizability of biological adjustments, therefore, remains uncertain in many cases and has led to great interest in the correlations between psychophysiological responses in the laboratory and field as well as in the predictive power of individual differences in acute response.

The second major setting for psychophysiology in behavioral medicine and psychosomatics is naturalistic or ambulatory monitoring. These studies take many forms, from recordings during challenging tasks, such as speaking in public, to repeated measures of blood pressure or salivary cortisol over an ordinary day. Some of these techniques are extensions of methods used in clinical investigation, as in the use of ambulatory blood pressure monitors for evaluating hypertension, or *Holter*, monitoring of the electrocardiogram (EKG) in patients with coronary heart disease (CHD). The purpose of these psychophysiological methods is to assess biological activity under natural conditions, and to examine the covariation between everyday activities, emotions, and biology. For example, one study of patients with bronchial asthma and a nonasthmatic comparison group involved repeated spirometric

measurements and mood assessments several times a day for three weeks. Naturally occurring negative mood states were found to relate to reduced forced expiratory volume in asthmatic participants but not in controls (Ritz & Steptoe, 2000). Measurements of muscle tension from surface electrodes have been made in supermarket checkout clerks, and have shown heightened trapezius muscle tension during work that is associated with complaints of neck and shoulder pain (Lundberg et al., 1999).

Naturalistic monitoring methods have the advantage of ecological validity because psychophysiological activity is measured in real life rather than the artificial conditions of laboratory or clinic. Associations between psychosocial factors and biological responses may be observed that are not detectable when measures are taken in a single situation such as a physician's office. Unfortunately, naturalistic methods have several limitations. First, the range of biological markers that can be assessed is relatively small in comparison with the more sophisticated possibilities available in the laboratory or clinic. Second, measurement techniques need to be relatively unobtrusive, so as not to interfere with ongoing activities. Some techniques, such as repeated blood sampling or esophageal pH probes, are very stressful in themselves, so associations with psychosocial factors may be obscured. Third, several extrinsic factors that influence biological function must be taken into account, which includes cigarette smoking, time of day, food and caffeine intake, sleep, and physical activity. This raises complex statistical issues and techniques such as multilevel modeling may be required in analyzing the data (Schwartz & Stone, 1998).

The third setting in which psychophysiological methods are used is in epidemiological surveys. Observational epidemiology is the core technique for establishing the contribution of psychosocial factors to the development of physical disease. A typical study involves measuring a range of potential biological and behavioral risk factors for the disease under investigation (e.g., breast cancer, diabetes, or CHD) in a large sample of healthy individuals. The cohort is tracked, often for years, until a sufficient number of clinical cases have accrued to allow multivariate analysis of associations between risk factors and health outcomes. Physiological measures can be introduced so as to identify the biological mediators of the associations observed. For instance, lower socioeconomic status (SES) is consistently associated with increased risk of CHD (Mensah, Mokdad, Ford, Greenlund, & Croft, 2005). It has been found by adding biological measures to epidemiological surveys that plasma fibrinogen and C-reactive protein are elevated in lower SES individuals, while the incidence of the metabolic syndrome (characterized by abdominal adiposity, high blood pressure, and elevated lipid levels) is also raised (Brunner et al., 1996; Wamala et al., 1999). In mediational analyses, these physiological variables account for a proportion of the variance in CHD attributable to SES, so it is probable that they are on the pathway linking SES with CHD.

Epidemiological studies have the advantage that prospective study designs can be employed and objective disease endpoints studied. Biological measures can be obtained from large samples at relatively low cost, and potential confounders can be taken into account statistically. However, the biological measures in epidemiological studies are generally recorded on a single occasion under resting conditions (in a screening clinic or medical office) that are not typical of everyday life. Such studies therefore provide limited information about the dynamics of psychophysiological responses.

All these approaches are valuable in the investigation of psychophysiological processes in behavioral medicine and psychosomatics, but an integrated strategy is required to exploit these methods to the full. The later sections of this chapter therefore present findings derived from all these different settings.

PSYCHOPHYSIOLOGY IN THE ETIOLOGY AND PROGRESSION OF PHYSICAL ILLNESS

There is an extensive literature relating psychosocial factors with physical illness. Acute and chronic life stress, social support and social networks, psychological distress, and emotions like anger and depression have been associated with a range of health outcomes. In some cases, psychosocial factors are thought to contribute to the development of disease in initially healthy individuals, while in others these factors may influence the progression of pre-existing disorders. In a condition like CHD, psychosocial factors may affect both the development of the underlying pathology (atherosclerosis) and the triggering of acute clinical events in people with existing disease.

Psychophysiology is central to understanding the pathways and processes through which psychosocial factors influence disease risk and health outcomes. However, the way in which psychophysiological processes are involved differs markedly across medical conditions (Steptoe & Ayers, 2004). This is illustrated in the following sections that focus on some of the major health problems studied in behavioral medicine and psychosomatics. In each case, the disorder is briefly described and the evidence linking its development or maintenance with psychosocial factors is summarized. Particular emphasis is placed on prospective observational epidemiological studies on population samples because these provide more robust data than cross-sectional and clinical studies on selected populations. I then review the ways in which psychophysiological studies have helped us understand how these effects are mediated.

Space prevents an exhaustive review of literature related to all health conditions. I have not, therefore, included discussion of a number of outcomes including stroke, gastrointestinal illness, HIV/AIDS, cancer, and gynecological conditions. Some of these disorders are described in detail elsewhere in the *Handbook*, while others follow similar principles to the conditions that are discussed – namely

CHD, hypertension, metabolic disorders, infectious illness, autoimmune conditions, and musculoskeletal problems.

Two issues are critical to understanding the contribution of psychophysiological investigations to disease etiology. The first is that individual differences in the duration and magnitude of psychophysiological responses appear to be relevant to risk of many adverse health outcomes. In some diseases, heightened responsivity is associated with increased risk, but in other conditions reduced responsivity may be problematic. Either way, individual differences are crucial. The second pivotal concept is exposure. Disturbances of psychophysiological responsivity are only likely to contribute to disease etiology if they are elicited in the person's ordinary life and not just in a laboratory test. Repeated or continued exposure to adverse psychosocial conditions will, therefore, moderate whether or not an individual difference in responsivity is actually relevant to etiology.

Coronary heart disease

Coronary heart disease is the single largest cause of death in men and women in the USA, United Kingdom, and many other countries. In the USA, 38% of deaths in 2002 were caused by cardiovascular disease, of which 53% were CHD fatalities (American Heart Association, 2005). The estimated prevalence of CHD in 2002 was 8.4% of men and 5.6% of women, and the average number of years lost as a result of a heart attack was 11.5. Although CHD is a disease of old age, it also afflicts many younger people. In the UK, it accounted for 22% of male and 13% of female deaths in people under 75 years old (British Heart Foundation, 2004). The major risk factors are high blood cholesterol levels, high blood pressure, smoking, diabetes, and family history. These are in turn affected by behaviors such as physical inactivity, food choice, and alcohol consumption. The INTERHEART study has shown that the potentially modifiable risk factors for CHD are similar across genders, ethnic groups, and geographical regions of the world (Yusuf et al., 2004).

The process underlying CHD is coronary atherosclerosis, a condition starting early in life and developing progressively through adulthood. Coronary atherosclerosis typically comes to clinical attention with angina pectoris, sudden cardiac death, or an acute coronary syndrome. Conceptualization of coronary atherosclerosis has changed in the last two decades, and it is now considered to be a chronic inflammatory condition rather than a passive lipid storage disease (Libby & Theroux, 2005; Ross, 1999). Coronary atherosclerosis develops at a variable rate in the population, but by middle age a substantial proportion of men and women will have definite coronary artery disease.

Understanding of advanced CHD and acute coronary syndromes has also changed over recent years. Acute coronary syndrome constitutes a spectrum of clinical condi-

tions, including ST elevation myocardial infarction (MI), non-ST elevation MI and unstable angina. The notion that acute coronary syndromes are caused simply by progressive narrowing of coronary arteries until blood flow is blocked is inconsistent with angiographic findings that culprit lesions are mostly not flow limiting. Rather, coronary events occur when atherosclerotic plaques either rupture or erode, leading to direct contact between the blood and the lipid-rich plaque core and the formation of a thrombus (Davies, 1996). The most angiographically severe lesions are not necessarily at highest risk of rupture, and rupture does not always result in acute coronary syndromes (Libby & Theroux, 2005; Monaco, Mathur, & Martin, 2005). Other factors are involved, notably "vulnerable blood," in which blood platelets are prone to activation, the coagulation system is in a prothrombotic rather than fibrinolytic state, and high levels of circulating inflammatory factors are present. During an acute coronary syndrome, there is a marked inflammatory response with increases in IL-6, IL-1 receptor antagonist (IL-1Ra), tumor necrosis factor (TNF) α , and C-reactive protein. These inflammatory markers predict poor prognosis.

The implication of this pathological sequence is that psychophysiological processes may be relevant both to the longterm development of atherosclerosis, and to the acute events that initiate an acute coronary syndrome in the vulnerable patient. The important variables include vascular endothelial function, lipids, proinflammatory cytokines, C-reactive protein and hemostatic variables. Cardiovascular responses including raised blood pressure, heart rate, and total peripheral resistance are important in that they may heighten shear stress across arterial plaques, which increases risk of rupture.

Psychosocial risk factors

There is a large literature using observational population-based prospective designs that has examined psychosocial factors predicting future CHD. Systematic reviews of this work are in agreement that chronic stressors, social factors, and certain psychological characteristics are associated with future CHD independently of standard risk factors (Everson-Rose & Lewis, 2005; Kuper, Marmot, & Hemingway, 2005). Among chronic stressors, there is particularly strong evidence for work-related factors such as job strain (high demand/low control) and effort-reward imbalance, though other sources of stress such as financial strain, informal caregiving, and marital conflict are also relevant (Iso et al., 2002; Lee, Colditz, Berkman, & Kawachi, 2003). The social factors that have been associated with increased CHD risk include social isolation, small social networks, and low levels of emotional support. Research on psychological factors has highlighted depressive mood and anger/hostility with more limited but still consistently positive results for anxiety as a risk factor (Steptoe, *in press*; Suls & Bunde, 2005). Additionally, there is a pronounced socioeconomic gradient in CHD with higher levels among less privileged groups as defined by

educational attainment, occupational status, and income (Mensah et al., 2005). Low SES is in turn associated with greater work, financial and neighborhood stress, greater social isolation, and increased ratings of depression and hostility, so the psychosocial risk factors for CHD are more prevalent in low SES groups.

The impact of psychosocial factors on underlying disease can be investigated using noninvasive measures of subclinical atherosclerosis. Carotid ultrasound scans detect carotid plaque and the intima-medial thickness (IMT) of the carotid artery wall, while a more direct scanning technique, electron beam computed tomography (EBCT), can image advanced plaque in the coronary arteries themselves. Associations have been described between carotid artery atherosclerosis and low SES, job strain, poor marital quality, and hostility (Diez-Roux, Nieto, Tyroler, Crum, & Szklo, 1995; Everson et al., 1997a; Gallo et al., 2003). At least 10 population studies have been published relating carotid IMT or coronary artery calcification with depression, hopelessness, and psychological distress (Steptoe, in press). For instance, in the Work Site Blood Pressure Study, depressed mood at baseline predicted carotid plaque 10 years later, after adjustment for cardiovascular risk factors including age, gender, ethnicity, education, cholesterol, body mass index (BMI), diabetes, smoking, blood pressure, and family history (Haas et al., 2005). Another study tracked a cohort of 726 French men and women aged 59–71 years with no history of CHD (Paterniti et al., 2001). Men with higher anxiety scores showed greater progression in carotid IMT over a four-year period than did less anxious individuals with a similar but weaker effect among women.

Psychosocial factors can also act more acutely, triggering cardiac events in people with advanced underlying coronary artery disease, as has been found in studies of natural disasters and acts of war and terrorism and in clinical investigations of patients admitted to hospital with acute MI (Strike & Steptoe, 2005). For example, on the day of the Northridge earthquake in the Los Angeles area in January 1994, there was an abrupt rise in the number of sudden cardiac deaths, total CHD mortality and hospital admission for acute MI (Leor, Poole, & Kloner, 1996). Interviews with patients in hospital who have survived acute cardiac events have shown an increased risk following acute episodes of anger and stress (Mittleman et al., 1995; Moller, Theorell, de Faire, Ahlbom, & Hallqvist, 2005). A study in which the relatives of 100 men who suffered a sudden cardiac death were interviewed showed that victims were more likely to have experienced moderate or severe stress in the 30 minutes prior to onset than had patients admitted to hospital with an acute MI (Myers & Dewar, 1975). Factors like depression, work stress, social isolation, and low social support also predict future cardiac morbidity in patients following hospital admission for acute coronary syndrome (Kuper et al., 2005; van Melle et al., 2004). Thus, there is evidence for a contribution of

psychosocial adversity to many stages of the CHD disease process.

Psychophysiological processes

Psychophysiological methods are used extensively to investigate the ways in which social, emotional, and behavioral factors impact on the development of CHD. The literature is extensive and fast moving, so this chapter will highlight some important themes rather than providing a comprehensive review.

Pathological responses and psychosocial factors. Psychophysiological studies of CHD began in the 1950s when the principle physiological measures were blood pressure, heart rate, and corticosteroid metabolites. In the past decade, interest has focused on whether psychological stimulation affects physiological parameters that are more directly involved in the pathogenesis of CHD, and whether the magnitude and duration of these responses are related to psychosocial risk factors.

One of the earliest stages of atherogenesis is vascular endothelial dysfunction. The healthy endothelium maintains vascular tone and inhibits cell adhesion and migration into the subendothelial layer. Ghiadoni and coworkers (2000) demonstrated that endothelial function was impaired following acute stress induced by simulated public speaking. Interestingly, responses were maintained up to 90 minutes poststress, long after the 3-minute speech task had terminated, which indicates that brief psychological stimulation can have extended effects. The effect can be blocked by metyrapone, a drug that inhibits cortisol production, and suggests that the hypothalamic-pituitary-adrenocortical (HPA) axis is involved (Broadley et al., 2005). Impaired endothelial function has also been described in depressed patients without other cardiovascular risk factors (Broadley, Korszun, Jones, & Frenneaux, 2002).

As noted earlier, inflammatory cytokines such as IL-6 and TNF α , and acute phase reactants like C-reactive proteins are also implicated in atherogenesis. Blood levels of C-reactive protein are elevated in population studies of depression and depressed mood (Ford & Erlinger, 2004), and associations between proinflammatory cytokines and hostility have been described (Suarez, Lewis, Krishnan, & Young, 2004). Chronic stressors such as caring for a dementing relative stimulate heightened plasma IL-6 with accelerated increases over time in caregivers (Kiecolt-Glaser et al., 2003). Low SES is associated with heightened levels of several markers of inflammation, including von Willebrand factor, C-reactive protein, and fibrinogen (Brunner et al., 1996; Kumari, Marmot, & Brunner, 2000). Psychophysiological studies have demonstrated that these inflammatory markers respond acutely to psychological stimulation, and responses are greater in individuals with psychosocial CHD risk factors. Thus, the acute stress-induced increase in IL-6 is larger in people of lower SES (Brydon, Edwards, Mohamed-Ali, & Steptoe, 2004), while

acute fibrinogen responses are elevated in people experiencing low control at work (Steptoe, Kunz-Ebrecht, Owen, et al., 2003), and in lonely individuals (Steptoe, Owen, Kunz-Ebrecht, & Brydon, 2004).

Closely linked with inflammatory processes are hemostatic factors involved in the development of thrombotic states. Hemostatic factors are highly sensitive to psychological stimulation with a combination of procoagulant (or prothrombotic) and anticoagulant responses (von Kanel, Mills, Fainman, & Dimsdale, 2001). The magnitude and duration of stress-induced responses appears to be greater in more depressed people (von Kanel et al., 2004) and in lower SES groups (Steptoe, Kunz-Ebrecht, Rumley, & Lowe, 2003).

Another mechanism linked both with the longterm development of atherosclerosis and with acute cardiac events is autonomic balance in cardiac control with greater parasympathetic activation being protective. Heart rate variability is often used as an index of parasympathetic activity, and it is notable that lower SES, greater job stress, and depressed mood are characterized by reduced heart rate variability (Hemingway et al., 2005; Kim et al., 2005).

Longitudinal significance of psychophysiological responses. Biological responses relevant to CHD can be elicited by behavioral stimulation, and responsivity is related to psychosocial risk factors. However, these cross-sectional effects do not demonstrate that response profiles are causally significant. Fortunately, over recent years, longitudinal results have begun to emerge, which indicate that individual differences in responsivity do predict acceleration of risk profiles or subclinical disease progression. A good example is the discovery by Jennings et al. (2004) that blood pressure stress responses predict increases in carotid IMT. The study involved 756 Finnish men who were administered a battery of psychophysiological stress tests. Individual differences in systolic pressure reactivity were positively related to changes in carotid IMT over a seven-year period independently of baseline IMT and other risk factors. Prospective effects relating individual differences in stress responsivity in other CHD risk factors such as blood cholesterol concentration with subsequent levels have also been described (Steptoe & Brydon, in press). These individual differences in psychophysiological stress responsivity will be relevant if they are representative of the individual's experience during daily life. As noted earlier, heightened responsivity per se is not likely to increase risk of CHD. Psychophysiological factors will contribute to CHD risk if reactive individuals are exposed over months or years to environments that elicit damaging patterns of intense response. Thus, in addition to evaluating the impact of cardiovascular stress responsivity, it is necessary to monitor exposure to life stress. Thus far, there has been comparatively little work of this kind. However, one example is from the Kuopio study in Finland, in which an interaction between blood pressure

stress reactivity and exposure to chronic life stress (in this case, work place demands) was observed (Everson et al., 1997b). These two factors interacted in predicting progression of carotid IMT; over a four-year period, the increase in subclinical atherosclerosis was greatest in men who were stress reactive and had been exposed to high work demands.

The model underlying these psychophysiological processes in CHD and some other health problems is outlined in Figure 31.1. Heightened or prolonged psychophysiological stress responsivity is sustained by individual differences or propensities, arising from genetic, early life, and adult psychological factors. Various types of psychosocial adversity, including low SES, chronic life stress, and social isolation, not only elicit this heightened or prolonged responsivity, but also increase responsivity over the long term. The impact of this process on disease risk depends on continuing exposure to adverse psychosocial conditions that not only stimulates repeated activation, but also serves further to increase the responsivity of the vulnerable individual. The impact of this pathway is set against a background of constitutional and biological risk and lifestyle factors that independently contribute to CHD risk.

Psychophysiological responses in people with CHD. The summary of psychophysiological processes given above applies primarily to the etiology of CHD and the development of subclinical disease. Psychophysiological methods also throw light on the mechanisms triggering clinical events such as MI in people with established disease. Research with clinical groups is difficult to conduct, partly because of ethical concerns about patient safety, and partly because the medication status of patients can obscure psychophysiological responsivity. For instance, there is good evidence that sympathovagal imbalance, indexed by low heart rate variability and suppressed cardiac baroreceptor reflex sensitivity, predicts negative clinical outcomes in CHD (La Rovere, Bigger, Marcus, Mortara, & Schwartz, 1998). This has lead to the clinical recommendation in most countries that CHD patients are medicated with β -blockers. In turn, this reduces the opportunities for assessing heart rate variability in relation to psychosocial factors. Although depression in CHD patients has been associated with low heart rate variability in some studies (Carney et al., 2001), this effect has proved difficult to replicate, in part because of medication problems (Gehi, Mangano, Pipkin, Browner, & Whooley, 2005). However, a secondary analysis of postmyocardial patients in the Enhancing Recovery in Coronary Heart Disease (ENRICHD) study compared 24-hour electrocardiograms in 311 depressed and 367 nondepressed patients (Carney et al., 2005). Heart rate variability was reduced in the depressed patients, and partly accounted for the increased mortality in the depressed group over a 30-month followup period.

Psychophysiological studies using conventional measures such as blood pressure and heart rate to compare

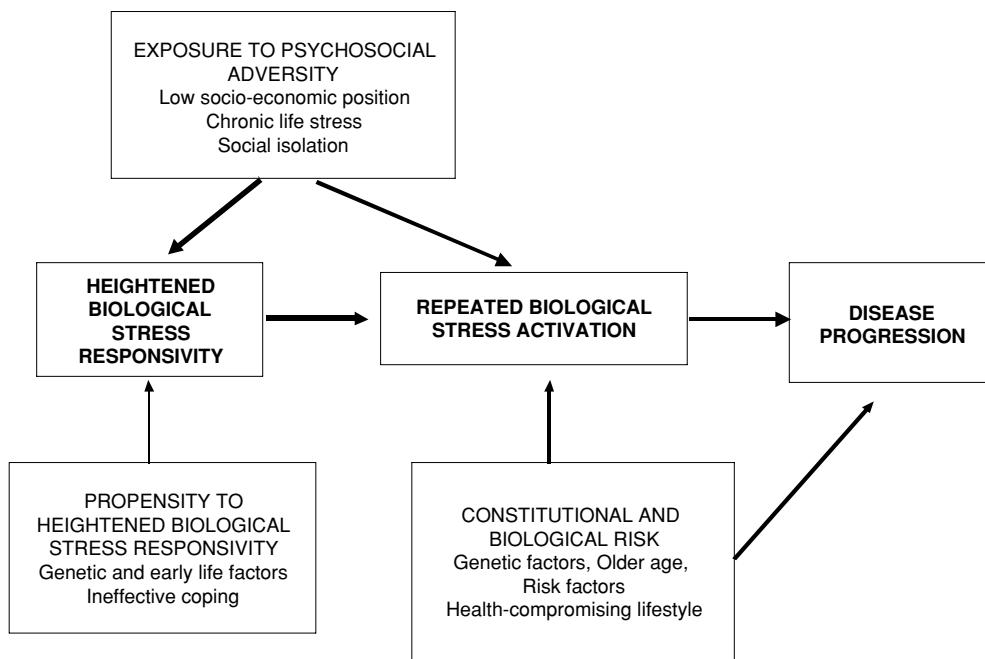

Figure 31.1. Schematic summary of the contribution of psychophysiological processes to disease development.

coronary artery disease patients with controls have also been conducted. Sundin, Ohman, Palm, and Strom (1995) showed that patients exhibited greater total peripheral resistance responses to stress than did controls with no poststress return to baseline. A similar pattern was observed by Strike and coworkers (Strike et al., 2004), who reported that peripheral resistance continued to rise up to 75 minutes poststress in coronary artery disease patients but not in controls. This group also recorded more sustained stress-induced activation of platelets in cardiac patients.

The most extensive psychophysiological research of the past decade has focused on stress-induced transient myocardial ischemic responses (Strike & Steptoe, 2003). Transient ischemia occurs when there is a temporary interruption of blood supply to the working muscle of the heart because of supply not keeping up with demand. This may be a result of the reduced capacity of the diseased coronary vessels to supply sufficient blood (as in exercise-induced ischemia), abnormal responses in the epicardial coronary arteries and microvasculature, or aberrant α -adrenergic vasoconstrictive responses. More than 50 studies have been published assessing stress-induced ischemia with a variety of measures including EKG assessments, radionuclide imaging, and coronary angiography. Psychophysiological stress tests such as mental arithmetic and simulated speech tasks appear to induce transient ischemic responses in 35–50% of patients with coronary artery disease (Strike & Steptoe, 2003). Most of these episodes are not accompanied by pain, and occur at lower levels of oxygen demand than ischemia induced by physical exertion. Stress-induced hemodynamic changes, particularly increases in systemic vascular resistance and coronary

artery vasoconstriction may also contribute. Importantly, it has been demonstrated in at least four prospective studies that mental stress-induced myocardial ischemia is of prognostic significance, which predicts further cardiac events such as myocardial infarction (e.g., Krantz et al., 1999; Sheps et al., 2002).

Ambulatory psychophysiological techniques can also be used to investigate cardiac ischemic responses. Results from 24 or 48h Holter EKG monitoring records can be analyzed for the presence of transient myocardial ischemia by detecting changes in the ST segment of the EKG. These episodes are more likely under conditions of increased mental stress or tension (Gabbay et al., 1996). Gullette et al. (1997) investigated 132 patients with coronary artery disease, of whom 45% showed transient ischemia during ambulatory monitoring. Patients also completed mood and activity diaries, and it was found that episodes of sadness, frustration, and tension were associated with a two to five-fold increase in risk of ischemia. In another study, ischemic episodes during ambulatory monitoring were shown to be preceded by a reduction in high frequency heart rate variability spectral power, indicative of vagal withdrawal (Kop et al., 2001). It is notable that this association between depressed high frequency variability and ischemia was present when patients reported engaging in high but not low levels of mental activity, which suggests that parasympathetic influences on the myocardium mediated the impact of psychological activation.

A novel field of psychophysiological cardiac research has emerged in recent years with the study of patients with implantable cardioverter-defibrillators (ICDs). These devices are implanted in individuals at high risk of serious arrhythmias as a result of CHD and other cardiac diseases.

By combining monitoring of the times at which the ICD administered shocks with diary ratings of mood and activity, Lampert et al. (2002) demonstrated an increased risk of shocks following episodes of anger. More recently, it has been found that depression is a risk factor for greater numbers of shocks from ICDs for preventing dangerous ventricular arrhythmias (Whang et al., 2005). In animal models of depression, reduced heart rate variability and increased susceptibility to ventricular arrhythmias have been described (Grippo et al., 2004). Taken together, this evidence suggests that disturbances in autonomic function are probably responsible for the impact of psychosocial factors on cardiac arrhythmia, and potentially sudden cardiac death.

Hypertension

Hypertension, or high blood pressure, is a major health problem worldwide. The definition of hypertension is somewhat arbitrary because the distribution of blood pressure level in the population is continuous and not bimodal. Nonetheless, the current definition of hypertension is a systolic blood pressure ≥ 140 mmHg and diastolic pressure ≥ 90 mmHg. Most authorities regard a blood pressure in the range 130–139/85–89 mmHg as high-normal, although the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure has defined levels of 120–139/80–89 mmHg as prehypertensive (Chobanian et al., 2003). It has also concluded that risk of cardiovascular disease begins with blood pressures greater than 115/75 mmHg, indicating that levels previously regarded as benign may carry some health risk. Between 1999 and 2002, 28.7% of men and 30.5% of women in the United States were hypertensive (National Center for Health Statistics, 2004). However, blood pressure tends to rise with age, so these overall figures disguise a substantial increase in hypertension in middle age. Thus in the USA, prevalence increased from 8.1% men and 2.7% women aged 20–34 years, to 44.9% and 53.9% of those aged 55–64 years. There are also striking ethnic variations with high rates in African Americans and in African Caribbean people in the UK.

Blood pressure is moderately heritable, so family history is a major risk factor for hypertension. It also shows tracking through life; individuals with higher pressures within the normal range being at increased risk for hypertension in the future. In addition, factors such as body weight, diet (in particular salt consumption), sedentary lifestyle, and alcohol intake contribute to its development.

White coat hypertension

Hypertension is typically diagnosed in the physician's office. But there is one diagnostic problem that has psychophysiological origins. This is *white coat hypertension*, the phenomenon of having a high blood pressure when it is measured in the clinic by a physician but lower blood pressure levels in everyday life. White coat hypertension

has become increasingly recognized because of the development of ambulatory blood pressure instruments that allow everyday levels to be recorded as well as the growing popularity of blood pressure self-monitoring. The clinical significance of white coat hypertension remains unclear despite several years of investigation. Some studies have shown an increased risk of cardiovascular disease intermediate between that of normotensives and hypertensives (Gustavsen, Hoegholm, Bang, & Kristensen, 2003), while others have not (Verdecchia et al., 2005).

Because white coat hypertension depends on the measurement situation, it can be seen as a psychophysiological stress response to the circumstances and implications of assessments in the physician's office or clinic. There is little evidence for an unusual psychological profile in people showing white coat effects (Siegel, Blumenthal, & Divine, 1990). However, a number of studies have shown that white coat effects are associated with heightened cardiovascular stress responses (Lantelme, Milon, Gharib, Gayet, & Fortrat, 1998). White coat effects are also correlated with cortisol output (Nystrom, Aardal, & Ohman, 1998) and disturbances of autonomic balance with greater low-to-high frequency ratio in the heart rate variability spectrum (Neumann, Jennings, Muldoon, & Manuck, 2005).

Psychosocial factors

Hypertension was one of the classic psychosomatic disorders studied in the heyday of psychodynamic research with the belief that high blood pressure emerged because of inhibition of emotional conflict and other intrapsychic forces. A major problem with the early research is that studies were carried out with individuals known to be hypertensive. High blood pressure is generally asymptomatic, so a substantial proportion of hypertension is undetected in the population. Clinical samples may not be representative of people with hypertension in general, and awareness of high blood pressure in itself may lead to psychological distress (Rostrup, Mundall, Westheim, & Eide, 1991).

The most convincing evidence for psychosocial contributions to hypertension derives from population-based epidemiological studies rather than clinical investigations. Many studies have documented associations between work stress as defined by the demand/control model and blood pressure with elevated levels among individuals who work in high demand/low control jobs (Schnall, Landsbergis, & Baker, 1994). In the Work Site Blood Pressure Study in New York City, job strain (high demand/low control) was an independent predictor of hypertension after controlling for age, body mass index, Type A behavior, 24-h sodium excretion, physical activity at work, education, smoking, and alcohol consumption (Schnall et al., 1990). Longitudinally, individuals exposed to more years of high job strain had higher blood pressure (Landsbergis, Schnall, Pickering, Warren, & Schwartz, 2003).

Exposure to other types of chronic stress has been linked with hypertension as well. In elderly spousal caregivers for

dementing relatives, caregiver burden predicts increases in blood pressure over a seven-year period (Shaw et al., 2003). Individuals with a lack of cohesion in their marriages have higher ambulatory blood pressure, as do people who report poor marital role quality (Barnett, Steptoe, & Gareis, 2005). The experience of racism may contribute to high blood pressure in African Americans (Williams, Neighbors, & Jackson, 2003), while factors such as acculturation stress and status incongruity are relevant. Perhaps one of the most elegant illustrations of the impact of psychosocial experience has been a study of a cohort of Italian nuns living in a secluded order who have been compared with lay women from the same region over a 30-year period (Timio et al., 1997). The blood pressure of the nuns has remained low and stable throughout adult life, compared with the usual rise with age that was observed in the comparison group. There was also a difference in cardiovascular morbidity with fewer fatal and nonfatal cardiac events among the nuns. The predictable, peaceful, and socially supportive lifestyle of the nuns may be responsible for this difference.

A range of psychological characteristics has been associated with hypertension, including anger inhibition, anxiety, and depressive traits (Rutledge & Hogan, 2002). Early research in this field highlighted anger coping styles, and developed the notion that the inhibition of anger expression in people living or working under stressful conditions was a potent stimulus to hypertension (Jorgensen, Johnson, Schreer, & Kolodziej, 1996). Subsequent prospective studies have provided further support for the influence of psychological traits. Jonas and Lando (2000) analyzed data from 3310 initially normotensive adults tracked for up to 22 years, and found that negative affect predicted hypertension after adjusting for other risk factors such as baseline blood pressure and adiposity. In a follow-up of the Framingham cohort, anxiety but not anger was an independent predictor (Markovitz, Matthews, Kannel, Cobb, & D'Agostino, 1993), while hostility was associated with future hypertension over a 15-year period in the CARDIA study (Yan et al., 2003).

Psychophysiological processes

Psychophysiological studies can help to define the pathways through which psychosocial factors influence blood pressure. However, it should be recognized that adverse psychosocial experience might also stimulate behavior patterns that influence blood pressure levels directly. In the Air Traffic Controllers Health Change study, an accelerated rate of development of hypertension was found in controllers. This was found to be mediated in part by increased alcohol consumption, rather than direct sympathoadrenal responses (DeFrank, Jenkins, & Rose, 1987). The increases in blood pressure recorded among young adults from the Luo tribe in western Kenya who migrated to Nairobi are not primarily attributable to the strain of moving to a stressful urban environment, but to higher salt intake and greater body weight (Poulter et al., 1990).

Nonetheless, disturbed psychophysiological responsiveness also appears to contribute to hypertension. As in the case of CHD, the disturbance may take the form of heightened stress reactivity or impaired recovery. The hypothesis governing much of this research is that heightened reactivity or impaired recovery not only stimulate acute increases in blood pressure, but lead to progressive vascular remodeling and dysregulation of autonomic, endocrine, and renal regulatory mechanisms, so that more responsive individuals are at increased risk. Acute psychophysiological stress testing has been the main method of investigation, which has been supplemented over recent years by ambulatory monitoring techniques.

Within this paradigm, several different types of study have been conducted. The simplest is the comparison of stress responses in hypertensives and normotensives. Since the work of Jan Brod in the 1950s, it has been known that hypertensives tend to show enhanced blood pressure responses to acute behavioral stress accompanied by greater renal vasoconstriction and increased norepinephrine turnover. However, it is possible that this exaggerated cardiovascular responsivity is the result of the complex physiological adjustments that occur in hypertension, and is secondary rather than primary. Additionally, awareness of high blood pressure influences cardiovascular, neuroendocrine and hemostatic responses, so studies of clinical samples may be compromised (Rostrup et al., 1991).

A second approach that attempts to overcome these problems is the study of people with normal blood pressure who are at increased risk for the development of hypertension in the future. Two risk factors, a family history of hypertension and raised blood pressure within the normal range, have been investigated. The principle underlying these studies is that if disturbed psychophysiological responsivity precedes the onset of the condition, then it should be present in people who have a raised risk. Many studies comparing young adults with and without these risk factors were carried out in the 1970s and 1980s, and were reviewed by Muldoon, Terrell, Bunker, and Manuck (1993) and more recently by Pierce, Grim, and King (2005). About one third of studies found that individuals with a positive family history showed greater blood pressure or heart rate stress reactivity than negative history groups. Much of this work has been criticized for the weak evaluation of family history, which often relies on reports by young people on their parents' medical condition, and classification on the basis of a single parent's history. Unfortunately, more recent studies that have involved more rigorous assessment of hypertension in both parents have continued to generate somewhat inconsistent results (de Visser et al., 1995; Gerin & Pickering, 1995; Manuck et al., 1996).

A number of factors may account for this inconsistency. First, the emphasis in most of the literature has been on heightened reactivity. Delayed recovery may be as important as an indicator of disturbances of normal

physiological regulatory processes, and several studies indicate that young normotensives at raised risk for future hypertension show impaired post-stress cardiovascular recovery (de Visser et al., 1995; Gerin & Pickering, 1995). Second, the psychological characteristics of participants may be important. In the light of the epidemiological literature outlined earlier, Vögele and Steptoe (1993) hypothesized that psychophysiological reactivity might be especially important among people who inhibit anger expression. They studied adolescent boys whose parents' blood pressure had previously been measured, and found heightened reactivity among those with high parental blood pressure who were also anger inhibitors. Third, it appears that differences in cardiovascular reactivity are more likely to emerge with actively demanding tasks eliciting sympathoadrenal activation, rather than other types of challenge. Pierce et al. (2005) have also argued that differences between positive and negative history groups are likely to emerge when the responses of negative history group are small, rather than there being a clear pattern of exaggerated reactivity in the positive history groups.

There is in addition an important limitation to the use of both family history and raised normal blood pressure to determine whether disturbances of psychophysiological reactivity precede the development of hypertension. That is, in both groups, there are already detectable changes in vascular physiology, including changes in cardiac morphology, increased end organ reactivity, and minimal arteriolar resistance, which may mean that disturbed reactivity is secondary rather than primary.

Longitudinal studies

Stronger evidence concerning the role of psychophysiological reactivity in the evolution of hypertension emerges from prospective studies. These test the possibility that high reactivity or impaired recovery predicts future rises in blood pressure. Early work on this topic was based primarily on the cold pressor test as a stimulus, and produced mixed results. Subsequent studies have assessed responses to actively challenging tasks; several large-scale investigations show that cardiovascular reactivity is an independent predictor of future elevated blood pressure (Carroll, Ring, Hunt, Ford, & Macintyre, 2003; Carroll et al., 2001; Markowitz, Raczyński, Wallace, Chettur, & Chesney, 1998). Impaired poststress recovery is also relevant. In a recent three-year followup of 209 middle-aged men and women, we found that increases in resting blood pressure were predicted by poor poststress recovery in systolic and diastolic blood pressure and in total peripheral resistance independently of baseline blood pressure, age, gender, socioeconomic status, hypertensive medication, body mass, and smoking (Steptoe & Marmot, 2005). The adjusted odds of an increase in systolic pressure ≥ 5 mmHg were 3.50 (95% confidence interval 1.19 to 10.8) for individuals with poor compared with effective post-stress recovery.

Nonetheless, findings have been somewhat inconsistent, primarily because of limitations in study design. Again

the issue of exposure to adverse experiences in everyday life is relevant, so in addition to evaluating cardiovascular reactivity, it is necessary to monitor exposure to life stress. Thus, Light et al. (1999) demonstrated that high stress reactivity predicted increases in blood pressure over a 10-year period only if it was associated both with family history and with high levels of daily stress. In the same vein, a 20-year followup of the Air Traffic Controller Health Change Study sample reported that risk of hypertension was increased among those who showed raised blood pressure reactions to chronic work stress (Ming et al., 2004). Including assessments of exposure to situations likely to provoke psychophysiological responses is likely to increase the strength of associations with future hypertension.

Inflammatory stress responses and hypertension

Psychophysiological investigations of hypertension have largely been limited to the measurement of cardiovascular and autonomic processes, but recent research has linked hypertension with inflammatory responses. Cross-sectionally, blood pressure is correlated with C-reactive protein, IL-6, sICAM-1, TNF α , and fibrinogen in population studies (Chae, Lee, Rifai, & Ridker, 2001; Chrysohou, Pitsavos, Panagiotakos, Skoumas, & Stefanadis, 2004). These inflammatory markers could be involved in hypertension pathogenesis in several ways, including stimulation of sympathoadrenal and HPA axes, effects on hemostasis, and direct influences on vascular remodeling (Intengan & Schiffrin, 2001; Pasceri, Willerson, & Yeh, 2000).

Psychophysiological studies of inflammation and hypertension are in their infancy. There is evidence that stress induced leukocyte adhesion is heightened in hypertensives compared with normotensives (Mills et al., 2003). Brydon and Steptoe (2005) found that individual differences in the acute stress responses of plasma IL-6 and fibrinogen predict 3-year changes in ambulatory blood pressure. The fact that these effects were independent of any association between future elevated blood pressure and cardiovascular reactivity suggests that there may be separate stress-related inflammatory pathways to hypertension. The challenge over the next decade is to discover whether these psychophysiological processes mediate the impact of psychosocial factors on hypertension.

Metabolic disorders

The metabolic disorders discussed here are diabetes and the metabolic syndrome. Diabetes mellitus is a heterogeneous metabolic disease, the central feature of which is high blood glucose (hyperglycemia). It is the leading cause of nontraumatic limb amputation, new cases of end stage renal disease, and blindness in adults (World Health Organization, 2002). It is a major cause of death in itself, while also contributing to CHD and stroke. The prevalence in the USA in 2002 has been estimated at 8.7% of adults aged 20 and over, of whom more than a quarter are undiagnosed

and, therefore, unaware of their condition. Prevalence rises to more than 18% of people aged 60 and over, and is lower in people of white European than African American or Hispanic descent.

There are two forms of diabetes, of which Type 2 is much the more common, accounting for some 90% of cases. Type 1 (insulin dependent diabetes) is due to failures in insulin secretion which result in there being insufficient insulin action on peripheral target tissues, while in Type 2 diabetes there is a diminished tissue response to insulin. Type 1 diabetes typically occurs in early life, and is an autoimmune condition in which the body's immune system destroys insulin-synthesizing beta cells in the pancreas. Type 2 diabetes is more likely of adult onset, and begins with insulin resistance, in which cells in tissues such as muscle, liver, and adipose tissue are not able to use insulin effectively. The need for insulin consequently rises, and the pancreas progressively loses its ability to produce insulin. Diabetes is associated with disturbances in protein, carbohydrate, and fat metabolism as well as hyperglycemia, and there is a hereditary component to both forms.

The metabolic syndrome is a constellation of cardiovascular risk factors that includes abdominal adiposity (a large waist circumference or waist/hip ratio), elevated blood pressure, high fasting glucose (hyperglycemia), and triglyceride levels, and low fasting high-density lipoprotein (HDL) cholesterol. It is strongly related to insulin resistance and, thus, to risk of Type 2 diabetes, so has a similar demography. Behavioral factors are relevant both to the development of Type 2 diabetes and the metabolic syndrome in which physical inactivity and eating habits lead to excessive energy intake and obesity being critical.

Several psychosocial factors apparently increase risk for diabetes and the metabolic syndrome. At least three prospective epidemiological studies have documented associations between depressive symptoms and future Type 2 diabetes that were independent of other risk factors (Musselman et al., *in press*). Diabetic individuals in turn have an elevated risk of depression, and depressed diabetics are prone to poor glycemic control and a high prevalence of diabetes complications (de Groot, Anderson, Freedland, Clouse, & Lustman, 2001). The relationship between insulin resistance and depression is less consistent with both positive and negative associations being described (Everson-Rose et al., 2004; Lawlor, Smith, & Ebrahim, 2003). In the Whitehall II epidemiological study, low SES, depression, and work stress (effort-reward imbalance) were related to future Type 2 diabetes and impaired glucose tolerance (Kumari, Head, & Marmot, 2004). Components of the metabolic syndrome have been associated with psychosocial factors such as low social support, hostility, and marital conflict (Horsten, Mittleman, Wamala, Schenck-Gustafsson, & Orth-Gomér, 1999; Knox, Weidner, Adelman, Stoney, & Ellison, 2004; Troxel, Matthews, Gallo, & Kuller, 2005). An analysis from the Normative Aging Study indicated that the metabolic syndrome when combined with hostility predicted a fourfold increase in

odds of developing a myocardial infarction over a 13-year follow-up period (Todaro et al., 2005).

Evidence concerning psychosocial factors and the development of Type 1 diabetes is more controversial, but Sepa, Wahlberg, Vaarala, Frodi, and Ludvigsson (2005) recently reported a study of 4,400 infants in which diabetes-related autoantibodies were more likely to be present in the blood of infants whose mothers experienced high parenting stress, life events and low education independently of family history of diabetes. By contrast, studies of stressful life events in adult life show no convincing association with onset of Type 1 diabetes (Cosgrove, 2004). Nonetheless, it has been found that psychosocial factors modulate glycemic control in type 1 diabetes with impaired control in individuals experiencing personal life stressors (Lloyd et al., 1999).

Psychophysiological processes

There has been relatively little conventional psychophysiological research in relation to Type 1 diabetes. Some investigators have investigated whether Type 1 diabetics show hyperglycemic responses to acute laboratory stress, but results have been inconsistent (Kemmer et al., 1986; Moberg, Kollind, Lins, & Adamson, 1994). Naturalistic studies involving simultaneous measures of everyday stress and blood glucose have shown positive associations only in a minority of individuals (Riazi, Pickup, & Bradley, 2004). Nevertheless, this is a topic that merits further investigation. A recent analysis of 188 Type 1 diabetics assessed whether associations between hyperglycemia and depression were mediated by poor self-care behaviors such as failure to monitor glucose, eat and exercise appropriately (Lustman, Clouse, Ciechanowski, Hirsch, & Freedland, 2005). It was found that these behaviors did not account for the relationship of depression to poor glycemic control, and suggested that more direct psychophysiological processes might be responsible.

There has been more work related to the Type 2 diabetes, metabolic factors, and obesity. One approach has been to assess acute lipid responses to stress. The concentration in the blood of total and low density lipoprotein (LDL) cholesterol increase following acute laboratory stressors, but there has been controversy about whether these effects represent increased lipids in the bloodstream or are secondary to reductions in blood volume (Muldoon et al., 1995; Stoney, Bausserman, Niaura, Marcus, & Flynn, 1999). The significance of individual differences in cholesterol responsiveness is uncertain, but Steptoe and Brydon (2005) have recently found that raised fasting LDL-cholesterol and total/HDL-cholesterol ratio were predicted by heightened cholesterol stress responses measured three years earlier.

Psychophysiological studies of abdominal adiposity in behavioral medicine and psychosomatics have explored both neuroendocrine and autonomic function. Abdominal adiposity is associated with disturbances of glucocorticoid function (Björntorp, 2001). A number of studies have demonstrated that cortisol responses to acute stress are

positively correlated with waist/hip ratio, although effects have been observed more consistently in women than men (Epel et al., 2000; Ljung et al., 2000). Naturalistic monitoring studies have shown that waist/hip ratio in men is correlated with the cortisol awakening response, which is a measure of cortisol secretion in everyday life that is regarded as a marker of stress-induced HPA dysregulation (Steptoe, Kunz-Ebrecht, Brydon, & Wardle, 2004).

There is also a relationship between obesity and cardiovascular stress responsivity. Both adults and adolescents with higher central adiposity exhibit heightened blood pressure responses during psychophysiological stress testing, which may be sustained by increased peripheral vascular resistance (Barnes, Treiber, Davis, Kelley, & Strong, 1998; Jern, Bergbrant, Bjorntorp, & Hansson, 1992). We recently assessed the relationship between cardiovascular reactivity and recovery and changes in waist/hip ratio over three years in a sample of 225 middle-aged men and women (Steptoe & Wardle, 2005). It was found that increases in waist/hip ratio were predicted by impaired poststress recovery of systolic blood pressure and cardiac output in men independently of baseline waist/hip ratio, age, SES, alcohol intake, and baseline cardiovascular function. It, therefore, appears that individual differences in psychophysiological responses may reflect patterns of dysregulation that contribute to the development of abdominal adiposity.

Psychophysiological research on the metabolic syndrome and insulin resistance is sparse to date. Certainly it appears that the metabolic syndrome is associated with increased excretion of cortisol and norepinephrine metabolites, raised levels of IL-6 and C-reactive protein, and reduced heart rate variability (Brunner et al., 2002). Abnormal vascular reactivity to stress has also been described (Sung, Wilson, Izzo, Ramirez, & Dandona, 1997), while studies of cortisol output in everyday life suggest that stress-related alterations in HPA function are also present (Rosmond, 2005). One study has demonstrated an association between cortisol/testosterone ratio and future CHD over a 16-year followup period that was independent of smoking, social class, and other confounders (Davey Smith et al., 2005). This relationship was markedly attenuated when insulin resistance was taken into account, suggesting that HPA effects may be mediated through metabolic pathways.

Infectious illness

Scientific research on the influence of psychosocial factors on risk of infections illness has been in progress for more than 40 years (Cohen & Williamson, 1991). In an early study, Meyer and Haggerty (1962) took throat swabs every three weeks from families over several months to assess the presence of streptococcal infection. An increased likelihood of both infection and overt illness was recorded during periods following acute life stress or daily hassles. Life

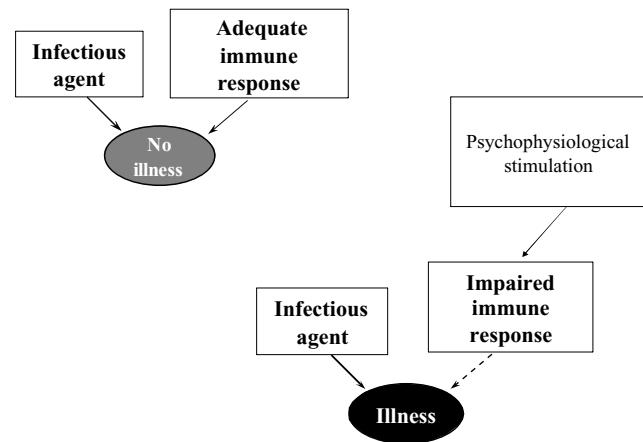

Figure 31.2. Schematic illustration of the interaction between host resistance, exposure to infection, and psychophysiological processes. The upper panel represents effective host resistance to infection, whereas in the lower panel, psychosocial stimulation has induced down-regulation of immune defenses, so that the infectious challenge leads to illness.

event stress was also found to predict upper respiratory tract infection in a later longitudinal family study as well, though effects were moderated by coping style (Turner Cobb & Steptoe, 1996). Associations between psychosocial factors and recurrent infections have also been described. Cohen, Kemeny, et al. (1999) studied 58 women with a history of genital herpes on a weekly basis over a six-month period. There were frequent herpes recurrences during the study period, and these were predicted by persistent stress (continuing for more than one week), after other factors had been taken into account.

It is plausible that these associations are mediated by psychophysiological processes, particularly impairment of host resistance. The immune system is responsible for defending the person against infectious agents such as bacteria, viruses, and fungi. There is ample evidence, as noted in other chapters in the *Handbook*, for stress and other psychosocial factors promoting downregulation of protective immune responses (Segerstrom & Miller, 2004). Figure 31.2 summarizes the possible sequence of events. The upper panel illustrates the pattern of healthy normal response to minor infections in which the individual mounts an adequate defense that excludes the infection and prevents illness. In the lower panel, exposure to the infectious agent takes place against a backdrop of impaired immune function because of psychosocial stimulation, and this is not sufficient to prevent illness from developing.

However, alternative pathways might be involved. First, there may be changes in exposure. Because infectious diseases are caused by pathogens, any changes in exposure that are stimulated by psychosocial factors may influence the chances of becoming ill. Some people respond to distressing events in their lives by seeking social support and mobilizing social networks, and this might have the unwanted effect of exposing the individual to more

respiratory infections. Alternatively, people may withdraw socially and reduce contact with airborne pathogens. Exposure to pathogens is a key issue in HIV/AIDS, and in the prevention of outbreaks of serious waterborne, airborne, and sexually transmitted infections in the developing world.

Second, health behaviors and lifestyle have an influence on infectious disease. Smoking, alcohol consumption, and physical exercise all influence vulnerability to infection and the duration of symptoms. Malnutrition is probably the principle cause of diminished immunity and susceptibility to infection across the world. Although severe protein energy malnutrition is rare in developed countries, undernutrition is common among the elderly and impairs immune resistance. The pattern of health behavior can be altered in response to psychosocial factors, such as work stress, so the acquisition and course of infectious disease may be modified. Behaviors can have direct effects on infectious disease, for example, when sexual behavior stimulates the reactivation of latent herpes virus, the acquisition of human papilloma virus, and subsequent risk of cervical cancer (Waller, McCaffery, Forrest, & Wardle, 2004).

Third, variations in symptom reporting may be involved. People differ in the extent to which they attend to physical sensations and recognize them as symptoms of illness. Illness behavior research has shown that the same infection, depending on levels of psychosocial stress, may elicit quite different levels of complaint, work absence, and health service utilization. Negative affect can influence symptom reporting and illness behavior with more symptoms being reported in distressed individuals independently of objective illness.

There are also plausible sequences of events that differ from the two possibilities outlined in Figure 31.2. One is that immune downregulation may occur in the absence of exposure to an active infection. Under these circumstances, a change in host resistance may have no adverse consequences. Another is that the infection is very severe and leads to illness, despite the mounting of a vigorous immune response. When this happens, it is not necessary to postulate any psychophysiological mediated alteration in immune function.

It is for these and other reasons that some research groups have turned to experimental studies as a means of understanding psychosocial influences. This approach has been championed by Sheldon Cohen, and has involved healthy volunteers being inoculated with standard doses of virus (Miller & Cohen, 2005). If an appropriate dose is administered, not everyone will become ill; thus, differences in the subsequent rates of infection and illness must then be due to differences in vulnerability. Social activities are limited by quarantine in these studies, and health behaviors such as smoking are controlled. Cohen, Tyrrell, and Smith (1991) demonstrated with this paradigm that susceptibility to common cold viruses was directly asso-

ciated with a psychological stress index created through an amalgam of measures of major life events over the past 12 months, perceived stress, and negative affect. The dose-response association was independent of age, allergic status, and other risk factors. Later work established that chronic stressors such as longterm work problems and relationship difficulties are particularly relevant. By contrast, social networks have a protective effect in which there is lower susceptibility to experimental infection among volunteers with more extensive and diverse social networks (Cohen et al., 1997). Associations with psychological characteristics such as negative emotional style and sociability have also been established (Cohen, Doyle, Turner, Alper, & Skoner, 2003).

Psychophysiological processes

This work clearly demonstrates that psychosocial factors can influence vulnerability to infectious disease. There has been less success in identifying psychophysiological mediators because susceptibility is not related to catecholamines, cortisol, or various markers of immune function. However, one study from Cohen's group showed that associations between psychological stress and the severity of symptoms were related to the levels of IL-6 production in the nasal passages following influenza virus administration. More severe symptoms were experienced by participants who reported higher perceived stress which was accompanied by raised IL-6 (Cohen, Doyle, & Skoner, 1999). This suggests that inflammatory mediators may be involved in symptom production in stressed individuals.

Another method of investigating psychophysiological processes in infectious illness is to study responses to vaccines and immunization. This approach is based on the fact that immunizations such as those for influenza, rubella, and hepatitis B involve injecting antigen (a foreign substance), which elicits an antibody response. The effectiveness of the immunization is indexed by the quantity of antigen-specific antibody that is produced over subsequent days and weeks. Although the literature is somewhat inconsistent, several studies have shown that antibody responses are impaired by psychosocial adversity. Two studies have shown that antibody responses following influenza vaccination are reduced in informal caregivers for dementing relatives compared with controls (Kiecolt-Glaser, Glaser, Gravenstein, Malarkey, & Sheridan, 1996; Vedhara et al., 1999). In one, concomitant disturbances in inflammatory cytokine production was observed, while in the other study, caregivers had heightened cortisol levels in the morning.

Laboratory-based psychophysiological studies can be used to understand these processes, though findings to date have been inconsistent. Marsland, Cohen, Rabin, and Manuck (2001) tested cardiovascular and immune responses to a stress test (simulated public speaking) in undergraduates who were undergoing a course of hepatitis B immunization. Lower antibody responses to the

vaccine were predicted by a diminished stress-induced lymphoproliferative response to phytohemagglutinin. Another smaller study of students found that poorer antibody responses were associated with low cortisol responses coupled with heightened cardiac output responses to acute stress (Burns, Ring, Drayson, & Carroll, 2002). Individual differences in corticosteroid responsivity have also been implicated in the expression and reactivation of latent viruses such as Epstein-Barr (Cacioppo et al., 2002). Phillips, Carroll, Burns, and Dryson (2005) reported that antibody responses to influenza vaccination were negatively associated with cortisol responses to mental arithmetic stress, and also with neuroticism. Findings of this type suggest that differences in cardiovascular, immune, and neuroendocrine regulation in response to stress are involved in impaired resistance to infectious illness. However, it remains to be seen whether these psychophysiological pathways mediate the links between life stress and infection.

Allergic and atopic conditions

The allergic disorders that have been investigated in behavioral medicine and psychosomatics include bronchial asthma and atopic skin conditions. Bronchial asthma is characterized by reversible airway obstruction, increased airway responsiveness to a range of stimuli, and airway inflammation. Atopic dermatitis is a chronic inflammatory skin disease characterized by eczematous inflammation of the skin, recurrent episodes, and severe pruritus (itchiness). These allergic conditions involve activation of allergen-specific T and B cells which produce allergen-specific immunoglobulins (i.e., IgE). There are thought to be distinct immediate and delayed phases of allergic conditions. Immediate responses result from the release of mast cell products, such as histamine, that have a variety of effects including smooth muscle contraction, mucus release, and increased capillary permeability. Different symptoms arise depending on the site of antigen contact. Delayed responses may occur after several hours and result from the synthesis of other mediators that stimulate the accumulation of eosinophils and basophils. The immune system, and in particular balance between Th1 and Th2 immune responses is critical, while in asthma autonomic control of airways caliber is also involved.

The National Health Interview Survey in 2001 in the USA estimated that more than 31 million (11.3%) Americans had been diagnosed with asthma at some point in their lives with around 20 million currently having asthma. There is a higher rate (14.4%) in children aged 5–17 years. The number of physician office visits for asthma is around 10.8 million annually. Women and African Americans have higher rates than men and white Europeans. There are ethnic variations in other atopic conditions as well, and African Americans more likely to seek medical care for dermatitis than people of white European origin (Janumpally,

Feldman, Gupta, & Fleischer, 2002). The economic cost of asthma in direct health costs and lost productivity has been estimated at \$14 billion annually.

Quality of life is adversely affected by many atopic conditions, and anxiety and depression are frequent. In allergic dermatitis, associations between depression and the extent of body surface affected have been found, and depression is closely linked with the perception of pruritis (Gupta & Gupta, 2003). A recent review concluded that in both child or adolescent and adult groups, about one third of people with asthma meet the criteria for a comorbid anxiety disorder (Katon, Richardson, Lozano, & McCauley, 2004). These psychological difficulties may have an impact on self-care and functional status. In a followup conducted among asthmatic patients admitted for emergency care, elevated anxiety or depression was associated with an increased risk of relapse (Dahlen & Janson, 2002). However, a study of risk factors associated with asthma death in a large representative sample in the UK showed no association with a number of psychosocial factors including family problems, domestic abuse, or social isolation. Financial difficulties and psychosis did increase risk, while prescription of antidepressant medications was protective (Sturdy et al., 2002). There have been few prospective studies of infants and young children susceptible to atopic disorder. But in work on newborns at elevated genetic risk of atopy, Wright, Cohen, Carey, Weiss, and Gold (2002) found that stress reported by caregivers over the first three months of the infants' lives was associated with wheeze at 14 months independently of other risk factors such as smoking, low SES, and parental asthma. A direct psychophysiological link between psychosocial experience and atopy is therefore plausible (Wright, Cohen, & Cohen, 2005).

Psychophysiological processes

Atopic conditions are especially interesting from the psychophysiological point of view because processes that are thought to be potentially pathological for other health problems are beneficial for this group of disorders. In particular, corticosteroids have a positive anti-inflammatory effect on asthma and atopic skin conditions and are widely used therapeutically. Medications that mimic sympathetic nervous system activation have favorable effects on bronchial asthma, while heightened activity in the vagus causes bronchoconstriction. Thus the psychophysiological pathways that are implicated in mediating risk in many other conditions appear to have positive effects in atopic disorders.

Early psychophysiological studies of asthma focused on the responses of the airways to challenge and showed that asthmatics display bronchoconstrictive responses while healthy individuals do not (Steptoe, 1998). Subsequently, Ritz, Steptoe, DeWilde, and Costa (2000) found that increased airways resistance emerged not only with stressful tasks but also in response to emotional stimuli

with both positive and negative valence. Interestingly, airways responses to negative emotional stimuli in the laboratory were associated with alterations in airways function that occurred with negative mood states in everyday life, which indicates some generalizability of responses to standardized testing (Ritz & Steptoe, 2000).

There is growing evidence that atopic individuals display inhibited stress-related HPA responsiveness. For example, Buske-Kirschbaum et al. (1997) reported that children with atopic dermatitis produced lower cortisol responses to standardized challenges than nonatopic controls, and a similar pattern was observed in asthmatics (Buske-Kirschbaum et al., 2003). This pattern was replicated in a larger sample of adolescents with a range of atopic conditions including allergic rhinitis (Wamboldt, Laudenslager, Wamboldt, Kelsay, & Hewitt, 2003). Interestingly, this pattern may not be present from birth, but evolve during the early years of life. A recent study tested the stress responsivity of newborn babies by assessing cortisol responses to a standard heel prick (Buske-Kirschbaum, Fischbach, Rauh, Hanker, & Hellhammer, 2004). The offspring of parents with atopic conditions showed larger rather than smaller cortisol responses than controls, the opposite of the pattern observed in people with established atopy. It may be that this early hyperreactivity is followed by down-regulation of the HPA axis in later years with a corresponding increase in allergic responses.

As noted earlier, acute inflammation in atopic conditions is controlled by activated T lymphocytes and the Th1/Th2 balance. Th2-type cytokines promote the production of IgE. It is possible that the neuroendocrine responses manifest in atopic individuals shift the immune balance towards Th2 responses. Consistent with this hypothesis, Wright et al. (2004) observed in their birth cohort that family stress when the infant was 6–18 months old was correlated with increased IgE expression and with levels of the Th2 cytokine TNF α . This is an area of research in which psychophysiological methods are poised to make a major contribution to behavioral medicine through helping to tease out the complex interaction between psychosocial experience, neuroendocrine, and immune function.

Autoimmune conditions

Autoimmune conditions are a disparate collection of chronic medical disorders in which the immune system attacks the body's own biology instead of alien material, which leads to inflammation and other problems. Because hormones and neurotransmitters regulate the activity of the immune system, it is possible that psychophysiological processes are involved in the development and progression of autoimmune conditions. Most research has focused on neuroendocrine and inflammatory processes in autoimmune conditions, though work on autonomic function is becoming more prominent. Several autoimmune

conditions have been investigated, but this chapter will highlight two topics – rheumatoid arthritis and multiple sclerosis.

Rheumatoid arthritis

Rheumatoid arthritis is a systemic disease involving inflammation of the synovial membrane that lubricates joints, which leads to erosion of cartilage and bone. T cells, B cells, cytokines, and macrophages are produced locally by these cells and contribute to joint deformation. Inflammation and deformation of joints are responsible for the pain in rheumatoid arthritis. The disease affects multiple organs and is associated with increased risk of CHD and other health outcomes. No specific cause has been identified that initiates the autoimmune response, but this becomes self-perpetuating. Prevalence is around 1–3% of the adult population with peak occurrence between the ages of 30 and 55 years, and the condition is more common in women than men. Incidence is higher in Native Americans, African Caribbean, and Asian groups than in Caucasians. A particularly distressing form is juvenile idiopathic arthritis, an inflammatory joint disease of childhood, some forms of which are irreversible.

There is an extensive literature concerning the role of life stress in the etiology of rheumatoid arthritis (Herrmann, Scholmerich, & Straub, 2000). Almost all studies have been retrospective and results have been mixed, although findings have been more consistently positive for juvenile forms. The evidence is stronger for psychosocial factors exacerbating the course of rheumatoid arthritis. More than a dozen prospective studies have shown that minor life stress predicts future disease activity (Herrmann et al., 2000). The presence of depression, a common concomitant of rheumatoid arthritis, amplifies the effect of interpersonal stress on disease activity (Zautra et al., 2004). There is also some evidence that emotional support is protective, although at least one large study has found cross-sectional but not longitudinal associations between social support or networks and functional limitations and distress in rheumatoid arthritis (Demange et al., 2004).

An interesting feature of autoimmune conditions shared with atopic conditions is that corticosteroids, normally released during emotional stress, are immunosuppressive. Indeed, they are widely used in the treatment of rheumatoid arthritis. Norepinephrine is also immunomodulatory. It might, therefore, be hypothesized that psychosocial adversity stimulates an impaired HPA response, so that inflammatory reactions are not inhibited. Animal studies certainly indicate that blunted HPA activity is associated with increased susceptibility to arthritis (Sternberg, 2001). Unfortunately, experimental psychophysiological studies of humans are very limited. However, Jacobs et al. (2001) found that acute stress induced a blunted interferon- γ response in rheumatoid patients,

while increased C-reactive protein responses to stress have also been described (Veldhuijzen van Zanten, Ring, Carroll, & Kitas, 2005). An increase in IL-6 production following acute stress is present in juvenile rheumatoid arthritis patients but not age-matched controls, despite comparable norepinephrine responses (Roupe van der Voort, Heijnen, Wulffraat, Kuis, & Kavelaars, 2000). The time course of neuroendocrine and inflammatory responses following behavioral change is clearly crucial, and sympathetic stimulation may have both pro and anti-inflammatory effects (Straub, Dhabhar, Bijlsma, & Cutolo, 2005). For example, Viswanathan and Dhabhar (2005) have demonstrated how acute stress induces increased trafficking of leukocytes to the site of immune activation in animals. This may enhance immunoprotection during infection or surgery, but exacerbate pathology in autoimmune conditions.

Multiple sclerosis

Multiple sclerosis involves inflammatory damage to the myelin sheath of neurons in the central nervous system. It is a relapsing-remitting illness with many clinical manifestations including double vision, unsteady gait, poor coordination, weakness of the limbs, and slurred speech. It is fortunately relatively rare, and preferentially affects people of Caucasian origin. One reason why it may be particularly relevant to psychophysiological investigation is that disease exacerbations and relapses may be triggered by emotional factors (Brown, Tennant, Dunn, & Pollard, 2005). A meta-analysis of 14 studies relating stressful life events with disease exacerbation was published by Mohr, Hart, Julian, Cox, and Pelletier (2004). A consistent positive association was observed with a medium effect size ($d = 0.53$). An increased risk of onset of multiple sclerosis following the very severe trauma of the death of a child has been seen in one large study (Li et al., 2004), but otherwise data concerning psychosocial factors and disease onset are limited.

As with the psychophysiological research on other autoimmune conditions, it appears that immune responses to standardized behavioral challenge are disturbed in multiple sclerosis. Heesen et al. (2005) compared 23 patients with 25 controls in their responses to a 40-minute cognitive challenge. The multiple sclerosis patients had a reduced heart rate response to the task and showed a blunted interferon- γ response, which suggests autonomic dysfunction coupled with impaired TH-1 stress reactivity. Blood pressure and heart rate stress responses were assessed at the start of a year-long study of multiple sclerosis disease exacerbation by Ackerman et al (2003). Over the year, exacerbations of disease state were more likely in periods following the experience of stressful life events than at other times, while greater cardiovascular stress reactivity also predicted the number of disease flares. In multiple regression analysis, disability level, medication use, cardiovascular reactivity, baseline heart rate, and life events together explained 30%

of the variance in the proportion of weeks during which patients were ill. The results of these studies are, therefore, somewhat mixed, but suggest that further psychophysiological investigation of multiple sclerosis will prove fruitful.

Musculoskeletal conditions

Musculoskeletal disorders constitute a range of syndromes including low back pain, neck and shoulder pain, repetitive strain injury, carpal tunnel syndrome, tendonitis, and others. Many musculoskeletal disorders are work related and a major public health problem. According to the National Institute for Occupational Safety and Health in the USA, musculoskeletal disorders affect 7% of the population, and account for 19% of hospital stays. It has been estimated that nearly 70 million physician office visits occur annually because of musculoskeletal disorders, and that in 1999 around one million Americans were off work because of treatment for or recovery from work-related musculoskeletal pain (Institute of Medicine, 2001). The annual cost is a staggering \$50 billion as a result of compensation, lost earnings, and lost productivity. These conditions differ from many other major health problems in that symptoms can appear early in life and after a relatively short exposure to adverse environmental conditions. In repetitive work, for example, pain syndromes may be reported after only 6–12 months on the job.

The role of bad ergonomic conditions at work, heavy lifting, and physically monotonous or repetitive work in the development of neck, shoulder, and lower back pain problems is well established (Institute of Medicine, 2001). What is remarkable, however, is that the considerable ergonomic improvements of the work environment over recent decades have not resulted in a reduced incidence of musculoskeletal disorders, and that musculoskeletal disorders are frequent not only in physically demanding jobs but also in light physical work (Lundberg, *in press*). This indicates that other factors are involved.

There is substantial evidence linking psychosocial aspects of work with upper extremity musculoskeletal problems (Sauter & Moon, 1996). Factors such as low autonomy, lack of role clarity, low job satisfaction, and high work pressure, have all been associated with pain in the neck and shoulder regions, and with hand or wrist problems. A recent systematic review confirmed these observations, but also pointed to evidence relating upper extremity problems with psychosocial factors outside work such as low social support and general stress (Bongers, Kremer, & ter Laak, 2002). For example, a large survey of working people in Finland showed that the prevalence of nonspecific shoulder pain was 12% and was positively associated with burnout and depression (Miranda, Viikari-Juntura, Heistaro, Heliovaara, & Riihimaki, 2005). Prospectively, a study of workers in diverse occupations initially assessed near the beginning of their employment revealed that the onset of new pain conditions over the following year was

predicted by initial psychological distress, job demands, and low social support at work (Nahit et al., 2003). In a 12-month investigation of car mechanics, low job control and low social support were the best predictors of new cases of neck and low back pain after adjustment for baseline measures (Torp, Riise, & Moen, 2001). Nor are these problems confined to workers in Western countries. Recent work with nurses in China has documented a high prevalence of musculoskeletal complaints that were associated with high mental pressure, boring, repetitive tasks, and low social support at work (Smith, Wei, Zhao, & Wang, 2004). Work-related upper extremity disorders are particularly common in jobs with a static load involving monotonous and repetitive tasks, even when physical demands are only low or moderate. Computer data entry, cashier work in supermarkets and other outlets, routine scientific bench work, and traditional assembly line work all have these characteristics. Musculoskeletal problems are particularly common among women, partly because they are likely to work in these lower status jobs, and partly because much ergonomic design is still based on male stature and physique (Klumb & Lampert, 2004).

Psychophysiological processes

Much research on musculoskeletal disorders is based on self-report or physical examination. However, direct measurement of muscle tension using surface electromyography (EMG) provides valuable additional information. Miniaturized transducers and telemetric equipment are available that allow readings to be obtained from free-moving individuals. Positive correlations have been reported between objectively assessed muscle tension and feelings of stress and exhaustion during work, but correlations with pain are often not obtained (e.g., Rissen, Melin, Sandsjo, Dohns, & Lundberg, 2000). Studies of this kind indicate that the perception and appraisal of muscle tension may be important as well as objective differences in tension.

Laboratory experiments provide clues about how psychosocial factors might contribute to the development of musculoskeletal problems by interacting with physical demands. Marras, Davis, Heaney, Maronitis, and Allread (2000) monitored trunk motion and EMG while 25 volunteers carried out lifting tasks with different degrees of trunk extension. The tasks were carried out under stressed and unstressed conditions. In the stress condition, feedback to participants about their movement and speed was manipulated to indicate that they were failing task demands, which led to verbal criticism from the experimenters. It was found that stress increased spine compression and lateral shear because of increased activity of several trunk muscles. Similar effects have been observed in response to mental processing tasks being performed at the same time as lifting tasks with substantial increases in spine loading and compression coupled with less controlled movements and greater muscle coactivation (Davis,

Marras, Heaney, Waters, & Gupta, 2002). Such patterns could increase risk for low back pain.

Musculoskeletal disorders are also common among people engaged in light physical work with effects on muscle tension that can be very subtle. Even computer work using a mouse elicits increases in EMG in the forearm, shoulder and neck, and there is greater tension when people are performing more mentally demanding tasks (Laursen, Jensen, Garde, & Jorgensen, 2002). Interestingly, these differences are also associated with shifts in heart rate variability towards sympathetic activation and vagal withdrawal (Garde, Laursen, Jorgensen, & Jensen, 2002). It is possible that sustained or repeated low-level muscle activity induced by psychological demands may initiate a pathogenic mechanism resulting in muscle pain.

Lundberg (*in press*) has pointed out that unlike the physical demands of work that stop with the end of the work period or during breaks, psychosocial issues are persistent. Concern about job satisfaction, low income, work-home conflict, and interpersonal relationships at work are experienced on a more sustained basis, both before and after work. A psychophysiological concept that may be relevant to this difference is that of EMG silence or "gaps." These are episodes in which muscular electrical activity is very low. It has been hypothesized that short periods during which muscle tension is very low are essential to avoid shoulder and neck problems. Hägg and Astrom (1997) compared medical secretaries with and without musculoskeletal complains during their work, and found that the former had fewer EMG gaps during the day. A prospective study of industrial workers found that women who developed trapezius myalgia over the first year of employment had higher muscle activity during breaks at work but not during actual work than those who remained healthy, and had fewer EMG gaps (Veiersted, Westgaard, & Andersen, 1993). Such findings indicate that lack of relaxation during breaks at work and after work may be an important risk factor for musculoskeletal disorders.

Commonalities

It will be apparent from this discussion of psychophysiological contributions to understanding the etiology and maintenance of physical illnesses that quite different types of relationship operate with different health outcomes. In conditions such as CHD, hypertension, and some metabolic and musculoskeletal disorders, the psychosocial evidence suggests that causal relationships may be present, and aberrant psychophysiological responses may contribute to the primary etiology of the condition. Such effects are best studied in longitudinal, population-based studies, which inevitably involve larger samples and longer time frames than are typically implemented in psychophysiology. In health problems related to infection, psychophysiological processes do not play a direct etiological role, but may have a permissive function in modulating host resistance so that the primary pathogen

has a greater or lesser chance of causing disease. The research designs required to study these processes are quite different and involve experimental infection or more intense longitudinal tracking of the covariation between psychophysiological factors, exposure to pathogens, and illness. In a third set of health conditions including atopic and autoimmune illnesses, it is likely that the primary role of psychophysiological processes is in modulating disease course and mediating acute exacerbations in people with pre-existing illnesses. Investigations of these pathways require a clinical research approach and intensive studies of patients, so as to assess their psychophysiological responses to different life experiences and subsequent effects on health status.

Nevertheless, there are a number of commonalities across health problems in psychophysiological studies of disease etiology and progression in behavioral medicine and psychosomatics. The first is the importance of the interplay between background psychosocial conditions (e.g., life stress, social factors, and psychological characteristics), the acute or immediate psychosocial environment (e.g., momentary demands) and biological responses. These relationships must be understood if psychophysiological factors are to be put in context. Second, it is apparent that recent research in behavioral medicine and psychosomatics emphasizes the balance of responses in different physiological systems, rather than simple hyper-reactivity. Some health conditions are associated with reduced physiological activity and some with heightened activity, but the complex interplay between biological systems always needs to be taken into account. Finally, it is striking how little research there has yet been into the manipulation of psychophysiological responses in order to understand disease etiology. A key tool in the armory of biomedical research is to interrupt postulated causal pathways in order to see whether this has the anticipated effect on the health outcome. There is of course extensive work on treatment in behavioral medicine, but little intervention with pharmacological, behavioral, or psychosocial methods in order to understand mechanisms. As these disciplines become more mature, it is essential that this approach be developed.

PSYCHOPHYSIOLOGY AND THE MANAGEMENT OF PHYSICAL ILLNESS

Much of the original impetus for behavioral medicine came from the promise of psychophysiological methods for managing physical illness. In the 1970s and 1980s, there was hope that biofeedback would revolutionize the treatment of chronic illness, allowing patients to become responsible for their own care by self-regulation of physiological functions that had not previously been regarded as amenable to voluntary control. Biofeedback was developed for the management of conditions such as epilepsy, hypertension, migraine, tension headache, asthma, and incontinence. Other psychophysiological techniques like progres-

sive muscle relaxation and autogenic training were also brought into play and were advocated for the management of stress, tension, and psychosomatic problems.

The optimism surrounding these direct applications of psychophysiological techniques dissipated for a number of reasons: limited efficacy in randomized controlled trials, the immense amount of intervention required to generate effects (often incompatible with the constraints of managed care), the growth in clinical psychology of the cognitive-behavioral movement, and the introduction of more effective pharmaceutical agents. Biofeedback and allied methods have never joined the mainstream of medical care, but flourish in the complementary and alternative medicine sector. For example, the Association for Applied Psychophysiology and Biofeedback recommends the use of these methods for more than 30 conditions, including various types of pain, psychological, and behavioral problems such as anxiety, insomnia, and substance abuse as well as number of chronic medical conditions.

Nevertheless, the development of integrated stress management methods has led to psychophysiology retaining an important role in the management of physical illness. In this section, I will summarize evidence for the effects of direct psychophysiological therapies such as biofeedback and relaxation in the treatment of physical illness, then outline ways in which psychophysiological methods illuminate broader behavioral treatments such as cognitive-behavioral stress management.

Direct psychophysiological therapies

Direct psychophysiological therapies are treatments or interventions in which physiological monitoring plays a central role. The archetypal direct therapy is biofeedback, and this is applied in two different ways. First, biofeedback can involve the monitoring and provision of a feedback signal from the physiological measure, which is disturbed in a clinical condition, such as blood pressure in hypertension, blood flow in Raynaud's syndrome, and airways resistance in asthma. Second, biofeedback may involve learning voluntary control over a physiological system that is not a direct index of the disorder, but a correlate of it; two examples are the use of heart rate variability biofeedback in asthma and skin conductance biofeedback for hypertension. Biofeedback used in this way is often an adjunct to other direct physiological self-regulation therapies such as muscle relaxation and meditation techniques.

Hypertension

Direct blood pressure feedback was difficult to develop when biofeedback first emerged because conventional measures of blood pressure with a sphygmomanometer provide a reading every 30–60 seconds at best. If patients were provided with feedback of these readings, they would receive information about fewer than 5% of cardiac cycles, as well as ending up with rather sore arms through repeated squeezing. Imaginative adaptations of standard

sphygmomanometry and indirect measures of blood pressure were devised, but curiously little research has used the continuous finger blood pressure measurement instruments based on vascular unloading such as the Finapres and Portapres. More research has been carried out with other psychophysiological methods like relaxation, thermal feedback, and meditation.

The methodological quality of research in this area has been limited with small samples, nonrandomized designs, inadequate comparison conditions, and poor characterization of participants (Blumenthal, Sherwood, Gullette, Georgiades, & Tweedy, 2002). A recent meta-analysis of studies using Transcendental Meditation, for example, was only able to locate one randomized trial that had involved documented hypertensives, even though the method has been advocated for this condition (Canter & Ernst, 2004). Another major difficulty lies in the establishment of an adequate baseline blood pressure against which to assess changes. Even if patients are not white coat hypertensives, levels tend to diminish with repeated testing, so treatments might apparently have effects that actually are due to adaptation. This was evident in Johnston et al.'s (1993) comparison of relaxation-based stress management with control procedures in 96 hypertensive patients. The intervention was preceded by a 12-week baseline period, during which blood pressure continued to fall, so that stress management generated no additional effect. Meta-analysis of relaxation and biofeedback studies in hypertension indicates that effects are no greater than those stimulated by nonspecific behavioral treatment comparisons (Nakao, Yano, Nomura, & Kuboki, 2003). It is notable that in evidence-based guidelines, direct psychophysiological approaches such as relaxation and biofeedback are given little attention compared with behavioral methods such as weight reduction through physical activity and dietary change, restriction of salt intake, control of alcohol intake, and methods of improving adherence to medication (Chobanian et al., 2003).

Bronchial asthma

Asthma might be considered a more promising target for psychophysiological treatments because direct noninvasive measures of lung function and airways resistance are available. However, the implementation of direct biofeedback of airways function has proved difficult with only limited effects after prolonged training (Ritz, Dahme, & Roth, 2004). One difficulty is that patients often resort to active respiratory maneuvers to reduce airways resistance, for example, increasing functional residual capacity, and these are not therapeutic in the long run. Indirect feedback of frontalis EMG has generated more positive effects, but studies have suffered from various design flaws (Ritz et al., 2004).

A promising application of heart rate variability biofeedback was recently developed by Lehrer and coworkers (2004). Ninety-four adult asthmatics were randomized to heart rate variability feedback coupled with abdominal

breathing training, heart rate variability feedback alone, placebo biofeedback (EEG training), and waiting list control. The study involved extensive respiratory assessments and monitoring of medication by a physician blinded to treatment allocation. The two heart rate variability feedback groups showed significant reductions in medication over the 10-week treatment in comparison with controls. This result is intriguing, not least because it appears to be contrary to the known effects of autonomic regulation on asthma. As noted on page 736, increases in parasympathetic or vagal activity stimulate bronchoconstriction. Heart rate variability biofeedback is intended to increase parasympathetic control, so precisely how it may promote bronchodilation is puzzling (Ritz et al., 2004).

Epilepsy

One of the earliest applications of biofeedback involved the monitoring of EEG and provision of feedback to epileptics of rhythms considered to be incompatible with seizure activity (Sterman, 2000). Despite the efforts of pioneers in this field, the approach has remained experimental and has been little used outside a few centers. Promising results have been reported for the self-regulation of slow cortical potentials with substantial reductions of seizure activity in about a third of patients who adhere to training (Strehl, Kotchoubey, Trevorrow, & Birbaumer, 2005). However, few clients and physicians have the patience and resources to persist with the prolonged training over months that appear to be required.

Pain conditions

Behavioral medicine approaches to the management of pain in arthritis and cancer have not been psychophysiological in orientation, but have emphasized coping skills training, emotional disclosure and pain education (Keefe, Abernethy, & Campbell, 2005). The pain conditions in which psychophysiological methods have been more prominent are in migraine and tension-type headache. The early applications of psychophysiological methods were based on pathophysiology models that emphasized the role of contraction of muscles in the head and neck in the etiology of tension-type headache and the effects of paroxysmal vasodilation of the cranial circulation in migraine headache (Holroyd, 2002). Thus, thermal feedback, relaxation, and EMG biofeedback were applied to migraines, while EMG feedback and relaxation were the main methods used with tension-type headaches.

These pathophysiological models have been revised substantially over recent years. Tension-type headaches are now thought to result from central nervous system (CNS) dysfunction rather than heightened peripheral nerve input with sensitization of pain pathways and reduced thresholds for transmission to higher centers (Ashina, 2004). Migraine is thought to be a CNS rather than vascular problem in which there are disturbances in activation of the trigeminal innervation of the vascular system and CNS

modulation of trigeminal pain (Goadsby, 2005). Nevertheless, meta-analyses indicate that behavioral treatments are efficacious, with effect sizes of 0.75 to 1.25 for relaxation, biofeedback, and other psychophysiological methods (Holroyd, 2002). The explanation may be that these techniques work through cognitive-attributional pathways rather than directly through regulating physiological dysfunction, although it should be pointed out that many studies have involved small samples of nonrepresentative participants with weak control conditions and limited evidence of generalisability (Rains, Penzien, McCrory, & Gray, 2005). These problems need to be rectified if psychophysiological methods are to gain widespread acceptance as therapies.

Psychophysiological aspects of behavioral treatments

As noted earlier, many of the interventions and treatments used in behavioral medicine and psychosomatics are not psychophysiological in orientation, but involve techniques such as cognitive-behavioral therapy, attitude change, coping skills training, behavioral modification, and social support intervention (Slater et al., 2003). The emphasis even in the management of disorders such as hypertension, diabetes, and arthritis is not on psychophysiological methods, but lifestyle modification, self-monitoring, education, and skill training (Astin, Beckner, Soeken, Hochberg, & Berman, 2002; Blumenthal et al., 2002; Ismail, Winkley, & Rabe-Hesketh, 2004). Nevertheless, psychophysiology has a role to play in the broader remit of behavioral medicine, even when it is not the primary intervention modality.

Objective indicators of physiological change

The first role of psychophysiology is to provide objective information about the impact of cognitive-behavioral methods on biological function. It has been known for many decades that the effect of relaxation training and other behavioral arousal control methods is the reverse of stress activation, which result in reduced muscle tension, lower heart rate and blood pressure, and increases in alpha wave activity in the EEG. These effects of stress management on biological function have been confirmed with measures of neuroendocrine and autonomic activity. For instance, Antoni and colleagues (2000; 2000) randomized HIV+ men to group-based cognitive-behavioral stress management or a waiting list control condition. After the 10-week training period, there were significantly lower levels of anxiety and perceived stress following stress management coupled with reduced 24-hour excretion of norepinephrine and cortisol. The reduction in cortisol correlated with decreases in depressed mood, while anxiety changes correlated with norepinephrine responses. The evaluation of other behavioral interventions also benefits from psychophysiological assessment. An example is the effect of exercise training on resting heart rate, which is thought to be due partly to enhanced vagal modula-

tion. Sandercock, Bromley, and Brodie (2005) have carried out a meta-analysis of heart rate variability measures in response to exercise training. In 13 studies assessing heart rate variability by spectral analysis, there was a consistent increase in high frequency power with a medium effect size of 0.48.

The impact of behavioral intervention on disease markers

The psychophysiological measures described in the last section were employed as nonspecific indicators of physiological activation. A more interesting use of psychophysiology is in evaluating the impact of behavioral interventions on processes that are directly related to disease. In these applications, psychophysiology provides information about the effects of treatments on the putative biological targets of therapeutic effects. At its simplest, this merely involves the measurement of a biological marker of disease state. For instance, the majority of psychological interventions for the management of Type 2 diabetes have involved assessments of blood glucose level or glycated hemoglobin as markers of glycemic control (Ismail et al., 2004). But nuanced evaluations are also possible.

An instance is the assessment of the effects of emotional disclosure. The idea that the written expression of emotional material might be therapeutic was formulated by Pennebaker in the 1980s. Since then, numerous studies have reported potential benefits in relatively healthy groups in terms of physician visits, mood, and self-rated health (Smyth, 1998). Effects have also been recorded on symptom levels in conditions such as rheumatoid arthritis and fibromyalgia (Broderick, Junghaenel, & Schwartz, 2005; Smyth, Stone, Hurewitz, & Kaell, 1999). One problem with such findings is that they might reflect effects on symptom reporting and subjective status only and not on objective function. Psychophysiological methods have, therefore, been used to corroborate these results and discover whether effects are present at the biological level as well. Smyth et al. (1999) randomized asthmatic patients to write about stressful events or emotionally neutral topics, and found four months later that lung function assessed spirometrically had improved by more than 15% in the emotional disclosure group. Unfortunately, this effect has not been replicated in a more recent trial (Harris, Thoresen, Humphreys, & Faul, 2005). Petrie, Booth, Pennebaker, Davison, and Thomas (1995) examined the impact of emotional expression on antibody responses to vaccination. Forty medical students wrote about personal traumatic experiences or neutral topics for four consecutive days. They were then vaccinated against hepatitis B and antibodies were assessed at four and six months. The antibody levels were greater in the emotional expression group, and are indicative of more effective immune responses to the vaccination. Favorable effects on immune function in HIV+ individuals have also been observed (Petrie, Fontanilla, Thomas, Booth, & Pennebaker, 2004).

A more elaborate use of psychophysiological methods to evaluate behavioral intervention is found in a recent study of the effects of physical activity training and stress management in CHD patients (Blumenthal et al., 2005). One hundred thirty-four patients with documented CHD were randomized to routine care, 16 weeks of supervised aerobic training or 16 weekly sessions of stress management, which involved education, coping skills training, relaxation training, and social support. The evaluation included assessments of mental stress-induced myocardial ischemia and cardiac wall motion abnormalities (see page 729), vascular endothelial function, and heart rate variability. It was found that after training, both the aerobic and stress management groups showed reduced myocardial ischemia in response to mental stress, and improved endothelial function. Additionally, heart rate variability and baroreceptor reflex sensitivity were enhanced in the stress management condition but not the aerobic training group. These findings suggest that the behavioral interventions had positive effects on markers of clinical risk, even though the study was not large enough to detect differences in hard clinical endpoints.

Combining psychophysiological with medical interventions

One of the principal methods of determining causality in biomedical research is to modify putative causal pathways and assess impact on outcome. Unfortunately, psychophysiological methods have not yet been used extensively to test causal models in this way, for example, by blocking physiological responses to determine whether they are the mediators of psychosocial influence on disease. Such an approach has been used in animal research, for example, by using beta-adrenergic blockade to assess whether sympathetic activation mediates the impact of social stress on atherosclerosis development in primates (Kaplan, Pettersson, Manuck, & Olsson, 1991). At present intervention approaches have yet to be exploited fully in psychophysiological research in many health care settings.

Nevertheless, a limited amount of research has combined psychophysiological with pharmacological methods in disease management. A good example is the combination of relaxation-based stress management and antidepressants in the treatment of tension-type headaches reported by Holroyd et al. (2001). Two hundred three chronic headache patients were randomized to tricyclic antidepressants, antidepressants combined with brief stress management training, stress management plus placebo medication, or placebo medication only. Both antidepressants and stress management stimulated larger reductions in headache activity, disability, and analgesic use than did placebo, but the effects of antidepressants were more rapid. Interestingly, a higher proportion of patients in the combined treatment group showed clinically significant ($\geq 50\%$) reductions in headache index scores than did those in the antidepressant only condition

(64% versus 38%), and suggests that a combined approach may be fruitful.

CONCLUSIONS

Psychophysiology is a pivotal discipline in behavioral medicine and psychosomatics, and complements work in the psychosocial, behavioral, and cognitive domains. Psychophysiology plays a central role in understanding how life experiences and psychological characteristics relevant to health get under the skin and affect the development and management of physical health problems. The panoply of psychophysiological methods has still not been fully exploited in behavioral medicine. Techniques such as CNS imaging, genetic analysis, and molecular biological approaches to gene expression will become more prominent in this field over the next decade. We are also likely to see greater integration of behavioral medicine work on systemic diseases with studies of behavioral and psychiatric problems. Already there are commonalities emerging, for example, in research linking central serotonergic function both with problems of depression and aggression as well as with cardiovascular and metabolic disease (Manuck, Flory, Muldoon, & Ferrell, 2002; Muldoon et al., 2004). At the same time, behavioral medicine and psychosomatics must prompt psychophysicists to take a broader conceptualization of their discipline. Population-based approaches to study sampling, as opposed to the psychophysiological tradition of convenience sampling, is becoming mandatory in this context. The integration of psychophysiological techniques into biomedical etiological studies requires larger samples and prospective designs. The evolution of clinical trials methodology embodied in consensus documents such as the CONSORT guidelines means that psychophysicists need to attend to a wider set of design issues if they wish their work to become part of evidence-based medicine (Moher, Schulz, & Altman, 2001). Psychophysicists working in behavioral medicine and psychosomatics are taking up these challenges and this is likely to result in a new era of research in which psychophysiological methods have an even greater impact on health and health care.

RUSS J. PARSONS

1. INTRODUCTION

Every scientific psychology must take into account whole situations, i.e., the state of both person and environment. (Lewin, 1936, p. 12)

In this chapter we examine how psychophysiological constructs and methods can be used to understand human transactions with the physical environment. Although psychophysiologists appreciate the power of changing physical contexts to influence human behavior and often hold aspects of the physical environment constant in their research, they do not typically focus on human-environment transactions per se. Conversely, environmental psychologists (and other environment and behavior researchers), whether through limited resources, lack of expertise, or ignorance, rarely use psychophysiology in their work. Despite these trends, a good deal of work is being done where these two broad research areas meet, which reflects, perhaps, a natural tendency to see "embodied" humans as intimately related to their environments (Atran, 1998). This work has been called *environmental psychophysiology*, and is formally defined as "the study of relationships between organism-place transactions and physiological events" (Tassinary, 1995). The conceptualization of environment and methodological approaches used in environmental psychophysiology derive largely from three disciplines within the life sciences: *environmental psychology*, in which relationships between human behavior, and sociophysical environments are studied (Stokols & Altman, 1987); *psychophysiology*, in which psychological phenomena related to and revealed through physiological principles and events are studied (Cacioppo & Tassinary, 1990); and *environmental physiology*, in which the study of animal-environment relationships with particular attention given to the biological effects of changes in the geophysical environment are studied (Schmidt-Nielsen, 1997). Environmental psychophysiology can also be distinguished from the related subdisciplines of cognitive psychophysiology and social psychophysiology. The former is concerned with *intra-organismic* information processing, while the latter focuses on *inter-organismic* information

processing (see Cacioppo, Tassinary, & Berntson, this volume).¹ This fairly broad disciplinary heritage implies an extensive purview for this new field. However, we will limit the scope of our coverage of environmental psychophysiology in this chapter to minimize overlap with other chapters in this volume, especially those in the social processes section. The focus of this chapter will be the physical aspects of environments ordinarily encountered, and the level of analysis will emphasize the psychological import of the physical environments of daily life.

The research in environmental psychophysiology has focused on relatively discrete physical environmental dimensions and features, especially those features that can be conceived of as environmental stressors. Although some studies have considered whole environments or situations, most have examined particular environmental dimensions, such as light or sound. This follows in part from a desire to understand the effects of different environmental stressors, but some research has also been motivated to discover information that can inform the design and management of environments in which we live, work, and relax. This is the second noteworthy characteristic of the research to be reviewed: its applied orientation. From examinations of traffic congestion to the design of lighting for work environments and the effects of overflight noise in elementary school districts, research in environmental psychophysiology has generated information of direct relevance for policy and decision makers who can

¹ Readers familiar with Andreassi's (1995) psychophysiology text will recognize that "environmental psychophysiology" is not being minted here. Andreassi's use of the term, however, is somewhat more restricted than ours, though his definition obscures the fact. He maintains that environmental psychophysiology refers to "the effects of physical environments on the physiology of a behaving person" (p. 360). This seemingly broad consideration of potential effects belies the narrowly focused content of his environmental psychophysiology chapter. The physical environment of interest is the *internal* physical environment, primarily as it is influenced by changing hormone levels, the ingestion of drugs and exposure to neurotoxic chemicals. As indicated in the introduction, our understanding of the physical environment is conceived more broadly so to keep with Lewin's and other psychologists' longstanding admissions to consider "whole situations."

influence the design and management of everyday environments.

The pages that follow cover work in three broad areas: (1) environmental stress, (2) palliative environments, and (3) topographic cognition. These areas both exemplify existing work and suggest the broad potential for the application of psychophysiological constructs and methods to the study of human transactions with the physical environment. The research ranges from commonly encountered psychophysiological applications in environmental stress, through more recent applications of similar constructs and methods to examine the restorative and analgesic potential of large-scale outdoor environments, to the emerging use of functional brain imaging and other psychophysiological techniques to draw inferences about the neural substrates of wayfinding and related spatial behaviors. In keeping with the major themes of this volume, an appropriate historical context for the material covered in each of these sections is provided, as well as discussions of relevant biological (i.e., anatomical, neural, or hormonal substrates) and experimental (e.g., research setting and individual differences) contexts.

2. ENVIRONMENTAL STRESS: HUMAN TRANSACTIONS WITH NOISE

The term *environmental stress* is typically construed broadly to include both social and physical environmental stressors, though socially-oriented daily life events are often of primary interest.² Here, however, we examine what is perhaps the quintessential physical environmental stressor, noise. Stress is a psychophysiological state arising from one of two general types of suboptimal person-environment transactions: 1) the environment presents demands that a person is ill-prepared to meet, or 2) environmental opportunities for goal attainment are either absent or thwarted. Most environmental psychologists (see Evans & Cohen, 1987) advocate a relational concept of stress wherein appraisal of the fit between the environment (demands and opportunities) and oneself (capabilities and goals) is central to the stress that is experienced and the coping that is engaged. Despite this interactive or relational perspective, we must acknowledge the possibility of normative environmental stressors, such as noxious odors or nociceptive sounds, which are widely experienced as noxious (see Moos & Swindle, 1990). We must acknowledge as well the possibility that chronic environmental stressors may go largely unnoticed and yet contribute to the stress that is experienced over the course of a day. What these and other limitations of the relational perspective suggest is that there is more to the stressor-appraisal-coping process than can be learned from self-

reports of daily life events. Thus, knowledge of individual differences, psychophysiological assessments of situational experience, and objective measurements of physical conditions can all help to understand a process that is unlikely to be completely available to or accurately represented by conscious recollection.

2.1. Noise

Noise, n. A stench in the ear. Undomesticated music. The chief product and authenticating sign of civilization. (Bierce, 1911/1993, p. 85)

In antiquity there was only silence. In the nineteenth century, with the invention of the machine, Noise was born. Today, Noise triumphs and reigns supreme over the sensibility of men. (Russolo, 1913/1971, p. 166)

As these epigrams suggest, noise has long been regarded as an Industrial Age phenomenon with untoward psychological consequences. Much of the early research on the effects of noise, however, focused on establishing dose-response curves for potential hearing loss as a function of stimulus intensity and duration of exposure (see Kryter, 1994, for a review). Our primary concern here will be with the *nonauditory* effects of noise, which are all those effects not directly related to hearing loss (DeJoy, 1984). The modal definition of noise in this literature is "unwanted sound" (Belojevic, Jakovljevic, & Slepcevic, 2003; Kryter, 1994; Evans & Cohen, 1987; McLean & Tarnopolsky, 1977; Ward & Suedfeld, 1973), a definition that clearly implies the importance of cognitive interpretations and the psychological meaning of sound independent of its physical characteristics. In particular, the controllability and predictability of sound are critically important to understanding the nonauditory effects of noise. And, as we shall see, personality and other individual differences also can be used to predict psychophysiological responsiveness and the performance effects of noise, as can nonauditory situational attributes (e.g., effort) of transactions with the sociophysical environment. We begin with brief overviews of occupational epidemiology and human laboratory work on the nonauditory effects of noise, and highlight inferential issues pertinent to the conduct of field research. We then examine two areas of field research (noise in sleep and school environments) that exemplify the application of psychophysiological constructs and methods to human transactions with the physical environment.

2.2. Epidemiological research

Extensive research on the nonauditory effects of noise is a relatively recent phenomenon, arising 25–30 years ago out of public concern for possible health effects of noise pollution in industrial and other workplace environments (DeJoy, 1984). Reviewers of the epidemiological research on industrial noise exposure have generally

² This is especially true of the clinical literature. See, for instance, the "Environmental Perspective" section of a recent book on measuring stress (Cohen, Kessler, & Gordon, 1995) in which all four chapters are heavily slanted towards measuring socially-oriented life events, such as problems on the job and marital conflicts.

concluded that the strongest evidence for potential health effects is from long-term (3–5 years) exposure to noise at or above 85dB(A) (Stansfeld & Haines, 1997; Welch, 1979). Under these conditions, cardiovascular effects are typically reported (e.g., Parvizpoor, 1976; Zhao, Zhang, Selvin, & Spear, 1993), with peripheral vasoconstriction (e.g., Jansen, 1969) and elevated blood pressure (e.g., Anticaglia & Cohen, 1970; Tomei et al., 2000) being the symptoms most commonly associated with occupational noise (see DeJoy, 1984; McLean & Tarnopolsky, 1977; Smith, 1991; Thompson, 1996 for reviews). Occupational noise has also been associated with higher rates of cardiovascular disease (Knipschild, 1977; 1980) and myocardial infarction (Ising et al., 1996). It has been difficult to draw conclusions about health effects based on this work, however, because not all of the epidemiological studies suggest that there are deleterious effects (e.g., Cohen, Taylor, & Tubbs, 1980; Lees, Romeril, & Wetherall, 1980; van Dijk, Verbeek, & De Vries, 1987), while others indicate that harmful effects only accrue after very long exposures on the job (≥ 25 years; Lang, Fouriaud, & Jacquinet-Salord, 1992). Many of the studies that do show effects have not included adequate control groups, and others that do not show effects have often used inappropriate thresholds for high versus low noise exposure [85dB(A)], failed to account for the use of ear protection, or used dubious estimates of noise exposure rather than onsite measurements (Babisch, 1998; Ising & Kruppa, 2004). A meta-analysis of the relationship between noise exposure and cardiovascular disease reflects this ambiguity in the literature (van Kempen et al., 2002). The authors examined 43 epidemiological studies published from 1970–1999 and estimated that per 5 dB(A) increase in noise the relative risk of hypertension is 1.14 for occupational noise and 1.26 for aircraft noise, though the data were inconclusive for a relationship between noise and myocardial infarction.

Recent epidemiological and quasi-experimental field research efforts have begun to address some of these methodological concerns by more carefully measuring noise exposures, accounting for hearing protection, and using ambulatory psychophysiological instruments. A retrospective study of 27,464 lumber mill workers, for instance, used onsite visits and extensive personal dosimetry measurements to estimate noise exposures and found (marginally significant) elevated standardized mortality ratios (SMRs) for deaths from myocardial infarction for the full cohort, and significant SMRs for a subgroup without hearing protection, ranging from 1.3–1.5 for increasing exposures (Davies et al., 2005). The importance of incorporating methodological or statistical controls for hearing protection is underscored by field research in industrial work settings, which indicates that elevated postshift fatigue, irritability, cortisol (Melamed & Bruhis, 1996) and resting blood pressure levels (Lusk, Hagerty, Gillespie, & Caruso, 2002) can be lowered by using hearing protection. Other field researchers have paired personal dosime-

try with 24 hr ambulatory blood pressure and heart rate measurements to examine the extent to which occupational noise is associated with acute versus more chronic influences on cardiovascular functioning. These studies indicate that workers exposed to >85 dB(A) during the work shift experience significant work period increases in SBP (6–19mmHg), DBP (3–7mmHg; Chang, Jain, Wang, & Chan, 2003; Fogari et al., 2001), and heart rate (3 bpm; Fogari et al., 2001) relative to workers in quieter environments. There were also indications of possible chronic effects in this work, as both studies reported sustained cardiovascular effects in the evening (5pm–11pm) and night time (11pm–8am) hours, albeit not for all measures; and Fogari et al. (2001) found that noise-exposed workers had elevated 24 hr heart rates even when measured on a non-work day. The Fogari et al. data are particularly interesting because they controlled not only for typical cardiovascular risk factors (e.g., smoking, body mass, and age) but also for the physical exertion required of noise-exposed and nonexposed workers, something that is not routinely done; these data are interesting as well because 94% of the noise-exposed workers wore hearing protection. Taken together, these studies suggest that the cardiovascular effects of industrial noise extend beyond the 8-hr period when workers are exposed to noise. And, because these effects occur even when hearing protection is used, it appears that they can be elicited at levels far below the 85dB(A) threshold typically regarded as the dividing line between harmless and harmful exposures.³

Although the combined use of personal dosimetry and ambulatory psychophysiology is still rare in field research on occupational noise, the few studies that have used these techniques clearly illustrate the methodological power of densely measuring both halves of the putative cause and effect relationship between noise and health. First, the continuous measurement of sound and physiology allows for the discovery of relationships that might otherwise be missed. In both the Chang et al. (2003) and the Fogari et al. (2001) studies, differences in blood pressure and HR between noise-exposed and nonexposed workers only emerged when data were integrated over fairly long periods (8 hrs), both on and off the job; preshift, single point comparisons of resting blood pressure and HR did not discriminate these groups.

Second, continuous measurements of noise that extend beyond the work shift can be used to isolate the effects of occupational noise vis-à-vis evening and late night noise exposures, which can interfere with home life and sleep and may also have deleterious health effects. Chang et al.

³ Further evidence that the 85dB(A) threshold is outmoded comes from field research in much quieter office environments [<65 dB(A)], where there are indications that noise can elevate stress-related hormones (Evans & Johnson, 2000) and interact with psychosocial variables such as job strain to influence self-reported well being, job satisfaction, and organizational commitment (Leather, Beale, & Sullivan, 2003).

(2003) were able to confirm that workers who were exposed to high and low noise conditions on the job experienced similar sound intensities during the early evening hours at home. Thus they were able to ascribe the cardiovascular effects to occupational noise more confidently; they did not measure noise during the sleep period, however, and consequently their assertion of a cause and effect relationship is not as strong as it might have been. Using personal dosimetry to parse varying environmental noise exposures would be useful in non-occupational settings too. Research on the ill effects of noise at school, for instance, often fails to examine the potential cumulative or interactive effects of noise at home, even though as many as a third of the students may be cross-classified with respect to noise at home versus noise at school (e.g., noisy home environment, quiet school, or vice versa; Haines, Stansfeld, Job, Berglund, & Head, 2001a).

Finally, when noise and psychophysiological endpoints are both measured continuously, it is possible to track physiological responding to peak noise events, which can be useful in isolating specific sources of trouble in a given environment and assessing their relative value as pollutants. This would be especially useful in home environments, where road noise has been associated with increased risk of myocardial infarction (Babisch et al., 2005) and overnight catecholamine excretion (Babisch, Fromme, Beyer, & Ising, 2001), and aircraft over flights have been associated with increased risk of hypertension (Rosenlund et al., 2001). Although the current trend in the literature is to examine the health effects of these noise sources separately, and there is evidence that noise from aircraft, road, and rail traffic can be ranked from high to low in terms of annoyance (Miedema & Vos, 1998), it is by no means clear that individual analyses are to be preferred over cumulative or interactive models. Further research that pairs personal dosimetry with ambulatory psychophysiology could help to assess the relative merits of such models.

Thus, though it has been difficult to make causal inferences based on this literature, with continuing methodological improvements in epidemiological and field research, there is increasing evidence that longterm exposure to occupational noise at or above 85dB(A) compromises cardiovascular health. There are indications, as well, that this threshold is likely too high (see below), especially when the cumulative effects of nonoccupational noise are considered and other health effects are examined. Indeed, throughout this work the presumed mechanism of the cardiovascular effects of occupational noise is that noise is a stressor, and as such, this implicates a broad range of possible health effects. In the following sections we briefly review complementary laboratory work and highlight quasi-experimental research on the nonauditory effects of noise in sleep and school environments, all of which has emphasized the physiological concomitants of stress and coping.

2.3. Human laboratory research

With the exception of the effects of noise on sleep, much of the human laboratory research on the nonauditory effects of noise has emphasized effects on the performance of cognitive and psychomotor tasks. Very often, complete factorial designs (i.e., those including noise-only conditions) are not used, and thus it becomes difficult to assess the physiological effects of noise independent of the physiological activation required to perform the task. Those laboratory studies that have examined the effects of noise independent of task performance have generally found mild cardiovascular effects, including peripheral vasoconstriction (Kryter & Poza, 1980), increased diastolic BP, decreased systolic BP and sinus arrhythmia (Mosskov & Ettema, 1977a; 1977b), and a reduction in cardiac output (Andren, Hansson, Bjorkman, & Jonsson, 1980; Andren, Hansson, Bjorkman, Jonsson, & Borg, 1979). Many of these same cardiovascular effects emerge under task performance, and they are exacerbated when task performance is accompanied by noise (Carter & Beh, 1989; Conrad, 1973; Kryter & Poza, 1980; Millar & Steels, 1990; Mosskov & Ettema, 1977a; 1977b). Some sympathoadrenal and adrenocortical endocrine effects associated with task performance and noise have been found as well, including increased epinephrine (Evans & Johnson, 2000; Frankenhauser & Lundberg, 1977, aftereffects only) and elevated cortisol responding (Brandenberger et al., 1980; Follenius, Brandenberger, Lecornu, Simeoni, & Reinhartd, 1980; Persson-Waye et al., 2002), but the effects for these systems are less consistent.

Although laboratory research on the nonauditory effects of noise on humans has emphasized the ergonomics of performance, some of the findings from this work can be used to help interpret field studies of noise exposure in which the emphasis has been on the potential health effects of environmental noise. There are several reasons for this. First, laboratory work focusing on transient exposures to noise in the context of cognitive performance can offer a reasonable model for the effects of environmental noise in school and occupational settings. Though the specific tasks used in laboratory noise research typically do not have direct analogs in school and occupational settings, noise effects on the general psychological processes central to their performance (e.g., attention and short-term memory) likely do generalize to these environments (see Anderson & Bushman, 1997, for a fuller exposition of this point). The focus on *transient* noise in laboratory research is also relevant to nonlaboratory settings because much of the noise experienced in school, occupational, and other nonlaboratory settings is transient in nature (e.g., oscillating traffic volumes, airplane overflights, aperiodic neighborhood noise).

Laboratory research can also be used to isolate different aspects of human-environment transactions that can mediate the effects of environmental stressors. For instance,

experimental work indicates that task performance and psychophysiological responding can be influenced by the perceived predictability and controllability of the stimulus source. Though many laboratory studies have failed to find performance effects of noise exposures (e.g., Conrad, 1973; Millar & Steels, 1990), careful reviews of this varied and complex body of work have repeatedly concluded that noise can have definite effects on performance that depend upon both the nature of the noise and the nature of the task (see Broadbent, 1979; Kjellberg, 1990; Smith, 1991 for reviews). To the extent that environmental noise is uncontrollable, aperiodic or experienced for extended periods, as may well be the case in many occupational and school settings, then tasks requiring concentration and sustained attention are likely to suffer.

Several classic psychophysiological studies have found that autonomic responsiveness to noise is decreased when participants are given control over the noise, even when control is not exercised (Glass, Singer, & Friedman, 1969). Lundberg and Frankenhauser (1978), for instance, reported significantly elevated heart rates for students performing math under uncontrollable noise relative to those who could set noise levels. Breier et al. (1987) found significant increases in skin conductance during uncontrollable noise relative to controllable noise, as well as increased levels of epinephrine and adrenocorticotrophic hormone during performance of a postnoise anagram task among those who had experienced uncontrollable noise. And in a recent study focusing on uncontrollable open-office noise, Evans and Johnson (2000) reported elevated urinary epinephrine among experienced office workers exposed to low intensity noise [55dB(A)]. Although their performance of a simple typing task did not suffer relative to nonexposed participants, the noise-exposed group did exhibit postural invariance (a risk factor for musculoskeletal disorders), and they averaged fewer attempts at an unsolvable postnoise puzzle. Other, more lingering postnoise effects may also be associated with on-the-job noise exposures, as reported above for ambulatory field measures (Chang et al., 2003; Fogari et al., 2001) and as occasionally seen in experimental work. Gitanjali and Ananth (2003) found that 8 hr exposures to industrial noise [>75 dB(A)] were associated with disturbed sleep, elevated sleeping heart rates, and increases in morning-after serum cortisol. Thus, there is good experimental evidence that the actual and perceived stimulus characteristics of noise can influence both task performance and stress-related psychophysiological responding.

Other laboratory work suggests that an understanding of situational characteristics could be critical to the interpretation of potential health and other effects of environmental noise exposures in the field. Several studies relying on self-report measures indicate that exposure to noise can elicit negative changes in mood when noise interferes with ongoing activities (Aniansson, Pettersson, & Petersson, 1983; Jones & Broadbent, 1979; Öhrström & Rylan-der, 1982). Dimberg (1990) monitored facial EMG activation during exposures to loud [95 dB(A)] and moderate

(75 dBA) 1000 Hz tones, and found that activity recorded from *corrugator supercilii* and *zygomaticus major* muscle regions was congruent with the negative and positive emotional responses participants reported for the loud and soft tones, respectively. And, recent work on noise exposures and mood suggests that serotonin may moderate negative moods associated with uncontrollable noise (Richell, Deakin, & Anderson, 2005), a finding that may have implications for morning moods, as evidence indicates that the overnight serotonin profile changes significantly when slow wave sleep is disturbed by noise, trending down rather than up towards awakening (Rao et al., 1996). In both the shortterm and the longterm, noise-induced changes in mood could potentially have deleterious health effects (Stone, Cox, Valdimarsdottir, Jandorf, & Neale, 1987; Stone et al., 1994). Such changes could also have important implications in school and occupational settings, where changes in mood could influence self-imposed performance standards (Cervone, Kopp, Schaumann, & Scott, 1994), and possibly increase the stress of maintaining performance standards in challenging working conditions. A study by Tafalla and Evans (1997), which examined an “adaptive costs” model of physiological activation and performance under stress, highlights this possibility.

The autonomic effects of noise (and other stressors) in the laboratory coupled with reports of minimal negative performance effects for many tasks has prompted several research groups to propose the adaptive costs model of stress to account for both sets of findings (Cohen, Evans, Krants, & Stokols, 1980; Cohen, Evans, Stokols, & Krants, 1986; Frankenhaeuser, 1980; Glass & Singer, 1972). According to this model, adequate or superior performance levels are maintained under noise through dint of increased effort, which is reflected in increased autonomic responding. Thus, though performance may be maintained in the face of environmental noise, health costs are ultimately thought to accrue through repeated or sustained increases in autonomic activation, such as sustained increases in cardiovascular responding (Krantz, Contrada, Hill, & Friedler, 1988). Consistent with the adaptive costs hypothesis, there is good evidence in the psychophysiological literature that cardiovascular activation is greatest when effort and active coping are high (Lovallo et al., 1985; Obrist et al., 1978). Coping and sustained effort to perform in the face of noise in particular have been shown to elicit sustained increases in heart rate, blood pressure (Carter & Beh, 1989), and peripheral vasoconstriction (Millar & Steels, 1990).

Building on work by Frankenhaeuser and her colleagues (Lundberg & Frankenhaeuser, 1978; Frankenhaeuser & Lundberg, 1977) suggesting that there may be a trade-off between performance under noise and psychophysiological responding, Tafalla and Evans (1997) explicitly manipulated effort and environmental noise while participants performed mental arithmetic. The presence of uncontrollable noise did not impair performance when increased effort was encouraged, but these conditions did

elicit increases in heart rate, norepinephrine, and cortisol. Conversely, when increased effort was not induced, performance declined under uncontrollable noise but cardiovascular and neuroendocrine responding did not change from levels observed during task performance in quiet surroundings. These findings have direct implications for those occupational settings where workers are exposed to uncontrollable noise and yet have strong incentives to maintain performance levels (e.g., exacting quality standards or high productivity requirements). Such conditions may obtain in a wide range of occupations from blue collar industrial workers to white collar office employees, and they may also occur in urban school settings where various kinds of transportation noise are often unavoidable. An appropriate assessment of human-environment transactions in noisy (and other stressful) environments, then, should include an examination of sociophysical aspects of environments, such as controllability of potential physical stressors and psychosocial incentives to perform (see Evans, Johansson, & Carrere, 1994).

Apart from stimulus properties, situational characteristics and state-dependent individual responding, personality characteristics have also been examined in the laboratory. Perhaps the most pertinent personality characteristic is sensitivity to noise, though the evidence for sensitivity as a stable trait that accounts for variability in performance and physiological responding is somewhat checkered (see Kjellberg, 1990). Recent work indicates that sensitivity to noise is an evaluative construct that has no relationship to auditory functioning (e.g., auditory thresholds, intensity discriminations, or auditory reaction time; Ellermeier, Eigenstetter, & Zimmer, 2001), though several reviews have confirmed that self-reported sensitivity increases the annoyance associated with noise (Miedema & Vos, 2003; van Kamp et al., 2004). Noise-sensitive individuals may also be especially attuned to low frequency noise, even at low intensity [40 dB(A)], as they release more cortisol relative to nonsensitive participants when performing cognitively challenging tasks under these conditions (Persson-Waye et al., 2002).

Anxiety and neuroticism have been popularly linked to noise sensitivity, and a classic study by Bennett (1945) indicated that questions regarding annoyance with noise were useful in discriminating normals from those diagnosed as neurotic. More recent evidence, however, has been mixed. Several studies suggest that there is no relationship between self-reported sensitivity to noise and scores on the Eysenck Personality Inventory (EPI), Cattell's 16 PF or the MMPI (Griffiths & Delauzun, 1977; Moreira & Bryan, 1972). Conversely, those with an internal locus of control who believe they have control over a noise stressor exhibit lower cortisol in response to the stressor (Bollini, Walker, Hamann, & Kestler, 2004). And, introverts have been found to prefer lower environmental noise levels (Standing, Lynn, & Moxness, 1990) and lower laboratory noise stimulation levels (Hockey, 1972), findings that hold when scores for neuroticism are controlled (Geen, 1984). Geen (1984) also

reported greater cardiovascular and electrodermal reactivity among introverts compared to extraverts at moderate noise exposure levels [55–75 dB(A)], but in a second study, cardiovascular responding did not differ at very low [40 dB(A)] or very high [85 dB(A)] noise levels. Interestingly, there was no difference in physiological reactivity between introverts and extroverts when participants from each group were exposed to preferred noise stimulation levels (55 dB(A) and 72 dB(A), respectively), regardless of whether exposure levels were chosen or assigned.

Several researchers have suggested that inconsistencies in the evidence for noise sensitivity as a stable trait reflect the fact that putative measures of noise sensitivity may actually measure general annoyance with environmental stimuli (Kjellberg, 1990; Weinstein, 1980). Consistent with this, Thomas and Jones (1982) have reported that 35% of the variability in noise annoyance scores can be accounted for by responses to a general annoyance questionnaire. However, though discomfort thresholds for noise, light, heat, and cold are moderately related (pairwise r values range from .25–.52), sensitivity to below-discomfort-threshold noise seems to be unrelated to sensitivities to these other physical environmental stimuli (Öhrström, Björkman, & Rylander, 1988). This finding would not be predicted if noise sensitivity were simply an indication of a more general underlying sensitivity to environmental conditions. Thus, researchers have yet to conclusively determine the extent to which noise sensitivity and general environmental sensitivity overlap, or even whether either type of sensitivity constitutes a stable individual characteristic.

2.4. Field research

Except for epidemiological research on the effects of noise in occupational settings, much of the field research on noise has examined effects in sleep environments and the deleterious effects of noise on children in school and home environments. We will consider each of these broad areas in turn.

Sleep environments. Sleep environments research is conducted both in field and laboratory settings, with reasonably good evidence suggesting that laboratory methods and findings can generalize to nonlaboratory environments (Coates et al., 1979; Johns, 1977). Although noise-induced *awakenings* tend to be more likely in laboratory studies (see review by Pearsom, Barber, & Tabachnick, 1990), various sleep *disturbances* have been found in both field and laboratory settings. These disturbances often take the form of increases in cortical arousal or changes in sleep stages that do not lead to awakenings. For instance, early laboratory research suggested that relatively loud aircraft flyovers (peak intensities of [65–80 dB(A)]) reliably elicit increases in cortical arousal (LeVere & Davis, 1977) and are associated with performance decrements on reaction time (RT) tasks administered upon awakening, despite the absence of noise-induced awakenings

during the night (LeVere, Bartus, & Hart, 1972). These results parallel findings in the field, which indicate that body movements (Öhrström & Björkman, 1983), transient electroencephalographic (EEG) fluctuations (Vallet, Gagneux, Blanchet, Favre, & Labiale, 1983a), shifts to lighter sleep levels (Stevenson & McKellar, 1988; Vallet et al., 1983a) and phasic cardiovascular responding (Tulen, Kumar, & Jurriëns, 1986; Vallet et al., 1983a,b) are linearly related to dB(A) levels of noise events. Such linear relationships are often established by recording all instances of a particular class of outdoor noise event (e.g., automobile passbys or airplane overflights) and correlating peak SPLs for these events with various physiological measures. Apart from correlational analyses, these data sets lend themselves to more detailed examinations of transient physiological responding to nocturnal noise events. Heart rates of sleeping field participants, for example, tend to increase momentarily when cars or airplanes pass by, followed by a deceleration that mimics the receding noise level of the sound source (Muzet & Ehrhart, 1980).

In part because there are difficulties associating specific noise events with specific sleep disturbances (e.g., when there are multiple, simultaneous automobile passbys), many researchers have examined the quality of sleep in noisy versus quiet field settings. Sleep quality is typically inferred from sleep stage analyses based on EEG and electrooculogram (EOG) recordings in which the duration, distribution, and latency-to-onset of sleep stages are examined. Studies using quasi-experimental designs to manipulate noise exposure provide the strongest evidence for deleterious effects of noise on sleep quality. Manipulations of noise exposures in the field comprise the introduction of double-glazed windows (Öhrström & Björkman, 1983; Tulen et al., 1986; Wilkinson & Campbell, 1984), the use of sound-dampening insulation on single-glazed windows (Eberhardt & Akselsson, 1987), open versus closed windows (Griefahn & Gros, 1986; Tulen et al., 1986), earplugs versus none (Griefahn & Gros, 1986), and moving participants' sleep location from noisy to quiet parts of their homes (Vallet et al., 1983a). Two prominent findings emerge from this work indicating that both slow wave sleep (SWS), stages 3 and 4 (Bergamasco, Benna, & Gilli, 1976; Eberhardt & Akselsson, 1987; Griefahn & Gros, 1986; Wilkinson & Campbell, 1984) and rapid eye movement (REM) sleep (Jurriëns, 1981; Vallet et al., 1983a) can be adversely impacted by noise. Researchers have repeatedly found that latency-to-onset increases and duration decreases for both SWS and REM sleep as peak SPLs increase. Interestingly, these effects of noise are rarely observed for both types of sleep in the same study, an occurrence that Eberhardt and Akselsson (1987) attribute to the inhibition that each sleep stage exerts on the other. They suggest that the particular deleterious effects observed in any given study are a result of the distribution of peak noise events relative to the occurrence of sleep stages.

Several researchers have reported that peak characteristics of nocturnal noise events are more closely related to sleep quality (Eberhardt & Akselsson, 1987; Tulen et al., 1986) and transient sleep disturbances (Vallet et al., 1983a) than measures that integrate acoustic energy over protracted periods (e.g., Leq₈). There is some consistency among researchers who report peak SPLs suggesting that noise events producing indoor peak SPLs of 45–55 dB(A) and above are more likely to both cause transient disturbances or influence sleep stage parameters than noise events with lower peak SPLs (Eberhardt & Akselsson, 1987; Öhrström & Björkman, 1983; Vallet et al., 1983a). Despite some consensus regarding peak thresholds of noise that will cause disturbances, other peak characteristics have been much less carefully studied in field settings. Both the rise time (Tulen et al., 1986) and the duration (Lukas, 1976; Tulen et al., 1986) of peak noise events have been suggested as important stimulus parameters, though neither is reported with sufficient regularity to warrant a reasonable assessment of their respective contributions to sleep disturbances. Despite limited data about peak characteristics, the sharp rise times of aircraft noise have been used to explain the greater annoyance associated with aircraft relative to road or rail noise (Spreng, 2004). And, certain situational characteristics of peak noise events may also influence the likelihood and nature of sleep disturbances. For instance, the likelihood that a given peak SPL will elicit a sleep disturbance depends in part upon the background noise level (Vallet et al., 1983a; Vallet, Gagneux, & Simonnet, 1980). Thus, although there may be difficulties in obtaining data regarding the specific characteristics of each noise event over the course of a night's sleep, information such as time of occurrence, rise time, and relative magnitude may well be critical to understanding the potential deleterious effects of nighttime noise.

This conclusion is underscored by research concerning habituation to environmental noise after years of exposure. Sleep researchers have repeatedly found that the sleep quality of those who have slept in noisy environments for one or more years improves significantly when changes are introduced (sound insulation, double-glazed windows) to reduce indoor peak SPLs (Eberhardt & Akselsson, 1987; Griefahn & Gros, 1986; Vallet et al., 1983a; Wilkinson & Campbell, 1984). Laboratory and field research indicate that although behavioral habituation to nocturnal noise events does occur (e.g., awakenings decline; Thiessen & Lapointe, 1978), EEG arousals (Townsend, Johnson, & Muzet, 1973), shifts in sleep level (Thiessen & Lapointe, 1978), and phasic cardiovascular responding (Vallet, Gagneux, Clairet, et al., 1983) are much more resistant to habituation. These findings are consistent with animal research, which suggests that cells in the dorsal Raphe nuclei are responsible for regulating ultradian sleep cycles (e.g., Lydic, McCarley, & Hobson, 1987; Shima, Nakahama, & Yamamoto, 1986), and that these cells do not habituate to auditory and visual stimuli during sleep while other cells

in the classical reticular formation do (Heym, Trulson, & Jacobs, 1982). These findings are consistent as well with a recently presented model of subcortical stress responding to noxious auditory stimuli. Relying on animal and human literature showing the fear-conditioned plasticity of the amygdala, Spreng (2004) suggests that, once negative assessments have been associated with particular noise events, the amygdala becomes tuned to the event type (e.g., dominant frequencies and peak characteristics) and recruits fast-reacting neurons to subcortically trigger vegetative responses (stress hormone release) to future occurrences of the event. Thus, rather than habituating to environmental noise, this model suggests that we become hypersensitive to those noise events we have evaluated negatively. It seems unlikely, then, that complete adaptation to nocturnal noise events ordinarily occurs in field settings, highlighting the need to carefully characterize the potential health effects of chronic exposure to noise in sleep environments.

Several sleep researchers interested in sleep quality and the health effects of noise have examined endocrine responses to both acute and chronic noise exposures. Endocrine responses are interesting in part because certain patterns are seen as indicative of stress and have implications for stress-related disorders. Recent English-language reviews of German research over the past 10–15 years concur that night time (air and road) traffic noise are positively associated with stress-related hormone levels and negatively related to sleep quality (Maschke & Hecht, 2004; Ising & Kruppa, 2004). Babisch et al. (2001), for instance, reported that women whose bedrooms faced heavily traveled Berlin roads had elevated overnight urinary noradrenaline relative to those whose bedrooms faced quiet environments. However, perceived sleep disturbances were only related to noradrenaline for those women who failed to get relief from the traffic noise by closing their windows. Neither of these effects was found for women whose living rooms (rather than bedrooms) faced the noisy street, suggesting that night time noise per se elicited the negative responses. Sleep researchers have also begun to monitor endocrines during sleep as a way to help identify noise-related disruptions of ultradian, circadian, and circaseptan cycles of responding because such disruptions may diminish sleep quality (and thereby the functions of sleep) and ultimately have health effects. In particular, a distinction between SWS and REM sleep disturbances is gaining currency in the literature, with several researchers suggesting that increased cortisol during its circadian trough (first half of the sleep period, when SWS predominates) constitutes a biological marker for chronic stress (Born & Fehm, 2000; Maschke & Hecht, 2004). Although biological markers for chronic stress have yet to be substantiated (others have been suggested; see, e.g., Clow, 2004), given the evidence for nonhabituation to overnight noise and the slow metabolic rate of cortisol (60–130 mins; Spreng, 2004), chronically elevated night time cortisol is highly plausible for people sleeping in noisy

environments, which puts them at risk for a broad range of disorders.⁴

Children in home and school environments. The effects of chronic exposure to noise have also been the focus of research on children in home and school environments. Although noise in both environments can have deleterious effects on school performance and health, noise research with children has tended to focus on one or the other setting, and often on a particular type of noise (air or road traffic). And unlike research in sleep environments, there have been few quasi-experimental studies of children in which noise levels have been manipulated by the investigators.

Researchers have been able to capitalize on nonexperimental changes or differences in existing noise levels, however. In an early classic study, noise levels in apartment buildings that spanned a busy highway were associated with impaired auditory discrimination and reading abilities of children who lived in the apartments (Cohen, Glass, & Singer, 1973). Several early researchers highlighted cardiovascular and other stress-related physiological responding to examine the potential health effects of chronic noise exposure on school-age children. Studies examining aircraft (Karogodina, 1969) and road traffic (Karsdorf & Klappach, 1968) noise, for instance, suggested that children in noisy schools had higher resting blood pressure than their counterparts in quiet schools, and this has generally been confirmed by more recent work (see review by Evans & Lepore, 1993). Cohen and his colleagues (Cohen, Evans et al., 1980) reported cross-sectional data from an oft cited study of children attending noisy schools underneath busy air corridors (one flight every 2.5 mins.) surrounding Los Angeles International airport. Compared to matched children from quiet schools, children attending schools under the noisy air corridors had higher resting SBP and DBP, measured in a quiet environment. Subsequent longitudinal data did not support habituation of these effects over time (Cohen et al., 1981). Regecová and Kellerová (1995) reported similar results when traffic noise was the focus of a large-scale study ($n = 1542$) in Bratislava. Children attending schools in noisy urban areas (>60 dB(A) Leq₂₄) showed elevated resting SBP and DBP relative to that of matched children attending schools in quiet urban areas (<60 dB(A) Leq₂₄), and in both the Los Angeles and Bratislava studies, noise at home had little or no relationship to the cardiovascular measures.

Two research groups have published much of the recent nonauditory noise research on children, Haines and her colleagues focusing on the cognitive effects of aircraft noise in school environments, and Evans and his colleagues, who have examined stress-related and cognitive

⁴ Including cardiovascular diseases (e.g., hypertension and myocardial infarction), diabetes, osteoporosis, gastric ulcer and immunosuppression (see Spreng, 2000).

effects of noise in both home and school environments. Both groups have repeatedly found that noise is associated with less proficient reading (Evans, Hygge, & Bullinger, 1995; Haines et al., 2001b; Haines et al., 2001c; Stansfeld et al., 2005) and pre-reading skills (Maxwell & Evans, 2000), though occasionally these effects only occur for the most difficult reading items (Haines et al., 2001a; Hygge, Evans, & Bullinger, 2002), and the effects may disappear altogether when socioeconomic status is controlled (Haines, Stansfeld, Head, & Job, 2002) or if road noise is considered independently of aircraft noise (Stansfeld et al., 2005). Thus, as with the early research, negative effects on reading have been the most consistent finding in the recent literature, but there is still enough variability in the results to raise questions about the nature of any cause and effect relationships that might be responsible for these findings. Other negative psychological effects reported include decreased attention and social adaptability (Ristovska, Gjorgiev, & Jordanova, 2004), increased self-reported stress (Haines et al., 2001c; Evans et al., 2001), and behavioral problems in class (Lercher, Evans, Meis, & Kofler, 2002; Ristovska et al., 2004). These cognitive and other psychosocial effects are complemented by several reports of stress-related physiological effects, but these are not consistently found either. Evans and colleagues, for instance, have reported increased resting blood pressure for noise exposed children, but these have mostly been marginally significant effects (Evans, Hygge, & Bullinger, 1995; Evans et al., 1998; Evans et al., 2001). They have also collected overnight urinary endocrines in these studies, with epinephrine and norepinephrine discriminating between noise and quiet groups in two studies (Evans et al., 1995; Evans et al., 1998), and cortisol in one (Evans et al., 2001). Finally, Haines and her colleagues have not found noise-related cortisol or catecholamine effects in the two studies where they collected these data (Haines, Stansfeld, Brental, et al., 2001; Haines, et al., 2001b), but Ising and his colleagues have reported increased cortisol associated with low frequency night time road traffic noise (Ising & Ising, 2002; Ising et al., 2004).

Thus, the recent literature on noise and children presents a hodge-podge of somewhat contradictory findings. Though we might begin to interpret these contradictions by parsing the many differences among the studies (e.g., type and intensity of noise events, age of students, control of confounds, etc.), it may be more fruitful to examine some of their common weaknesses. First, and perhaps most important, is how sound is measured in these studies. Sound intensities are typically estimated for areas (e.g., neighborhoods, schools, communities) based on civil aviation and other transport-related contour maps and models, rather than measured on site.⁵ The accuracy of these estimates is only as good as that of the models, which is rou-

⁵ Evans and colleagues have measured noise on site in two recent studies (Evans et al., 1998; Hygge et al., 2002), but they used 24 hr measurements at school, which may or may not reflect noise exposures at home.

tinely not reported, and thus the error variance that sound estimates contribute to the relationship between noise and dependent variables is largely unknown.⁶ The accuracy of these estimates is clouded as well by the time period used to estimate exposures at school – usually 16 or 24 hours – which presumes either that the students are at school for the period in question (clearly unlikely), or that noise exposures at home and school are essentially the same. Though few of the recent studies have measured noise at home and school, those that have cast doubt on the suitability of this latter assumption. As mentioned above, Haines and her colleagues have found that roughly one third of students' have school noise exposures that do not match their home noise exposures (Haines, Stansfeld, Brentnall et al., 2001; Haines et al., 2001b), a mismatch that will contribute error variance to the extent that noise at home impacts the stress-related physiological and cognitive performance variables typically examined in these studies. As for physiological variables, we saw in the review of occupational literature above that noise experienced during working hours can clearly be associated with increased resting cardiovascular and endocrine levels measured at other times of the day. This suggests that mismatched home and school noise environments may add considerable error variance to the noise/stress-variable relationships examined in the child noise literature. As for the effects of noise at home on cognitive performance variables, we need to examine the effects of noise on learning, and this brings us to the second common weakness in recent research on children and noise: the understanding and measurement of learning.

Learning is usually not formally defined in the child noise literature. However, implicit in the focus on school environments and cognitive performance variables is the hypothesis that noise can disrupt learning. In particular, much of the recent work has focused on whether (and to what extent) noise disrupts the acquisition of knowledge in school settings. The effects of noise on knowledge retrieval are either methodologically controlled (Evans and colleagues) or regarded as a confounding factor (Haines and colleagues), and the effects of noise in other settings are interpreted vis-à-vis knowledge acquisition in school. For example, when the effects of noise at home are considered, the emphasis is on stress and other health-related outcomes that might impact both in-class motivation or over-generalized "tuning out" strategies that can interfere with knowledge acquisition. There is little acknowledgement in this work that learning is an ongoing psychophysiological process that extends beyond the school setting. A process that involves interim processes between acquisition and retrieval, processes that are closely tied to circadian and ultradian rhythms of endocrines and neurotransmitters,

⁶ And, even if the models are very accurate for reasonably small areas (e.g., neighborhoods), local conditions within these areas will always add noise to the data, as in the Babisch et al. (2001) study reported above, in which the difference between significant and nonsignificant effects of road noise hinged on whether or not bedrooms faced the busy street.

and thus they may also be vulnerable to the effects of noise. Learning, of course, relies heavily on memory, and the longterm retention of information requires that memories be stabilized, enhanced, and often reorganized to optimally integrate with existing knowledge and skills (Stickgold, 2005). A common umbrella term for these postencoding, interim processes is “consolidation,” and it has long been held that sleep is critical to memory consolidation. If this is true, it may be just as important to study children’s sleep environments as it is to study school settings if we want to fully understand the effects that noise can have on learning.

In the past 10–15 years, the sleep and memory research communities have shown a renewed interest in sleep-dependent memory consolidation, and this work has direct implications for the effects of noise on learning. Researchers have found that, relative to similarly long waking periods, sleep enhances memory for recently acquired knowledge and skills (for reviews, see Gais & Born, 2004a; Payne & Nadel, 2004; Stickgold, 2005), and may even inspire insight into problems encountered during the day (Wagner et al., 2004). And, there is increasing evidence that the consolidation of certain types of learning may be associated with different aspects of sleep. The primary distinction has been between SWS and REM sleep, which predominate in the first and second halves of the night, respectively. Consolidation of memory for declarative (episodic and semantic) information is associated with SWS periods, while the consolidation of memory for nondeclarative (procedural) information is associated with REM sleep periods. Researchers have also proposed two-step models of consolidation for procedural information that implicate both the early phase of SWS and the latter phase of REM sleep (Power, 2004; Stickgold et al., 2000).

One especially interesting aspect of this work (with respect to the effects of noise on children) is the relationship between circadian endocrine rhythms and sleep-dependent memory consolidation. In particular, increases in cortisol during its nighttime trough have been shown to eliminate the enhancement of memory for declarative information that is associated with SWS (Plial & Born, 1997, 1999).⁷ This result suggests a possible explanation for the contradictory or weak cognitive performance findings in the recent child noise literature. If noise experienced at home raises cortisol during its circadian trough, it may compromise learning (by disrupting consolidation) independently of noise experienced at school, which interferes with the acquisition of knowledge. Ising and Ising (2002) recently reported just such a finding with children, showing that cortisol during the first half of the night was correlated with low frequency road traffic noise levels, as well as with impaired sleep, memory, and ability to concentrate. These relationships were not found for cortisol levels during the latter half of the night, which

suggests that the noise-related increase in cortisol during SWS per se was responsible for the negative impacts on cognitive performance. In contrast to this work, studies that focus narrowly on noise at school and its effects on knowledge acquisition, as much of the recent research has, may well be mischaracterizing the potential that noise has to disrupt learning. This is because the reported cognitive performance effects reflect not only noise exposures during knowledge acquisition but noise exposures during consolidation as well. If noise exposures at home and school are substantially different (as we have seen they can be), it is virtually impossible to interpret the effects of noise measured only at school because many of the students will have been misclassified with respect to noise at home.

Perhaps the most important way, then, to address the apparent contradictions in the child noise literature is to more carefully measure noise, first by relying on onsite measurements rather than estimates,⁸ and second by measuring noise in those environments where children spend most of their time, not just in one environment to make assumptions about the others. Although the practical constraints of working with children may make the use of personal noise dosimetry impossible, more densely measuring exposures in multiple environments would vastly improve the power of research in the child noise literature. And, as illustrated above by some of the recent occupational noise research, when densely measured noise events are paired with densely measured physiological responding, relationships can be found that might otherwise go undetected. This is important not only for establishing possible health-related stress responses associated with noise in different environments, but dense measurements of both halves of this putative cause and effect relationship can also help us understand how noise experienced outside the school setting can negatively impact cognitive processes central to learning.

We turn now from our examination of this quintessential environmental stressor to a review of more positively toned transactions with the physical environmental, those that are thought to reduce psychological stress and restore cognitive functioning.

3. PALLIATIVE ENVIRONMENTS

the enjoyment of scenery employs the mind without fatigue and yet exercises it; tranquilizes it and yet enlivens it; and thus, through the influence of the mind over the body, gives the effect of refreshing rest and reinvigoration to the whole system. (F. L. Olmsted, 1865)

Beliefs in the beneficial effects of nature are as old as urban civilization itself (Ulrich & Parsons, 1992), and they have been a consistent theme in historical accounts of human relationships with the natural world (Eisenberg,

⁷ This is true of acetylcholine as well, which also reaches its nadir during SWS (Gais & Born, 2004b; Power, 2004).

⁸ Or, at the very least, report the accuracy of the models that are used to make estimates.

1998; Glacken, 1967). Typically, people cite unique opportunities to relax or unwind in natural environments as being key to their benefits. They usually attribute salutary psychological and physical effects to transactions with nature, transactions that are as engaging as a wilderness adventure trip, or as fleeting as a glance out the window. Beliefs such as these are currently very strong and very popular among laypersons (Korpela, Hartig, Kaiser, & Fuhrer, 2001; Ogunseitan, 2005), but also among a broad range of academics and policymakers, especially those in the design and healthcare fields (Frumkin, 2001; Schweitzer, Gilpin, & Frampton, 2004; St. Leger, 2003). In fact, confidence in these beliefs is such that Berry and colleagues recently told healthcare administrators that “healing gardens” can routinely be incorporated into hospital design because the estimated cost they add to a typical new hospital (\$1,000,000) can be more than offset by savings attributable to environmental distractors (see Berry et al., 2004, exhibits 1 & 2). Prudent readers may wonder what (beyond beliefs) justifies such claims, and as we shall see, the evidence for actual health effects of contact with nature is surprisingly thin, albeit growing. Although there is a broad empirical base of self-reports indicating that nature has beneficial effects, and some psychophysiological evidence that nature transactions reduce sympathetic arousal associated with stressful and other negative emotional states, there is almost no epidemiological data on health effects. In the following sections we will briefly review some of this evidence, describe two major theories that have been used to account for the findings, and then examine how psychophysiological constructs might be used to sharpen distinctions between these theories.

3.1. Empirical evidence for the beneficial effects of nature

The notion that certain environmental features are stress-reducing and thereby salutary is the obverse of the idea that environmental stressors have deleterious health effects. Unlike the environmental stress literature, however, epidemiologists have not examined the question of restorative natural environments, except for one research group in Japan. Takano, Nakamura, and Watanabe (2002) analyzed the five year survival data (1992–1997) of 3144 people born from 1903–1918 in two cities in the Tokyo metropolitan area. Independent of several control variables (age, sex, functional status, SES, environmental noise, etc.), those with nearby parks, tree-lined streets, and walkable areas were 14% more likely to survive than those without these environmental features. In an earlier study, Tanaka, Takano, Nakamura, and Takeuchi (1996) reported a negative correlation between mortality rates and land area devoted to woodland and/or farmland in cities with more than 4000 people per km², but not in less densely populated cities. Other researchers examining the relationship between urban green space and health have used self-reported health and quality of life mea-

sures rather than mortality or morbidity statistics, and they have reported similar outcomes. In a large and well-controlled Dutch study (10,000+ survey), for example, the amount of green space in urban living environments was positively related to self-reported physical and mental health, and negatively related to number of symptoms recently reported (de Vries, Verheij, Groenewegen, & Spreeuwenberg, 2003). Apart from being well-controlled, this study is also impressive because of the effect size reported: if the correlations reflect a true cause and effect relationship, then a 10% increase in urban green space would lead to a decrease in symptoms comparable to a five year decrease in age. The frequency of visits to and amount of time spent in urban green spaces have also been related to both self-reported restorative and preventative health benefits (Grahn & Stigsdotter, 2003), as has the presence of a garden or other greenery adjacent to one's dwelling (Stigsdotter & Grahn, 2004; Wells & Evans, 2003). Even the mere access to a window with a “green” view has been found to be beneficial (Kaplan, 2001; Ulrich, 1984).

While suggestive, especially when considered in toto, these studies are correlational in nature and thus it is difficult to infer cause and effect relationships between urban green space and health. In most studies, either exposure to nature or health effects are estimated by respondents, and in other studies respondents estimate both types of variables, which makes demand characteristics plausible if not likely alternative explanations. And, even in those cases where exposures to nature (e.g., the proximity of parks) are independently verified by geographic data and health status is gleaned from medical records or public health sources, there are still plausible alternative explanations, such as the beneficial effects of walking (Murphy, Nevill, Neville, Biddle, & Hardman, 2002; Osei-Tutu & Campagna, 2005),⁹ that preclude definitive statements about the effects of nature per se. Thus, we turn next to some experimental work that emphasizes the stress-reducing qualities of nature, the presumptive mechanism implicit in the epidemiological and other urban research on the beneficial effects of nature.

Perhaps the most influential study of the potential health effects of natural environments was not an experimental study at all, but a retrospective examination of patients recovering from gall bladder surgery under different environmental conditions. Matching patients on pertinent control variables, Ulrich (1984) found that those patients with a window view of a small wooded area recovered more quickly, used fewer potent analgesics and were generally easier to handle (according to chart notes) than those whose view was of a brick wall. In subsequent experimental work, Ulrich and colleagues (1991) explicitly tested the stress-reducing quality of natural environments

⁹ In fact, when public open spaces are nearby, large and attractive, people are 50% more likely to engage in high levels of walking than when these circumstances do not obtain (Giles-Corti et al., 2005).

by monitoring psychological and physiological recovery from a brief laboratory stressor. Following the stressor, participants viewed a videotaped traffic intersection, an urban pedestrian mall, or one of several natural environments. Those who viewed the natural environments showed quicker and more complete recovery from elevated frontalis, skin conductance, and pulse transit time measures. Psychological responding echoed these results, as well as those from an earlier study of psychological restoration (Ulrich, 1979), as the natural environment groups reported less anger and fear and more happiness following the environmental exposures than did the urban environment groups. Several conceptual replications followed, one assessing the relative importance of water as an element in restorative environments (Parsons, 1991a), and the other examining whether fairly minimal views of nature (as seen through the windshield of a moving car) would have restorative effects (Parsons et al., 1998). In both studies, nature-dominated environments elicited a greater reduction in sympathetic arousal following a stressor than urban environments did, although in the former study an urban scene with a substantial natural element (a river) elicited similar restorative effects. One interesting finding in the latter study was that exposure to a natural environment helped participants handle a subsequent stressor, which is consistent with recent data from Cackowski and Nasar (2003), who found that participants who viewed videotaped drives through tree-lined parkways showed greater tolerance for postdrive frustration than those who viewed more urbanized drives. Finally, a recent field study of inpatients in a cardiopulmonary rehabilitation program found that those who participated in a one hour introductory horticulture therapy session had lower heart rates and improved moods relative to those who attended a one hour patient education class (Wichrowski et al., 2005). Although the authors attributed these effects to the horticulture therapy session, which included a brief lecture, a tour of the garden/greenhouse, and repotting a plant, the therapy session also was more physically active than the patient education class, and this alternative explanation cannot be ruled out.

The research reviewed thus far has emphasized stress-reduction and other positive emotions people feel in response to natural environments. Other researchers have emphasized more cognitively oriented benefits, especially the restoration of voluntary or "directed" attention (see Kaplan & Kaplan, 1989). Ottosson and Grahn (2005), for instance, examined the focal attention of nonstressed elderly participants after spending a leisure hour indoors and an hour in an outdoor green area, and found that the latter intervention improved their concentration abilities but had no effect on HR or blood pressure. Hartig, Mang, and Evans (1991, study 2) found that after performing a demanding cognitive task, participants who walked through a natural environment performed better on a subsequent proofreading task than did those who walked through an urban environment or those who sat

quietly in a research room listening to music and reading magazines; there were no differences, however, in post-walk blood pressure or heart rate.¹⁰ In a recently reported similar study, Hartig and colleagues (2003) had participants drive to an urban or a natural research field site, after which half of the people in each setting performed cognitively demanding tasks for one hour to deplete directed attention capacity. Following their arrival (and tasks, if assigned), all participants then sat for 10 mins in either a windowless room (urban setting) or a room with a view of some trees (natural setting) before taking a 50 min walk in their respective environments. Regardless of whether they performed the cognitive tasks, participants who sat in the room with the nature view had lower diastolic blood pressure than those in the windowless room; and, lower systolic BP and diastolic BP also discriminated the nature group from the urban group during the subsequent walk. The two measures of directed attention capacity yielded conflicting results, however, with one indicating greater attentional capacity for the natural environment group, regardless of whether they had performed the depleting tasks, and the other showing no differences. Given the conflicting nature of the cognitive results, and the fact that both the physiological and cognitive effects occurred regardless of whether participants had performed the hour long, attention-depleting task, these effects might be more appropriately labeled "exposure" rather than "restorative" effects. That is, it may be that nature ordinarily elicits attention (as reflected in physiological responding) regardless of one's current capacity to direct attention and in direct proportion to its aesthetic value. Consider some conceptually related work in which natural stimuli appear to capture attention involuntarily, do not have the expected cognitive effects, yet the results are readily interpreted in terms of the environments' affective qualities.

Laumann, Gärling, and Stormark (2003) found that participants recovering from a cognitively demanding task had slower heart rates while viewing a nature video than participants who viewed an urban video, though the nature group performed worse on a subsequent selective attention task. Following Lacey and Lacey (1974), they interpreted the slower heart rates for the nature group as indicative of greater attentional or sensory intake for natural versus urban stimuli. They attributed the nature group's poorer performance on the cognitive task to the broader attentional set (reduced selectivity) that accompanies reduced physiological arousal (Easterbrook, 1959). However, the nature group only had slower heart rates while viewing the nature video, not during the subsequent cognitive task, so it seems unlikely that reduced physiological arousal accounts for the difference in performance between the two groups. Alternatively, had they measured emotional responding, they might well have found that the nature group's mood improved following the video, and, given

¹⁰ This may have been due to the delay involved in re-instrumenting participants after the walk (see Parsons & Hartig, 2000).

numerous reports by Isen and her colleagues (see Isen, 1999, for a review) showing that positive moods facilitate broad or inclusive thinking, they could reasonably have attributed poorer performance on the focal attention task to the moods elicited by the environments rather than to arousal. Larsen and colleagues (1998), for instance, have reported data on natural stimuli that suggest such an effect. They found that as the number of houseplants in an office environment increases, the mood of the occupants increases as well, though their performance on a narrowly focused cognitive task decreases.

Another group of studies on the cognitive effects of nature-dominated environments is also more readily interpreted when affective responding is considered, though most of the authors involved were not specifically studying emotions or the benefits of natural environmental stimuli. Researchers and clinicians interested in nonpharmacological adjuncts to pain relief have long used various distraction techniques, such as hypnosis (Rainville et al., 1999) music, (Good et al., 1999), and humor (Cogan, Cogan, Waltz, & McCue, 1987) to draw attention away from painful treatments and medical procedures. There is good evidence that painful stimuli monopolize attention in the absence of compelling non-painful stimuli (Eccleston & Crombez, 1999), and recent research suggests that certain classes of natural environmental stimuli constitute compelling distractions from pain. Clinicians performing various painful medical procedures have found that patients randomly assigned to view natural environment surrogates report reduced pain (Diette et al., 2003), or reduced pain and anxiety (Lembo et al., 1998; Miller, Hickman, & Lemasters, 1992) relative to control conditions, with some case study evidence suggesting that greater interactivity with environmental stimuli leads to greater pain reduction (Hoffman et al., 2001). Experimental studies with healthy volunteers support these clinical data, indicating that both pain thresholds and pain tolerance increase when viewing nature-dominated stimuli (Tse, Ng, Chung, & Wong, 2002), and that more compelling environmental surrogates are more effective analgesics than less compelling ones (Hoffman et al., 2004). Finally, recent fMRI research indicates that, in addition to self-reports of reduced pain, nature-dominated environmental stimuli also elicit reduced activation of several brain areas associated with the perceived intensity and unpleasantness of pain (Hoffman et al., 2004).

These data on reduced anxiety and the unpleasantness of pain are especially interesting, as they suggest that the pain relief attributable to nature-dominated stimuli may be a function not only of the cognitive distraction they provide but also of their valence. Indeed, though only one of the pain studies cited above explicitly tested the effectiveness of positively toned environmental stimuli (Diette et al., 2003), the authors of the other studies seem to have intuitively concluded that valence is important, as they have all used pleasant environmental scenes as *cognitive* distracters. Their successful use of pleasant environmen-

tal distracters (whether intentional or not) complements the results of other pain research, which suggests that valence mediates the effect of cognitive distracters, generally lessening perceived pain when distracters are positive and increasing it when they are negative (de Wied & Verbaten, 2001; Meagher, Arnau, & Rhudy 2001; Rhudy & Meagher, 2001; Villemure & Bushnell, 2002). Although it is still unclear how affect mediates pain perception, there is recent evidence that affect can influence the perceived unpleasantness of pain independent of its perceived intensity (Rainville, Duncan, Price, Carrier, & Bushnell, 1997; Villemure, Slotnick, & Bushnell, 2003), and that affect can also influence the attention that is paid to pain (Keogh, Ellery, Hunt, & Hannent 2001; see also, Dolan, 2002, on the pre-attentive processing of emotion-laden stimuli). Thus, the emotional distress caused by pain seems to be somewhat dissociable from the attention paid to its sensory qualities (e.g., intensity, quality, or location), and both components of pain perception appear to be vulnerable to the influence of pre-existing or competing emotions, including the positive emotions elicited by nature-dominated environments.¹¹

We have seen, then, that stressful, cognitively draining and painful states of mind all find succor in the pleasant diversion that nature-dominated environments provide. We have seen, as well, that the effects reported from both affectively-oriented (stress-reduction) and cognitively-oriented (attention restoration or distraction from pain) lines of research are best understood via significant affective mediation. That is, pleasant natural environments that have long been regarded as restorative cannot be adequately described either as involuntary-attention sinks or mere cognitive distracters: the positive emotions they elicit are central to the beneficial effects they produce. In the next section, we will see that the two dominant restorative environment theories emphasize affective and cognitive components of restoration, respectively, though neither of them integrates these aspects well enough to account for the empirical data reviewed here.

3.2. Restorative environments theory

Kaplan and Kaplan (1982, 1989) and Ulrich (1983, 1993) have proposed similar evolution-based explanations for restorative effects of natural environments, and in both cases the explanations grow out of their respective theories of environmental aesthetics. The evolutionary focus of these theories can be traced to numerous environmental aesthetics studies in the 1970s and 1980s showing overwhelming visual preferences for nature-dominated versus more urbanized environments, preferences that have been found in many cultures. The features of preferred environments include both certain types of natural contents (primarily water and green vegetation) and

¹¹ Whether this is true, as well, of negative emotions elicited by environmental stimuli is an open question: it has not been tried.

structural characteristics (open fore- and mid-ground, relatively low and even groundcovers, undulating topography, and occasional clumps of trees). These features represent the major empirical findings that must be accounted for in any theory of environmental aesthetics, and though the Kaplans and Ulrich both incorporate these findings in their models, they treat them somewhat differently.

Reasoning from the structural characteristics that predict preference, the Kaplans proposed that humans have two basic information processing needs that are central to functional capacity and health, exploration and understanding. People need to explore to acquire information from their surroundings, and they need to be able to quickly interpret the functional value of that information. The structural characteristics listed above are thought to facilitate both processes, and that is why they predict environmental preferences: they help to fulfill two basic human information processing needs. When opportunities for exploration and understanding are not immediately forthcoming (as they are in preferred environments), people must use directed (rather than involuntary) attention to acquire information and understand it. In developing their Attention Restoration Theory (ART), the Kaplans argue that the sociophysical environments of modern life present far fewer opportunities for ready exploration and understanding than our pre-urban environments did, and thus we rely on directed attention much more so than did our ancestors (Kaplan & Kaplan, 2003). However, because directed attention is a limited resource, it becomes depleted with both frequent and extended use and must be replenished before effective information acquisition and understanding (and thus, effective functioning) can resume. Discontinued use of directed attention (via *soft fascination*, which is involuntary attention to inherently interesting and positively toned environmental features and activities) is necessary though not sufficient for its restoration. We must also escape (either physically or psychologically) the sociophysical circumstances that depleted directed attention, to a place of sufficient scope and coherence as to be compatible with our psychological needs and behavioral inclinations. To the extent that environments embody these four components – fascination, being away, coherence and compatibility – they will restore directed attention, and the Kaplans maintain that nature-dominated environments are more likely than urban environments to have these features.

Although research indicates that these components predict the perceived restorativeness of environments (see Herzog, Maguire, & Nebel, 2003, for a review), there is relatively little evidence that they are related to actual restoration. In fact, there is a certain circularity to the work on perceived restorativeness, as the Kaplans derived these components in part from self-reports of the benefits of natural environments (e.g., Kaplan & Talbot, 1983). It is not surprising, then, that the reputed benefits of natural environments

(passed through an information-processing filter) are related to the perceived benefits of natural environments as measured by various perceived-restorativeness scales. Whether perceived restorativeness is a useful construct, however, is still unclear. Recent research indicates that perceived restorativeness may be little more than a proxy for visual environmental preferences (Herzog et al., 2003), and this suggests that the reputed benefits of natural environments are closely tied to their attractiveness – That is, to their capacity to elicit liking, which is the focus of Ulrich's model.

In contrast to the Kaplans, Ulrich emphasizes the contents of aesthetically preferred environments as much as their structural characteristics in his functional-evolutionary model of restorative environments. Thus, the potential safety and sustenance that elements such as water, trees, and flowering plants provide are as important as the promise of information gleaned from their spatial configuration. In more recent formulations of the model, Ulrich (1993) has adopted Orians' savanna hypothesis (Orians, 1980; 1986; Orians & Heerwagen, 1992) and Appleton's prospect and refuge notions (1975) to account for the positive regard we have for the structural features listed above. In particular, he emphasizes the feelings of safety and well-being that supportive savanna configurations engender, suggesting that opportunities to avoid harm and regain composure after threatening or challenging episodes are as important as the sustenance preferred elements in such environments provide. He also maintains that the positive emotions elicited by such supportive environments serve to block negative emotions and thoughts, facilitate restoration. This *opponent process* conception of emotions is congruent with current dynamic theories of emotion, which suggest that positive and negative emotions may occur simultaneously (and somewhat independently) under quiescent conditions, but tend to be negatively correlated under conditions of uncertainty or stress (Davis, Zautra, & Smith, 2004). Ulrich's notion of restoration, then, is considerably broader than the Kaplans' specific focus on attention restoration, encompassing all those situations that might elicit stress, including phasic episodes (e.g., encounters with predators or hostile conspecifics) and more tonic periods (e.g., extended vigilance during a hunt or while crafting a tool), as well as all the psychological and physiological effects that might accompany those situations. As befits a stress recovery model of restoration, and as evidenced by the review of research above, Ulrich has incorporated psychophysiological constructs and methods into his investigations of the restorative effects of nature-dominated environments. And, though the Kaplans and their colleagues have not emphasized psychophysiological investigations of attention restoration, there is no conceptual reason why more such studies could not be done. In fact, psychophysiological constructs and methods might help us sharpen the distinction between two theories that have a great deal of conceptual overlap.

3.3. Conceptual and methodological issues

There are a number of interrelated conceptual and methodological issues in the foregoing overviews of research and theory that warrant closer inspection. First, we will consider whether a distinction can be made between stress recovery and directed attention restoration, an issue with implications for choices regarding the selection, frequency, and timing of measures in studies of environmental restorativeness. As suggested above, there is a fair degree of conceptual overlap between these models. Ulrich et al. (1991), for instance, have suggested that the directed attention fatigue (DAF) construct can be accommodated by existing models of environmental stress, such as information overload models (e.g., Cohen, 1978; Cohen & Spacapan, 1978). Kaplan and Kaplan (1982), however, maintain that DAF can be experienced independently of stressful conditions, and that consequently it represents a distinct psychological state. Though several operationalizations of DAF have appeared in the literature (e.g., Cimprich, 1993; Hartig et al., 2003), they have not been adequately distinguished from stress manipulations (Kaplan, 1995), and thus the construct validity of DAF has yet to be empirically verified. As we have described, psychophysiological constructs and methods have been central to the development of the stress recovery model and only incidental to the directed attention restoration model. However, we see an opportunity for these psychophysiological tools to help determine the relative utility of DAF as a construct and, by extension, the ultimate heuristic value of distinguishing between stress recovery and directed attention restoration (cf. Hartig & Evans, 1993).

As an example, consider the problem of determining whether DAF can be experienced independently of stress. DAF is thought to occur through prolonged bouts of focal attention, and has been operationalized in terms of performance on tasks that require vigilance. The experience of stress is typically described as resulting from a perception of threat, harm, or frustrated goal attainment, and it is often operationalized in terms of autonomic reactivity, such as changes in blood pressure and skin conductance. Thus, to determine whether procedures thought to produce DAF were also stressful, we might monitor a measure such as skin conductance during administration of vigilance tasks. This approach is problematic, however, to the extent that our measure of stress is also responsive to manipulations of attention, which is the case for many autonomic measures, including skin conductance (Strube, 1990, p. 49). Clearly what we need is a pair of measures, one that indexes stress but is relatively nonresponsive to focal attention, and one that indexes focal attention but is relatively nonresponsive to stress. Tasks that lead to increases in the latter and quiescence (or decreases) in the former would be likely candidates for DAF procedures.

Though there may be no ideal measures that uniquely index stress and focal attention, psychophysiological measures that might be used to assess the suitability of DAF

tasks can be found among the growing number of components identified in event-related brain potentials (ERPs). Over the last 30 years, extensive evidence in the psychophysiological literature has established that the amplitude of negative ERPs occurring 100–150 ms (N100) after a target stimulus is related to selective attention (see Coles, Gratton, & Fabiani, 1990, for a review). Attended stimuli elicit larger (more negative) N100s relative to nonattended stimuli. Because the onset latency of a variant of the N100, *processing negativity*, has been associated with the allocation of attentional resources (see Coles et al., 1990; Hansen & Hillyard, 1983), this class of ERP may well be useful in tracking deteriorating attentional capacity (i.e., DAF). A more recently identified ERP component, the P50 (positive deflection, ≈50 ms peak latency), has been shown to be insensitive to changes in directed attention under certain circumstances, yet it is influenced by stress manipulations (White & Yee, 1997).

Apart from ERPs, there are other measures that might help environmental researchers discriminate between DAF and more stressful psychological states. One interesting example comes from research on tonic electromyographic (EMG) activity recorded from task-irrelevant musculature during the performance of protracted vigilance and other cognitive tasks. Rising EMG gradients during such tasks are often found in task-irrelevant muscles, and they have repeatedly been related to task difficulty, subjective effort, and stress elicited by the task (see Tassinary, Cacioppo, & Vanman, this volume). Because EMG gradients unfold over similar time courses as those used for putative DAF tasks, they appear well-suited to track the potential stressfullness of such tasks. Another measure that might be useful in this regard comes from the pain perception and related literatures in which numerous researchers have found that activations of the rostral and caudal portions of the anterior cingulate cortex (ACC) are associated with affectively- and cognitively-oriented tasks, respectively (see Bush et al., 1998; Whalen et al., 1998, for reviews). Interestingly, there is some evidence that the affective and cognitive divisions of the ACC are reciprocally inhibitory (Bantick et al., 2002), and that the cognitive division is part of a distributed attentional network activated by cognitively demanding tasks (Devinsky, Morrel, & Vogt, 1995). If we monitor the ACC, then, during the performance of a candidate DAF task, we would expect to see increased caudal activation throughout the task if it truly elicits DAF independently of stress. However, if we see initial activation in the caudal ACC giving way to more rostral activation, we would have to suspect that the task was becoming stressful. In fact, given the inhibitory relationship between the rostral and caudal ACC and the attentional focus of caudal activation, we could propose that rising activation in the rostral ACC contributes to DAF.¹² Of course, the timing of the change in ACC activation relative

¹² Note how this comports with Ulrich's contention that DAF can be incorporated into existing models of environmental stress.

to decreasing performance on the attentional task would be critical in making such a causal attribution.

Thus, in these three measures – ERP components, EMG gradients, and rostral versus caudal ACC activation – we have the beginnings of an analytical toolkit that may help us determine the construct validity of DAF and, more broadly, the relative utility of a distinction between the stress recovery and directed attention restoration models of environmental restorativeness.

A set of issues related to the conceptualization of DAF (i.e., its stressful/nonstressful character) concern operationalizations of restoration, which have been inadequately addressed in the literature on restorative environments. Restoration has not been consistently defined in the environmental literature, nor has recovery been consistently defined in the stress recovery literature. Haynes, Gannon, Orimoto, O'Brien, and Brandt (1991) have defined recovery from stress as “changes in stressor-induced responses following stressor termination” (p. 356). This broad definition incorporates both nonlinear and bidirectional changes in variables following stressor offset, which allows for “recovery” that does not necessarily reflect a return to prestressor response levels. In particular, however, if the word “stimulus” is used in place of “stressor” in this definition, then the simple notion of “changes following stimulus offset” is broad enough to capture the presumed depletion/replenishment cycle of DAF and restored attentional capacity as well as the experience of stress and the return to autonomic equanimity. “Stress recovery” would no longer be appropriate for the term being defined, though “restoration” is suitable, as it could be applied both to the replenishment of a capacity and to the return to physiological homeostasis.

Under this conceptualization, then, if restoration can involve the replenishment of a capacity, then the operationalization of restoration does not necessarily imply the measurement autonomic (and other) stress-related variables. For instance, just as the N100 ERP component may prove useful in determining the construct validity of DAF, the onset latency of processing negativity also may be useful in assessing the restoration of directed attentional capacity. The onset latency of processing negativity increases as the difficulty in discriminating between attended and unattended channels increases. And, presumably, the difficulty of a given attentional discrimination is related to the available directed attentional capacity, and as this capacity is depleted attentional discriminations become more difficult. Thus, the onset latency of processing negativity might be expected to increase as directed attentional capacity is depleted. That is, as DAF increases, discriminations among attended and unattended channels should be more difficult. Conversely, as directed attentional capacity is restored, the onset latency of processing negativity might be expected to decrease because attentional discriminations should become easier.

If DAF is eventually resolved to be a stressful psychological state, however, it may still be useful to distin-

guish it from other stressors, in part because of the complex nature of physiological mechanisms that underlie stress responses and stress recovery. As typically conceived (Kaplan, 1995) and induced (Hartig et al., 2003), DAF unfolds over a protracted period of focused cognitive activity. The slowly developing nature of DAF has direct implications for the stress-related physiological mechanisms that may be engaged by this psychological state and, ultimately, for any health-related consequences that may be inferred, which has been a prime concern in the restorative environments literature (see Parsons, 1991b). As Haynes et al. (1991) have noted, the duration of a stressor has important influences on patterns of physiological responding. Relatively brief, acute stressors (such as the math tasks, extemporaneous speeches, and iced appendages that abound in the stress literature) engage the sympathetic adrenomedullary system, which quickly leads to increased levels of immune activity and circulating epinephrine and norepinephrine. More long-lived stressors engage the hypothalamic-pituitary-adrenocortical system, leading to the release of cortisol, which has immunosuppressive effects. Thus, the physiological parameters that may be useful in assessing DAF and the associated restoration of directed attention, ERPs, corticosteroids, and immuno-competence, differ from the primarily cardiovascular and sympathetically-mediated (e.g., SCR) measures that have characterized empirical investigations of the stress recovery model of environmental restorativeness.

Finally, in closing this section we examine in passing methodological issues related to environmental sampling and representativeness, which have also been inadequately addressed in this relatively young field. Environmental psychologists have often been concerned with the representativeness of the environments under study. For our purposes here, this concern refers not only to the sampling of environments across the effective range of the physical variables of interest, but also to the restorative implications of sociophysical changes in environments over time, as was suggested by the Frankenhausen and colleagues (1989) study described above. In the empirical examinations of restorative environments thus far, environmental classes such as “natural” or “urban” have too often been represented by very small numbers of exemplars, leaving the interpretation of results open to attributions to particular environmental instantiations rather than to the environmental classes or variables of interest. While this particular problem in environmental sampling can be easily resolved (at least conceptually), others are less tractable, such as the selection of appropriate comparison or “control” conditions. Because people are never encountered outside of an environment, the concept of a “no-environment” control condition has no meaning (see Fredrickson & Levenson, 1998). Lastly, we raise the difficult issue of the ecological validity of environmental surrogates. Psychophysiological research on environmental restorativeness is more conveniently conducted in the laboratory than in the field, and thus a reliance

on environmental surrogates is a primary concern. If the restorative qualities of environments can be adequately represented visually, then high-quality photography and videography may well produce adequate surrogates. However, to the extent that the environmental qualities of interest (restorative or otherwise) are not well represented by visually-oriented technologies, then the adequacy of environmental surrogates is called into question. This issue, in the guise of adequately represented movement through space, receives more careful consideration in the final section of this chapter, on topographic cognition.

4. TOPOGRAPHIC COGNITION

Don't know where I am and got no mother to guide me home.
(Chariton, 1990, p. 141)

One can define spatial cognition broadly as any aspect of an organism's behavior that involves space and is informed by cerebral activity (Kritchevsky, 1988). Topographic cognition refers to a subset of these behaviors wherein cerebral activity guides an organism's movement through the molar environment. For purposes of this discussion, and as is typically conceived in studies of topographic cognition (e.g., Aguirre, Zarahn, & D'Esposito, 1998; Allen, 1985; Kuipers, 1982; Maguire, 1997), the molar environment is both large in scale or visually occluded so that it cannot be completely perceived from a single vantage point. Thus, walking a maze in a laboratory room, navigating a building, or exploring a city all constitute transactions with molar environments that engage topographic cognition.

Though we do it every day, mostly without thinking about it, finding our way through the world is both a critically important and quite complex behavior. Common animal behaviors that are crucial to survival, such as gathering food, finding mates or shelter, hunting prey, avoiding predators, and caching of young, all depend on an organism's ability to understand and navigate its physical surroundings (Spencer, Blades, & Morsley, 1989). While few of us still rely on our hunting skills for survival, case study evidence from clinical neuropsychology suggests that topographic disorientation can nevertheless be quite devastating (e.g., Cammalleri et al., 1996; Habib & Sirigu, 1987; Landis, Cummings, Benson, & Palmer, 1986; Whiteley & Warrington, 1978). Wayfinding is a complex behavior as well, as it requires the coordination of spatial perception, memory and attention, and often involves dynamic spatial processes, such as mental rotation and the construction of spatial imagery (Kritchevsky, 1988). In the [last section](#) of this chapter, we examine the contributions that psychophysiology can make to our understanding of these processes. We briefly review historical and recent work in clinical neuropsychology, psychobiology, and cognitive psychology, which suggests the importance of multimodal integration of perceptual information for topographic cognition. We then highlight some very interesting work that exploits recent advances in functional brain imaging tech-

niques to investigate wayfinding. The reliance on transactions with environmental surrogates in this research prompts a discussion of how representations of large-scale environments can be assessed in psychophysiology, which is still largely a laboratory science.

4.1. Origins and recent research on topographic cognition

The origins of our current understanding of topographic cognition can be traced to late nineteenth century Europe, when clinical reports of spatial disorders associated with topographic disorientation began appearing in the medical literature. There were reports of impaired wayfinding in familiar environments (Badal, 1888/1982; Jackson, 1876/1958), and the inability to recognize familiar places (Meyer, 1900/1996), as well as reports of retained spatial knowledge accompanied by the inability to apply it (Wilbrand, 1892/1982). Although most researchers during this period distinguished these spatial deficits from more common aphasias, they typically did not acknowledge a commonality among reports – that many of these problems were associated with posterior lesions in the right hemisphere (Morrow & Ratcliff, 1988). In an influential series of papers, Zangwill and his colleagues (Ettlinger, Warrington, & Zangwill, 1957; McFie, Piercy, & Zangwill, 1950; Paterson & Zangwill, 1944, 1945) documented the importance of the posterior right hemisphere for spatial behavior (DeRenzi, 1982), and, in particular, Paterson and Zangwill (1945) identified a key distinction between two visuospatial deficits (topographic agnosia and amnesia) that continues to inform the bulk of latter day theory and research on topographic cognition. Topographic agnosics have difficulty recognizing familiar buildings and landmarks, while topographic amnesics cannot readily specify routes within or draw maps of familiar territory.

Echoing these neuropsychological findings, complementary strands of research in psychobiology and cognitive and environmental psychology have developed similar distinctions between topographic recognition and memory abilities. Early Hullian stimulus-response accounts of spatial behavior and learning in nonhuman animals have been supplanted by "cognitive mapping" explanations (Tolman, 1948), which assume that animals use allocentric¹³ representations of the spatial relationships among environmental features to navigate their surroundings (see Allen, 1985, 1987; Schacter & Nadel, 1991). In particular, work with

¹³ The terms *allocentric* and *egocentric* are used in the general literature on spatial cognition to refer to types of frames of reference, environment-centered and person-centered, respectively. Egocentric frames of reference include retinocentric, craniocentric, and somatocentric, while allocentric frames of reference may include any (usually stable) element or set of elements in the environment other than the self. Developmentally, egocentric frames of reference emerge first, followed by simple allocentric reference frames focusing on proximal elements in the environment, progressing through allocentric frames focused on more distal elements including those beyond the immediate perceptual horizon.

animals suggests a clear maturational distinction between landmark learning ability (early onset) and map learning ability (later onset; see Schacter & Nadel, 1991), and this is echoed by work with humans (Pine et al., 2002). Neural localization studies with animals (primarily the rat) have also been important in isolating the hippocampal formation as central to cognitive mapping functions (see O'Keefe & Nadel, 1978 for a review and seminal theoretical account of this work). Cognitive and environmental psychologists have devoted much of their research efforts to identifying and understanding types of topographic knowledge. Following Shemyakin's (1962) early theoretical account, researchers have generally identified three types of topographic knowledge: landmark knowledge, route knowledge, and configural or survey knowledge (Allen, 1985; Golledge & Stimson, 1997; Schacter & Nadel, 1991; Siegel & White, 1975; Thorndyke, 1981). Landmark knowledge confers the ability to recognize previously encountered, distinctive environmental features, and to use them as reference points for locomotion through the environment. Route knowledge comprises spatiotemporal relations among sequentially ordered environmental features coordinated with motor actions required to traverse set paths through an environment. And, possession of the most complex form of topographic knowledge, configural or survey knowledge, implies the ability to infer spatial relations among multiply interconnected environmental features from an allocentric frame of reference (see Allen, 1987; Schacter & Nadel, 1991; and Thorndyke, 1981 for variations on these basic definitions). More colloquially, configural knowledge refers to the possession of a "cognitive" or "mental" map, which allows one to flexibly interact with the environment to recognize short cuts, generate new routes when existing ones are blocked, judge distance to and direction of occluded elements, etc.

Although most researchers acknowledge these three basic types of topographic knowledge and regard both the microgenetic acquisition and the ontogenetic development of landmark, route, and configural knowledge and abilities to be sequential (Allen, 1985; Golledge, 1987; Siegel & White, 1975), the consensus is not absolute (see Golledge & Stimson, 1997, Ch. 5; Spencer et al., 1989, Ch. 1). Some have questioned the evidentiary basis of configural knowledge (e.g., Pick, 1993) or suggested that true configural knowledge cannot develop independently of exposure to symbolic representations of the environment (Moeser, 1988), while others have questioned the sequential microgenetic acquisition of topographic knowledge types (Montello, 1998). What these questions suggest is that the simple description of an orderly development of topographic knowledge and abilities is likely overly simple, and perhaps wrong in several respects, as others have noted (e.g., Magliano, Cohen, Allen, & Rodrigue, 1995; Mandler, 1988; Montello, 1998; Pick, 1993; Spencer et al., 1989). In particular, two distinctions regarding the manner in which topographic information is acquired have important implications for the brain imaging research described below.

First, topographic information about the environment can be gained through direct experience with the world or through interaction with symbolic representations of the environment, such as maps or verbal descriptions of routes. Presson and Hazelrigg (1984) have labeled the former *primary* and the latter *secondary spatial learning*, and many researchers have found that performance on topographic tasks can depend upon this distinction (Howard & Kerst, 1981; Scholl, 1987; Thorndyke & Hayes-Roth, 1982). Evans and Pezdek (1980), for example, reported that latencies to judge the accuracy of spatial relations among triads of buildings are linearly related to rotational disparity from typical Cartesian presentation (i.e., 0° = North) for students who learned the building locations from a map, though latencies are unrelated to Cartesian coordinates for those who learned the locations *in situ*.

Second, evidence suggests that a distinction between *passive* and *active* primary spatial learning may be important (see Cohen & Cohen, 1985, for a review). In general, active engagement with the environment is thought to produce more flexible cognitive maps (Cohen & Cohen, 1985; Siegel & White, 1975), whereas passive interactions tend to produce orientation-specific representations (e.g., Hintzman, O'Dell, & Arndt, 1981). Both correlational (Acredolo, 1988; Appleyard, 1970; Beck & Wood, 1976; Golledge & Spector, 1978) and experimental work (Cohen & Weatherford, 1980, 1981; Klatzky, Loomis, Beall, Chance, & Golledge, 1998; Richardson, Montello, & Hegarty, 1999; Simons & Wang, 1998; Wang & Simons, 1999) support this distinction, and the importance of active engagement seems not to lie with movement through the environment per se, but with the opportunity to monitor the environment that movement affords (e.g., Acredolo, Adams, & Goodwyn, 1984; Böök & Gärling, 1980a, 1980b, 1981). Many researchers have suggested that the integration of perceptual information during locomotion is central to maintaining orientation in and constructing representations of environments (e.g., Caplan et al., 2003; Evans & Pezdek, 1980; Gärling, Böök, & Lindberg, 1985; Montello, 1998; Spencer et al., 1989). Although some researchers have emphasized the importance of integrating multiple visual perceptions over time (e.g., Heft, 1983), others have suggested that periodic attention to retinal flow information in the environment can be used to calibrate orientation estimates gleaned from biomechanical and proprioceptive afferents (e.g., Pick, 1993).¹⁴ Rieser and his colleagues (Rieser, Pick, Ashmead, & Garing, 1995) have shown that the accuracy of biomechanical estimates of distance (i.e., walking to a target with eyes closed) can be manipulated when prior biomechanical and visual

¹⁴ Pick (1993, p. 36) actually used the term *optical flow*, though the context suggests that the intended meaning was retinal flow. Retinal flow is motion as it is presented to the retina, and it comprises both rotational flow and optical flow. The former is due to motion produced by eye movements, while the latter is produced by movement of the observer through the environment (see Cutting, Springer, Braren, & Johnson, 1992).

feedback regarding rate of travel are mismatched. Rieser et al. (1995) observed similar inaccuracies for orientation judgments after participants experienced a rotational visual/biomechanical discontinuity. Scene recognition also suffers following a change in perspective that disrupts vestibular and proprioceptive feedback (Simons & Wang, 1998). These findings suggest that biomechanical actions (and associated kinesthetic afferents) performed during self-locomotion are important sources of information regarding course and distance knowledge, and that the accuracy of this knowledge is periodically updated by the opportunity to integrate visual and nonvisual information sources.

In sum, it seems clear that movement through the environment has the potential to influence the manner in which topographic information is acquired and used, and as we will see next, this has implications for the use of functional brain imaging techniques to study topographic cognition.

4.2. Topographic cognition, functional brain imaging and virtual reality

Researchers have used several functional brain imaging techniques to study topographic cognition in humans, including EEG, fMRI, and positron emission tomography (PET). Although interesting work on hippocampal theta rhythms associated with navigational movement is being done with intracranial EEG recordings (Caplan et al., 2003), most of the brain imaging research on topographic cognition has relied on the latter techniques in which inferences about brain activation are made based on magnetic or radioisotope evidence for regional cerebral blood flow (rCBF). Because of the restrictive nature of brain imaging equipment, research participants' transactions with environments are limited to either recollections of actual environments, or interactions with environmental surrogates, with the latter approach predominating. Environmental surrogates have included videotaped "walk-throughs," modified versions of commercially available computer games, and other computer-generated virtual environments that allow participants to control apparent movement through maze-like or town-like settings. Topographic tasks have included imagined point-to-point (PTP) traversals of previously learned actual environments, exploration of novel computer-represented environments, learning of videotaped environments, and traversals and directional judgments in previously learned computer environments. Despite these differences in environmental representations and tasks, as well as differences in specific research questions, the primary focus among researchers using functional brain imaging to study topographic cognition has been to localize neural substrates involved in the learning and retrieval of topographic information. They have found that learning and retrieval of topographic information activate many of the same structures in the medial temporal, posterior parietal

and occipitotemporal regions, including the hippocampus, parahippocampus, posterior cingulate (retrosplenial) cortex, fusiform and lingual gyri, precuneus, and the inferior and superior parietal lobules.

Activations of the hippocampus, parahippocampus, posterior cingulate, and precuneus, in particular, have consistently been associated with more complex topographic tasks, including those putatively requiring allocentric representations of the environment. Activation of these structures for complex topographic behavior is consistent with animal models of navigation, which suggest that egocentric (head- and body-centered) reference coordinates (based in part on externally acquired landmark information) are integrated with an internally generated sense of direction (based on vestibular, proprioceptive and motor afferents) to produce allocentric reference coordinates used to navigate complex environments (McNaughton, Knierim, & Wilson, 1995; Taube, Goodridge, Golob, Dudchenko, & Stackman, 1996). Evidence suggests that posterior parietal regions, including the precuneus, are important for generating egocentric coordinates (Andersen, Snyder, Li, & Stricanne, 1993), whereas several models have focused on the hippocampal formation for processing of idiothetic (internally generated) heading information used to produce allocentric coordinates (Burgess, Recce, & O'Keefe, 1994; McNaughton, Chen, & Markus, 1991). The contribution of the posterior cingulate to this process has alternatively been represented as the starting point for the transformation of coordinates from egocentric to allocentric (Vogt, Finch, & Olson, 1992), or as processing parietal coordinate information to update idiothetic position signals, which tend to drift independent of external verification (McNaughton et al., 1991; McNaughton et al., 1995).

This broad consistency between structures implicated in topographic cognition of intact humans with those structures being delineated as integral to navigational neural circuits in animals is encouraging. However, several important caveats must be raised regarding interpretation of the brain imaging work, and these caveats in turn have important implications for the ultimate utility of brain imaging methods for the study of human topographic cognition. We will briefly mention three issues that are common inferential concerns in functional brain imaging research, regardless of the psychological phenomena of interest, after which we will concentrate on a fourth issue that has specific import for those studying topographic cognition. First, with respect to fMRIs and PET scans, there are issues associated with the functional significance of neural activation inferred from rCBF. Though increased blood flow to a particular region may be associated with increased neural activity, the functional significance of that activity is difficult to determine in the absence of any information regarding the specific nature (e.g., excitatory/inhibitory) or patterns of neuronal firing (see Posner & Raichle, 1994; Sarter, Berntson, & Cacioppo, 1996, for discussion of similar concerns).

Second, though recent advances in brain imaging techniques have dramatically improved the spatial resolution of both PET and fMRI scans, the temporal resolution of these techniques is still rather limited (Brodal, 1998). Although the temporal resolution of fMRI can be as small as just a few seconds, brain scans of topographic tasks are often integrated over anywhere from 30–90 s, a long period of time during which participants may engage in both task-focused and off-task processing. While researchers may assume that off-task processing is randomly distributed among experimental conditions (though it is not clear how one could convincingly test this assumption), when cerebral localization of cognitive functioning is the primary purpose of the research, attempts should be made to limit the likelihood of off-task processing. Participants may also engage in *unexpected task-focused* processing, which may also limit the attribution of functional significance to particular brain regions when data from rCBF are integrated over long epochs. Aguirre and D'Esposito (1997), for example, trained participants to a 90% accuracy criterion for topographic knowledge of a computer-simulated town, and then gave them prescanning practice on two tasks that putatively discriminated landmark cognitive processing from survey (allocentric) cognitive processing. Importantly, these tasks were administered within subjects and were self-paced during (separate) 60 s scanning blocks. Given the prior training to a knowledge criterion (i.e., acquisition of both landmark and survey knowledge), exposure to both tasks beforehand, and the time to implement any desired strategies during scanned task performance, participants may well have used both types of knowledge for both tasks, regardless of the instructions and the presumed task requirements. That participants will adopt navigational strategies they are most comfortable with is clear from research that allows participants to learn environments without specific navigational instructions (e.g., explore the environment, find targets, and remember the environment for subsequent use). Under these conditions, some participants will spontaneously adopt route-learning strategies (memorizing left- and right-turn sequences), others will acquire allocentric knowledge based on relationships among landmarks, and still others will change strategies in mid stream (Bohbot, Iaria, & Petrides, 2004; Iaria et al., 2003). In this research, only those participants using allocentric landmark knowledge showed the expected hippocampal activation for wayfinding, and thus, a specific mapping of function to structure depends critically upon some measure of navigational strategies actually used, regardless of task instructions.¹⁵

These examples help to illustrate the third general caveat to the interpretation of brain imaging research: there are limitations associated with the *subtractive logic*, which is

routinely used to draw inferences about the functional significance of regional neural activity. In a continuously active system such as the human brain, observed activations at a particular period of time under a given set of conditions are only meaningful relative to activations observed under a comparison set of conditions. When observed activations associated with comparison conditions are subtracted from those associated with the experimental conditions of interest, the remaining activations are assumed to be functionally significant that is, selectively associated with the cognitive processes engaged by the experimental conditions. For a number of reasons (see Sarter et al., 1996), however, when such subtractions are made it is possible that information is lost regarding the neural substrates subserving the functions of interest. For example, regions that are active to a similar extent for both experimental and control tasks may be active for different reasons (i.e., they subserve different functions), and thus experimentally relevant, interpretable activations would be lost to subtraction. Andersen et al. (1993), for instance, report evidence for posterior parietal cell assemblies that contribute to the representation of space in both head-centered and body-centered coordinates, depending upon the conditions under which activation is elicited. In a situation where activations associated with both sets of conditions were directly compared, the subtractive logic of imaging techniques could well lead to a discounted role for this parietal region in both functions.

Given these concerns, it is important that brain imaging evidence for the localization of cognitive functions be interpreted in light of pertinent evidence from related disciplines, such as psychobiological work with animals and neuropsychological research with impaired human populations. Inferences for the localization of cognitive function to candidate neural structures based on brain imaging data become much stronger if it can also be shown that lesions of the same structures in animals and humans lead to deficits in behaviors that (putatively) require the function in question. To their credit, researchers using functional brain imaging of topographic cognition have usually marshaled psychobiological and neuropsychological evidence to support the neural localization inferences they have made.

However, there is one last set of concerns specific to the study of topographic cognition that requires further interpretational caution, and may suggest a modification of typical experimental procedures. This fourth set of concerns is related to a critical assumption that is often made when environmental surrogates are paired with brain imaging techniques to study topographic cognition, namely, that participants' interactions with environmental surrogates engage the same cognitive processes that encounters with actual environments engage (Aguirre et al., 1998). To illustrate the nature of these concerns, we will focus on conflicting evidence from recent brain imaging work regarding the relative contribution of the hippocampus to human topographic cognition.

¹⁵ See also Jordan, Schadow, Wuestenberg, Heinze, & Jänke (2004), in which navigation through a simple virtual maze elicited bilateral parahippocampal and left hippocampal activation among those reporting an allocentric strategy.

As briefly mentioned in the review above, there is good evidence from the animal literature that the hippocampus is central to processing that requires allocentric spatial representations. Much of this evidence comes from work with rodents (for reviews, see McNaughton et al., 1995; O'Keefe & Nadel, 1978), though research with avian species also supports the importance of the hippocampus for complex spatial behavior (e.g., Biegler, McGregor, Krebs, & Healy, 2001; Bingman & Jones, 1994; Sherry, Jacobs, & Gaulin, 1992). There has been some work with nonhuman primates that is supportive as well (e.g., Feigenbaum & Rolls, 1991; Rolls, Robertson, & Georges-François, 1995), though the issue of topographic cognition has been less intensively explored with these animals than with rodents. Finally, the evidence from clinical neuropsychology has been much less clearcut, in large part because focal damage to the hippocampus proper is a relatively rare event.¹⁶ There has been some neuropsychological evidence, however, that parahippocampal damage can lead to topographic disorientation (with primarily spatial location deficits rather than landmark agnosia; e.g., Habib & Sirigu, 1987). Aguirre et al. (1998) have cited this evidence of parahippocampal involvement in topographic cognition to support findings in their brain imaging work that also implicate the parahippocampus. They suggest that neural substrates for allocentric representations of space may differ in primates and rats, with the parahippocampus being more important in the former and the hippocampus in the latter. In two studies they collected fMRI data while participants explored either a computer-simulated maze (Aguirre, Detre, Alsop, & D'Esposito, 1996) or a computer-simulated town (Aguirre & D'Esposito, 1997). Although the specific research questions were slightly different in these two studies (acquisition versus retrieval of topographic information in one, and place identity versus topographic location, in the other), activations in the medial temporal regions implicated the parahippocampus in both studies, while the hippocampus proper was not recruited in either study.

In contrast, Maguire and her colleagues have reported three PET scan studies in which the right hippocampus was activated for both learning (Maguire, Frakowiak, & Frith, 1996) and retrieval (Maguire, Frakowiak, & Frith, 1997; Maguire, Burgess, et al., 1998) of complex topographic information relative to activations observed for less complex topographic and non-topographic tasks. Ghaëm et al. (1997) have also reported hippocampal activation using PET scan imaging during recall of complex environmental information learned on site. Considering possible reasons for this conflicting evidence regarding

¹⁶ Morris and his colleagues (Morris, Pickering, Abrahams, & Feigenbaum, 1996), however, have published a short report on the spatial abilities of temporal lobe resection (TLR) patients suffering from focal temporal lobe epilepsy. Resections, which were confined to the amygdala and the anterior two thirds of the hippocampus, impaired both egocentric and allocentric spatial performance of right TLR patients relative to left TLR patients and controls.

the contribution of the hippocampus proper to complex topographic cognition, we can quickly dispatch two possibilities by referring to a fourth study by Maguire and her colleagues. Although separate laboratories using different brain imaging techniques have reported this conflicting evidence (Aguirre et al. using fMRI, Maguire et al. and Ghaëm et al. using PET), Maguire, Frith, Burgess, Donnett, & O'Keefe (1998b) found that medial temporal activation for topographic tasks was limited to the right parahippocampal gyrus. Thus, the cross-study differences in implicated neural substrates do not appear to be attributable to differences in laboratories or imaging techniques per se, as Maguire, Frith et al. (1998) again used PET but this time failed to find activation of the hippocampus proper. Beyond the conflicting evidence from these research groups, others have found that allocentric navigation tasks recruit both hippocampal and parahippocampal activation, muddying the waters even further (Millet et al., 2000; Parslow et al., 2004).

A possible explanation for the conflicting evidence across studies regarding the contribution of the hippocampus to topographic cognition lies in the specific nature of the participants' environmental transactions. The three studies that failed to find hippocampal activation for complex topographic cognition all used relatively simple computer simulations of either mazes (Aguirre et al., 1996; Maguire, Frith et al., 1998), or a town with distinctly maze-like characteristics (Aguirre & D'Esposito, 1997).¹⁷ On the other hand, the three studies by Maguire and colleagues, in which the hippocampus was implicated in topographic cognition, all relied on much more complex environmental transactions. Maguire et al. (1997) scanned participants while they described routes through London based on their intimate first-hand knowledge of the city from years of driving taxis; Maguire et al. (1996) scanned participants while they viewed information-rich videotaped urban "walks"; and, although Maguire, Burgess, et al. (1998) did use a computer-simulated town, the published depictions and verbal descriptions of the town suggest that it was substantially more sophisticated than previously used simulations.¹⁸

Whether these differences in environmental transactions can account for the differential activation of the hippocampus across imaging studies is difficult to determine. At the very least, given the evidence from these initial imaging studies, it is probably premature to assume that all simulated environmental transactions engage the

¹⁷ The town is laid out in a 4×4 grid of named places, and though the presence of a background skyline suggests the possibility of using distal features for orientation within the immediate environment, the authors claimed that this was not possible (Aguirre & D'Esposito, 1997, p. 2513, figure 2). In other respects, the published map and first-person views of the environment are strongly suggestive of a maze.

¹⁸ The town comprised four streets with shops, bars, a cinema, church, bank, train station, and a video-game arcade, and the buildings were accessible and navigable, lending considerable complexity to environmental transactions.

same cognitive processes (or engage them to the same degree) as those engaged for transactions with actual environments. Although the environmental transactions in those studies that elicit hippocampal activation differ from the simple computer-simulated transactions in those that do not, the nature of those differences is not uniform. In one case we might focus on the visual complexity of videotaped environments (Maguire et al., 1996), in others on the visual and interactive richness of recalled actual environments (Maguire et al., 1997; Mellet et al., 2000), and in still others on visually and navigationally complex perceptual interactions with computer-simulated environments (Maguire, Burgess, et al., 1998; Parslow et al., 2004). The common thread among these environmental transactions is not obvious, other than a vague notion that each is more compelling or complex than transactions with computer-simulated mazes. However, recent work by Maguire and her colleagues (Hartley, Maguire, Spiers, & Burgess, 2003) suggests that a compelling or complex environmental transaction is not simply a matter of interacting with a reasonably complex environment. If the nature of the interaction is a simple one (e.g., route following), then complex environments do not elicit activation of the hippocampus proper. Furthermore, in this particular study, as in an earlier one (Maguire, Burgess et al., 1998), hippocampal activation was also tied to performance: good navigators, and other participants when navigating well, show hippocampal activation during wayfinding in a complex environment, but not during route following. Thus, a compelling human-environment transaction appears to be necessary to recruit hippocampal involvement in topographic cognition, where "compelling" comprises wayfinding (i.e., use of allocentric knowledge) in a reasonably complex environment. Whether accuracy of navigation should be included in the definition of compelling transactions is an open question in this inchoate research area, as others have reported hippocampal activation that was not tied to performance (Mellet et al., 2000; Parslow et al., 2004). Indeed, many factors that might bear on this question, such as preferences for navigational strategies (allocentric vs. egocentric, see above) and facility/familiarity with virtual environments (McNamara & Shelton, 2003), are not routinely assessed and thus it is impossible to determine the relative importance of accurate wayfinding for hippocampal activation.

Despite this uncertainty, we can speculate that more compelling environmental transactions are more likely to recruit hippocampal activation because they simulate movement through the environment more convincingly. As we have seen in the review above, active engagement with the environment may well influence the way people represent space and perform spatial tasks and, in particular, the opportunity to integrate visual and kinesthetic inputs when people move through space may play a key role in the cognitive processing of topographic information. Prominent animal models of hippocampal involvement in navigation have also identified movement through the envi-

ronment as being requisite for the generation of allocentric referents and the calibration of an idiothetic sense of direction (Burgess et al., 1994; McNaughton et al., 1991; McNaughton et al., 1995). These models were developed based on research with freely moving animals, and this work has provided abundant evidence, such as hippocampal "place" cells,¹⁹ for the involvement of the hippocampus in the performance of complex navigational tasks (see O'Keefe, 1991). Work with animals also indicates that the firing rate of hippocampal place cells is linked to the speed and direction of an animal's movement (Wiener, Paul, & Eichenbaum, 1989). Interestingly, hippocampal place cells cease firing almost completely when animals are passively restrained (Foster, Castro, & McNaughton, 1989), and, though video simulations of movement through the environment do not elicit place cell responding in primates, actual movement through the environment does (Froehler & Duffy, 2002).²⁰

Thus, information gleaned from movement through the environment appears to be an important component of topographic cognition, at least in animal models.²¹ This is a potential stumbling block for brain imaging studies of topographic cognition, as "wearable" brain scanning devices have yet to be developed and environmental simulations are likely to play an important role in this research for the foreseeable future. Thus, to the extent that environmental simulations can convincingly mimic the perceptual experiences of movement, they may be more apt to engage the cognitive processes central to topographic cognition, and thereby help to improve the internal validity of brain imaging studies. There is, therefore, a critical need for a conceptual framework that specifies criteria by which researchers can discriminate stronger from weaker environmental simulations, especially with respect to the simulation of movement, and we will briefly examine one framework that borrows heavily from concepts in the communications literature.

In developing a definition of virtual reality (VR), Steuer (1992) has proposed a set of criteria for assessing the *telepresence* of VR systems. Telepresence refers to a feeling of being in a physical environment that is both spatially and temporally removed from one's immediate physical surroundings, and the feeling is produced by mediated rather than direct perceptual experience. In Steuer's model, mediation is through any indirect form of communication, and thus even relatively simple technologies (e.g., letters or telephones) can function as VR systems. This expansive potential for VR is felicitous for examining the simulated environmental transactions used in brain

¹⁹ These are hippocampal cells selectively tuned for an animal's location in space, regardless of its orientation (i.e., its egocentric perspective).

²⁰ Monkeys, presumably, have little familiarity with egocentric video movement, and such simulations are unlikely to convincingly mimic movement through the environment for them.

²¹ For a full consideration of hippocampal and parahippocampal involvement in spatial cognition, see Burgess, Maguire, and O'Keefe (2002).

imaging research because it allows us to assess such media as maps, videotape, and sophisticated three-dimensional computer animations within the same conceptual framework. The criteria Steuer presents are similar in content to those developed by others in the communications field (e.g., Zeltzer, 1992), and focus on two dimensions of presentation media that are presumed to elicit a feeling of telepresence: *vividness* and *interactivity*. Vividness refers to the representational richness of a simulated environment and can be judged in terms of the *breadth* and *depth* of the sensory information presented. Breadth refers to the range of perceptual systems simultaneously addressed by a presentation medium. Redundant information contained in multimodal sensory presentations is thought to eliminate competing perceptual interpretations and thereby enhance a given perceptual experience. Depth is determined individually for each sensory channel and is gauged according to its resolution, or density of data. The second media dimension determining telepresence, interactivity, is the extent to which users can manipulate the content and form of a simulated environment. Interactivity can be assessed in terms of the speed (real-time or slower) and range of available manipulations, as well as the fidelity of actions required to manipulate simulated environments (often referred to as *mapping*). Using a steering wheel to control simulated driving, for instance, constitutes a more veridical VR interaction than would button presses or keypad-controlled motion.

This model is for illustrative purposes only, as the dimensions and underlying variables of telepresence mentioned above have not been empirically verified, nor are they likely to be the only relevant factors (see Biocca & Levy, 1995; Cutting, 1996, 1997). However, this model does give us a vocabulary and initial conceptual framework within which the simulated environmental transactions used in brain imaging research can be evaluated. For example, video game systems routinely trade-off visual depth and, thereby, vividness to retain real-time motion in the service of interactivity. If we compare Maguire et al.'s (1996) videotaped environmental simulation, which did activate the hippocampus, and the two simulated maze-environments used by Aguirre and colleagues (Aguirre et al., 1996; Aguirre & D'Esposito, 1997), which did not, we may reach the tentative conclusion that visually vivid simulations are more apt to recruit hippocampal involvement than are more visually impoverished (though) interactive simulations. Comparing Maguire, Burgess et al.'s (1998) more complex VR town with Aguirre's and D'Esposito's (1997) maze-like VR town, we can begin to parse the differences in complexity in terms of the former simulation's (apparently) greater visual depth and broader range of interactivity (provided by building accessibility and functioning doors). Comparisons with the remaining PET study eliciting hippocampal activation (Maguire et al., 1997) are problematic within this conceptual framework because the taxi drivers' environmental transactions were with recalled actual environments. This presents two problems. First,

the definition of telepresence specifies a mediated perception of being in a physical environment other than one's immediate spatiotemporal surroundings, but recalled (and imagined) environments are internally generated, not perceived. Thus, we need a term (and definition) similar to telepresence, yet broad enough to incorporate recalled and imagined source stimuli for simulated environmental transactions. As the growing community of virtual reality researchers has gravitated towards the term *presence*, we will use that term here to refer to a perceptual, mnemonic, or imaginal feeling of being in a physical environment that is either spatially or temporally removed from one's immediate physical surroundings. This definition is essentially the same as that for telepresence, yet it allows for mediated perception rather than requiring it and is expanded to include internally generated environmental transactions.

A second problem presented by a conceptual framework that must accommodate both internally and externally generated source material for simulated environmental transactions is the need for person-centered assessment dimensions to complement vividness and interactivity, which are technology- or medium-centered. As an example, consider *familiarity*, which can take at least two forms. *Environmental familiarity* refers to one's personal knowledge of the specific environments to be simulated. Given the behavioral evidence described above regarding the microgenetic and ontogenetic development of topographic knowledge and abilities, we might expect a shift in the cognitive processes used to perform spatial tasks as one's familiarity with a particular environment increases, a shift that may be reflected in patterns of recruited neural activation. There is minimal evidence of this in the topographic brain imaging research conducted thus far. Aguirre et al. (1996) did report greater parahippocampal activation for maze-environment acquisition relative to retrieval, but the issue largely has not been addressed. One interesting exception is Maguire's work with London taxi drivers, which suggests that extensive reliance on navigational skills can alter the shape and size of one's hippocampus, in direct relation to years on the job (Maguire et al., 2000), and seemingly independent of initial navigational ability (Maguire et al., 2003).

The importance of assessing environmental familiarity can also be illustrated by examining the critical (yet commonly made) assumption that transactions with virtual environments engage the same cognitive processes as transactions with actual environments. Heretofore, computer simulations used in brain imaging studies of topographic cognition have depicted nonexistent environments. Simulations of existing environments, however, would allow researchers to directly compare the behavior and neural activity of individuals who had acquired topographic information in actual environments versus those acquiring the same information through simulations. Similar regional patterns of neural activations across groups under these circumstances (e.g., during a topographic recall task) would help to support the assumption of

similar engagement of cognitive processes for simulated and real-world transactions. Mellet et al. (2000) conducted a study along these lines, having participants learn a novel environment either through actual exploration of the environment or via examination of a map. In terms of the framework above, a map likely elicits an anemic sense of presence because it engages a single sense modality, with relatively little information, the content and form of which cannot be manipulated. In short, the breadth, depth, and interactivity of a map are all rather limited. However, it does afford an immediate allocentric perspective, something that must be built up over time through actual engagement with the environment. After learning their respective environments, participants in both groups performed a series of imagined point to point navigations through the environment, based on memorized landmarks. PET scans during the imagined navigations indicated that both groups engaged the right hippocampus to perform this task, while those who learned the environment *in situ* also recruited the parahippocampus bilaterally. The latter result likely reflects the established finding of parahippocampal involvement in object and scene recognition (Aguirre et al., 1996; Epstein & Kanwisher, 1998), including recent evidence that the parahippocampus automatically stores navigationally relevant object locations after one pass through an environment, irrespective of attentional demands and subsequent memory for the objects (Janzen & van Turenout, 2004). The fact that the map learners did not engage the parahippocampus to perform the imagined navigations suggests that the colored dots and verbal labels used to designate landmarks on the map were insufficient to trigger object/scene encoding. As these research examples suggest, the study of environmental familiarity, and the means by which it is acquired, can help us address some of the methodological concerns of using functional brain imaging to study topographic cognition.

We might also expect the cognitive processes engaged by topographic behavior to differ as a function of one's *simulation familiarity* – familiarity with the means of environmental simulation. With respect to internally generated source stimuli, individual differences in experience generating environmental imagery, route information, relative spatial locations, etc., may lead people to develop different ways of processing topographic information. Cab drivers, for instance, routinely generate complex point-to-point route information, while bus drivers (with well-learned, set routes) would likely have less experience generating novel route information, as would those who are not professional drivers. With respect to externally generated source stimuli, there may be perceptual learning curves associated with the emergent technologies used to create and display environmental simulations, and individual differences in familiarity with such technologies could influence the cognitive processes they engage. Over the past 200 years, one psychologically interesting by-product of industrialization has been the continual creation of novel

sensory phenomena, the perceptual mastery of which has occasionally been physically unpleasant for members of our species (Schivelbusch, 1986). To use an example cited by Cutting et al. (1992), the advent of widespread train travel in the mid-nineteenth century was accompanied by clinical reports of eye fatigue, back strain, and overall body stress. The eye fatigue was presumably due to novice train travelers' inexperience in engaging the visual environment at previously unknown speeds.²² More recently, reports of "side-effects" associated with immersive VR environments include dizziness, headaches, eyestrain, and nausea (Regan & Price, 1994), symptoms that increase steadily with time spent in an immersive VR environment (Murata, 2004), but which can be reduced with the prior administration of antimotion-sickness drugs (e.g., scopolamine hydrobromide; Regan & Ramsey, 1996). Although it is not yet clear whether symptoms such as these would subside with increasing VR experience, their relatively common occurrence (e.g., upwards of 60% of participants experiencing at least one symptom, Regan & Price, 1994) represents *prima facie* evidence that VR environmental simulations may not engage the same cognitive processes as those engaged by actual environments. Indeed, one reason why videotaped environmental simulations elicit increased hippocampal activations while many computer simulations do not may be broad familiarity with the former medium relative to the latter, especially with respect to the perception of motion.

In sum, the brain imaging studies reviewed here represent a promising initial psychophysiological foray into the investigation of human topographic cognition. Serious concerns regarding the interpretation of neural substrates recruited during topographic behavior have been met with felicitous reference to pertinent theory and converging lines of evidence from neuropsychology, psychobiology, and cognitive and environmental psychology. Inferential concerns regarding the comparability of cognitive processing engaged by transactions with simulated versus actual environments, however, have been less well met. The importance of these concerns is thrown into sharp relief by the research described above regarding the distinction between primary and secondary acquisition of topographic information, the importance of active relative to passive engagement with environments, and reports of perceptual maladies associated with immersive VR environments. Because brain imaging techniques have the potential to make important contributions to our understanding of human topographic cognition, the assumption regarding transactional comparability between simulated and actual environments deserves careful scrutiny, and we have outlined a conceptual framework that can facilitate comparisons among simulated environmental transactions. Additional psychophysiological measures might

²² Scanning patterns that are appropriate at pedestrian speeds – roughly equal numbers of fixations on proximal and distal cues – are extremely difficult to maintain at high speeds, and attempts to do so should lead to eye strain.

also be used, however, to examine comparability among environmental simulations. If some simulations are substantially better than others, for instance, at depicting self-locomotion through the environment, then EMG recordings from muscle groups involved in locomotion may reveal increased activations associated with those more immersive simulations.

Beyond examinations of the comparability among simulations, there are other techniques (as well as constructs and research) within psychophysiology that can be brought to bear on the inferential issues raised by the use of brain imaging to investigate topographic cognition. For example, interpretation of the localization of neural substrates associated with the performance of various topographic tasks could benefit from an analysis of task-related activations in terms of both cortical and autonomic arousal. Some of the structures activated by topographic tasks in these brain imaging studies (and interpreted solely in terms of the cognitive processes engaged) have also been implicated in the production of skin conductance responses elicited by non-topographic tasks (Tranel & Damasio, 1994). Thus, increased activation in the right inferior parietal region may reflect cognitive processes associated with a survey-oriented relative to a landmark-oriented task (Aguirre & D'Esposito, 1997), but it may also reflect the relative difficulty of the tasks, independent of the specific cognitive processes engaged. To date, only one of the reviewed brain imaging studies (Ghaëm et al., 1997) has measured autonomic or other psychophysiological concomitants of rCBF during topographic cognition. Thus, it seems that there are broad opportunities here for the application of psychophysiological methods and constructs that could help brain imaging researchers address some of the inferential concerns inherent in laboratory studies of topographic cognition.

5. CONCLUDING REMARKS

As intimated at the beginning of this chapter, environmental psychophysiology is not an established field as such. However, the existing work regarding the significant effects that ordinary transactions with the physical environment can have on individuals argues strongly for the psychophysiological study of human-environment transactions. As the reviews of environmental noise, palliative environments, and topographic cognition indicate, psychophysiological constructs and methods have already been used profitably in this regard over a wide range of transactions. There are other areas as well, not reviewed here, where psychophysiology has contributed to our knowledge of how people engage the physical environment. These include other areas of environmental stress, such as thermal extremes and crowding (Taylor, Allsopp, & Parkes, 1995; Baum & Paulus, 1987), less obviously oppressive environmental transactions, including chrono-biological and other effects of light (Küller & Laike, 1998; Küller & Mikellides, 1993), as well as emerging fields of

investigation regarding the effects of environmental elements such as negative air ions and olfactory stimuli (Morton & Kershner, 1987; Miltner et al., 1994).

Although considerable work has been done in environmental psychophysiology as described above, more explicit recognition of this subdiscipline may well have advantages. The coordinated development and use of shared methodological approaches, for instance, would arguably be more easily accomplished with the institutional infrastructure (e.g., conferences and journal outlets) of a more formal discipline. In particular, given the repeated references in this chapter to the ecological validity of simulating large-scale environmental conditions in the laboratory, further development of lightweight, affordable ambulatory psychophysiological recording systems is a prime concern. Institutional imprimatur of this fledgling field could also facilitate the acquisition of research support and help to set research agendas that are responsive to needs in the field. For instance, as indicated in the section on topographic cognition, some psychophysiological methods (such as brain imaging techniques) that are ill-suited to field research must rely on environmental simulations and thus research questions regarding human transactions with various kinds of simulations will have to be addressed (e.g., to what extent and under what conditions do immersive VR systems elicit nausea?).

Thus, we present the material in this chapter in part to exemplify the application of psychophysiology to human transactions with the physical environment, but also to foster the recognition and nurture the development of environmental psychophysiology as a subdiscipline.

ACKNOWLEDGMENTS

Special thanks to Lou Tassinary and Phyllis Sanchez, who each in their own way have made this chapter possible. This work represents a revision and update of a previous chapter by Parsons & Hartig (2000).

**ELEMENTS AND
PRINCIPLES**

Experimental Design, Data Representation, and Data Analysis Issues

SECTION EDITOR: HOWARD C. NUSBAUM

33 Psychometrics

MICHAEL J. STRUBE AND LAUREL C. NEWMAN

All scientists grapple with the limitations of faulty observations. Rarely are the concepts that are embedded in theories easily revealed or conveniently available with little error. This is especially true in psychophysiology in which an attempt is made to link physical processes to psychological constructs. The ability to make these linkages rests on attention to important psychometric principles. After all, physiological measurement, like all other forms of measurement, is the replicable assignment of numbers to represent properties (Campbell, 1957). Accordingly, basic psychometric principles are as relevant to psychophysiological assessment as they are to the measurement of intelligence, assessment of job performance, or self-reports of emotion. Our goal in this chapter is to provide a guide to the issues requiring attention when inferences about psychological constructs are based on the collection of physiological data. In the discussion that follows, we will outline the core psychometric issues relevant to measurement in any area, but with an emphasis on their psychophysiological application.

A topic that is as broad as psychometrics cannot be covered comprehensively in a single chapter. It ranges widely and includes topics and issues that overlap with research design, statistics, and philosophy of science.¹ There is a danger that a chapter attempting to summarize this broad topic could devolve into a selective listing of formulas and facts. To avoid that problem, we will attempt to emphasize and illustrate a very simple theme that has wide-reaching implications: Science is essentially an error-correcting enterprise. The ability to uncover “truth” hinges on the ability to identify, estimate, and remove error from fallible observations. We will show how this theme underlies traditional psychometric principles and why psychophys-

ologists should be concerned about these principles. We will emphasize general principles rather than problems specific to particular modes of physiological measurement. The number of physiological systems now measured is so numerous and the technological advances are so rapid (e.g., Cacioppo and Tassinary, 1990b; Cacioppo, Tassinary, & Berntson, 2000; Coles, Donchin, & Porges, 1986; Druckman & Lacey, 1989) that a discussion of particular measurement problems would be highly selective and not particularly educational. Other chapters in this volume amply document the measurement nuances and idiosyncrasies for particular problem areas, and are reminders that inadequate technical knowledge and inadequate statistical representation can hinder inference for particular physiological measures (see Cacioppo and Tassinary, 1990a; Sarter, Berntson, & Cacioppo, 1996). We will focus instead on principles that are general to all psychophysiological measurement.

THE BASIC INFERENTIAL TASK

The behavioral sciences encompass a staggering number of topics and narrowing the focus to psychophysiology does not do much to reduce the impression of amazing diversity. Fortunately, all scientists attempt to solve the same basic problem depicted in Figure 33.1. The basic task of science is to make inferences about *hypothetical constructs* (e.g., stress, compliance, reactivity, attention, and memory) that cannot be observed directly. That requires operationalizing those constructs so that numbers can be attached to them in a meaningful way that can be replicated by others.² Once operational definitions are created, the logic and power of research design and statistics can be brought to bear on the problem. It is this operationalization stage that also makes necessary careful attention to psychometric principles because the quality of the

¹ We will not attempt to provide a comprehensive coverage of psychometric principles in this chapter; that task is ably accomplished in numerous book-length treatments (e.g., Ghiselli, Campbell, & Zedeck, 1981; Nunnally & Bernstein, 1994). Instead, the discussion will focus on key issues and their application. Similarly, discussion of closely related issues in research design and statistics can be found in numerous sources (e.g., Cohen & Cohen, 1983; Maxwell & Delaney, 1990; Myers & Well, 1991; Shadish, Cook, & Campbell, 2001; Whitley, 2002; Winer, 1971).

² To be sure, the “distance” from constructs to operations varies greatly and for some topics the leap is not all that great. For most areas in the behavioral sciences, however, the constructs are not isomorphic with their measurements and require careful attention to psychometric principles to avoid leaps of faith.

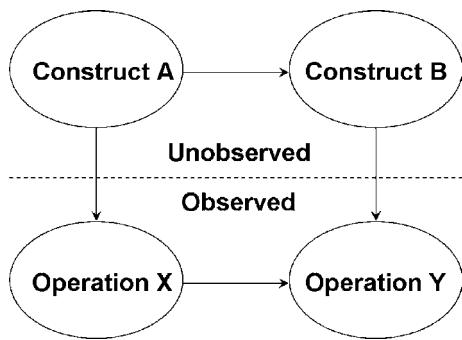

Figure 33.1. The basic inferential task in science.

inferences about constructs and construct relations will depend on the quality of the measurements, which will stand for or represent those constructs. The ability to make accurate and complete descriptive statements about the constructs (e.g., how much stress a sample is experiencing) and the ability to make logically justified inferences about construct relations (e.g., stress is caused by control loss) rests on the extent to which the observations that represent those constructs possess desirable psychometric qualities.

The problem is illustrated by a simple example shown in Figure 33.2. Suppose that a researcher posed the hypothesis that control loss is stressful. This implies a causal relation between two constructs. This hypothesis would presumably be derived from some carefully developed conceptual model. These constructs, however, cannot be observed directly. Instead, clear, specific, and measurable operational definitions must be defined that will "stand for," or represent, the underlying constructs. Control loss, for example, might be operationally defined as the number of daily frustrations from a list of 40 possible frustrations that a person claims to have experienced on a given day. Stress might be defined by a physiological measure of reactivity such as systolic blood pressure. Two inferential problems are immediately obvious. First, under what conditions can we safely infer that a causal relation exists between number of daily frustrations and systolic blood pressure? Second, given that such an empirical inference is warranted, under what conditions can we make

the more important inference that control loss is causally antecedent to the experience of stress? The answers to both questions rely on relatively error-free operational definitions. Psychometric principles guide the development of operational definitions that are (relatively) error free.

Before proceeding, it is important to emphasize another feature embedded in Figures 33.1 and 33.2 and assumed throughout this chapter: Scientific progress is guided by clear and carefully derived statements about constructs and construct relations. The ability to plan quality research and the ability to make clear inferences from that research depend on the clarity of the guiding conceptual model. The most conscientious attention to the psychometric principles, which we will discuss, will be wasted if those principles are applied to poorly defined conceptual hypotheses. Psychometric principles, then, are aids to, but not replacements for, creative thought and logical analysis.

With this basic view of the scientific inference process in mind, we can now turn to a discussion of the psychometric principles that guide the identification, estimation, and control of error in measurement.

RELIABILITY

The ability to make inferences about constructs depends upon the ability to "see" those constructs clearly, that is, to have relatively error-free representations of them. Estimating and controlling error in measurement requires a theory about measurement that defines the nature of error in operational definitions. In the sections that follow, two measurement theories will be described. The first, known as *classical theory*, is very simple and provides a convenient vehicle for introducing some important ideas about measurement. It also is the view of measurement upon which many common reliability estimates are based. The classical view of reliability, however, has two important limitations: It views error as entirely random and it views error as being a unitary entity. A more complex and more realistic view of measurement, called *generalizability theory*, overcomes these limitations and provides a very general and far-reaching approach to measurement.³

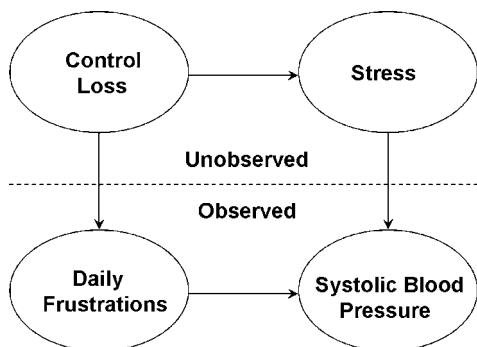

Figure 33.2. An example of the basic inferential task.

³ Another prominent measurement model – item response theory (IRT) will not be discussed in this chapter. The model has much to recommend it as a general approach to measurement. It focuses on individual item responses and estimates item parameters apart from the particular samples that may eventually complete a test composed of those items. When successful, IRT avoids features of classical theory that many measurement specialists find unrealistic or undesirable (e.g., item and test characteristics in classical theory can be sample dependent and test dependent). But, IRT is also impractical for many psychophysiological measurement problems because they are difficult to conceptualize in the latent trait or ability framework of the model and because the development of "items" in IRT requires very large samples of items and respondents in order to develop good estimates of item parameters. Interested readers can consult Hambleton, Swaminathan, and Rogers (1991) for an introduction to the topic.

The classical theory of reliability⁴. The classical theory of reliability assumes that an observation (x) is composed of a *true score* (t) and an *error score* (e), which are related in a very simple way:

$$X = t + e \quad (33.1)$$

The true score (t) is assumed to represent the standing of a given individual (or other *object of measurement*) on the construct of interest, that is, the score that would be obtained under ideal (i.e., error-free) conditions. The observed score deviates from the true score because of the influence of error, which in the classical view of reliability is assumed to be random. Random error is the noise against which the signal of the true score is detected, and large amounts of random error obscure the scientist's ability to see the true score clearly.

According to the classical view, if an obtained score is composed of a true score and random error, then the variability of a sample of obtained scores (symbolized as σ_x^2) will likewise be composed of true score variance (σ_t^2) and error variance (σ_e^2):

$$\sigma_x^2 = \sigma_t^2 + \sigma_e^2 \quad (33.2)$$

This view of obtained score variability provides the basis for the classical theory definition of reliability. A relatively error-free measure will produce scores that vary because they contain more true score variance than error variance. In other words, the obtained scores will vary because the objects of measurement are truly different on the construct being measured and not because of random differences. An intuitively appealing way to represent this idea is the proportion of obtained score variance that is due to true score variance:

$$\frac{\sigma_t^2}{\sigma_t^2 + \sigma_e^2} \quad (33.3)$$

This, in fact, is the classical theory definition of reliability, symbolized r_{xx} (e.g., Nunnally & Bernstein, 1994). The square root of the reliability coefficient estimates the correlation of obtained scores with true scores:

$$r_{xt} = \sqrt{r_{xx}} \quad (33.4)$$

and emphasizes quite clearly that as reliability increases, obtained scores are better estimates of true scores. Stated differently, as reliability increases people (or other objects of measurement) are more likely to get the scores they deserve. This definition also makes clear why the reliability of a measure is often described with such terms as *consistency*, *repeatability*, and *dependability*. If a measure is reliable, then similar obtained score distributions should emerge on different measurement occasions provided the

⁴ There are actually several classical views of reliability that make slightly different assumptions. Those differences are not important here but are described in detail elsewhere (e.g., Ghiselli et al., 1981; Feldt & Brennan, 1989; Nunnally & Bernstein, 1994).

true score component does not change over those measurement occasions. That latter assumption is critical – if the construct being measured moves out from under the measurement, reliability cannot be estimated.

Classical theory also allows for a more formal statement of the way random error obscures the ability to detect relationships between two operational definitions, and, thus, may thwart the goal of identifying causal relations (see Figures 33.1 and 33.2):

$$r_{xy} = \rho_{xy} \sqrt{r_{xx} r_{yy}} \quad (33.5)$$

in which r_{xy} is the obtained correlation between two different operational definitions (x and y), ρ_{xy} is their correlation under conditions of perfect measurement, and r_{xx} and r_{yy} are the reliabilities associated with the measurement of x and y , respectively. Equation 33.5 makes one point quite clear: Low reliability in either measure can impair the ability to detect relationships.⁵

Because classical theory assumes that error is random, it provides a convenient way to estimate reliability: the correlation between “parallel” measures over different measurement “occasions.” The logic is simple. If two measures of the same true score are correlated, that correlation can only be due to their shared true score variability; the random error components by definition cannot correlate with anything. By definition, a correlation is equal to a covariance between two measures divided by the standard deviations of those measures:

$$r_{xy} = \frac{\sigma_{xy}}{\sigma_x \sigma_y} \quad (33.6)$$

If x and y are in deviation score form and are measures of the same true score (i.e., parallel forms), then their covariance takes on a familiar form:

$$\begin{aligned} \sigma_{xy} &= \frac{1}{n} \sum_1^n (t_i + e_{xi})(t_i + e_{yi}) \\ &= \frac{\sum_1^n t_i^2}{n} + \frac{\sum_1^n t_i e_{xi}}{n} + \frac{\sum_1^n t_i e_{yi}}{n} + \frac{\sum_1^n e_{xi} e_{yi}}{n} \\ &= \frac{\sum_1^n t_i^2}{n} = \sigma_t^2 \end{aligned} \quad (33.7)$$

because true scores cannot correlate with the random error components nor can different random error components (e_{xi} and e_{yi}) correlate with each other. Furthermore,

⁵ Another point is more subtle, but also important. One of the variables in Equation 5 could be a manipulated independent variable in an experiment. It is easy to imagine that this variable will have perfect reliability. After all, everyone in a particular experimental condition gets the same score. But, the crucial question is whether everyone in an experimental condition is brought to the same psychological state (Strube, 1989). For example, an experiment that uses mental arithmetic to examine the physiological consequence of a cognitive challenge assumes that the experimental manipulation is equally challenging to all participants in that condition. This may not be true, however. Subtle variations in the delivery of the challenge act like random variability because all participants in a condition get the same score but not necessarily the score they deserve.

because the two measures are assumed to be parallel measures, σ_x and σ_y are assumed to be equal (at least in the population) so the denominator of Equation 33.6 can be assumed to equal the variance of either measure. The correlation between two measures of the same true score is equal to true score variance divided by obtained score variance according to the classical theory definition of reliability.⁶ Thus, if two parallel measures are correlated, those measures must each be composed of shared true score variance and the higher the correlation, the more true score variance (relative to error variance) they contain. This idea gives rise to three popular reliability estimates: *test-retest reliability*, *alternative forms reliability*, and *internal consistency reliability*.

Test-retest reliability is simply the correlation between the same measure on two different occasions. Alternative forms reliability is the correlation between two different measures, each assumed to measure the same true score, administered on different occasions. Internal consistency reliability is based on the correlations among multiple items of one test or measure given during a single administration. In each case, the different measurement occasions (i.e., different times, different forms, or different items) are assumed to differ only in their random components so that the correlation between occasions reveals the relative amounts of true score variance that the measures contain. Of course, as we pointed out earlier, if the true score has changed between measurement occasions (i.e., the construct is unstable), then the reliability estimate is ambiguous as an indicator of measurement error. These different estimates of reliability need not agree, which highlights a key problem with the classical view – error can come from many sources, but those multiple sources are not formally documented in the classical approach. Later, we describe generalizability theory as a remedy to this problem.

In addition to providing a means of estimating reliability, the classical theory also suggests an important way to reduce error and make measures more reliable: *aggregation*. If multiple observed scores of the same construct are combined, the random sources of error that contaminate each observed score have a chance to cancel out and leave standing a better estimate of the true score. If a measure of a construct is based on a single observation, then the obtained score for a given individual will be biased up or down to some extent because of the random error. If we have a second observation that is also a measure of the same true score, it also has an error component, but the direction in which this error influences the obtained score is likely be different than the first item because error is random in the classical view. If we average the two observations, that average might provide a better measure because the two error components might partly cancel out

each other. They will not completely cancel out each other unless their influences are directly opposite, but if we average more and more observations, each with its own random error source but measuring the same true score, then the odds of the error canceling out keep improving. This is a fundamental idea in measurement. Aggregating items or observations that measure the same true score will allow the random error components to cancel out and provide a more reliable measure (e.g., Kamarck, Debski, & Manuck, 2000). In fact, the well known Spearman-Brown prophecy formula is based on this idea (see Nunnally & Bernstein, 1994).

Although we have emphasized r_{xx} as a measure of reliability, there is another way to view reliability. We could just as easily think about reliability of measures in terms of the amount of error those measures contain (σ_e^2). The square root of this variance, the *standard error of measure* (σ_{meas}), gauges the uncertainty inherent in an obtained score by providing an estimate of how much obtained scores would be expected to vary on subsequent measurement occasions even though the true score has remained constant:

$$\sigma_{\text{meas}} = \sigma_x \sqrt{1 - r_{xx}} \quad (33.8)$$

The σ_{meas} communicates reliability in terms of the original scale of measurement, which can be very revealing. Furthermore, the σ_{meas} can be used to form confidence intervals around true scores to provide an even clearer sense of the error inherent in a measurement application and the degree to which score differences are meaningful.

Although the classical view is very popular and widely used, it suffers from an important flaw: It views error as a unitary entity. That flaw is apparent by considering closely the different ways that reliability can be estimated. Each defines error in slightly different ways and consequently the different estimates need not reach the same conclusions about reliability. For example, the internal consistency approach to reliability construes error as random fluctuations that vary across responses to multiple items given at the same time. Sources of error that might change from one day to another do not have any opportunity to show up as error. Indeed, on any one-measurement occasion, such sources masquerade as true score because they impose a constant influence on the observed scores for all items for a particular individual. For example, a bad headache could impair a person's concentration and influence responses to all items on a cognitive abilities test. Consequently, that person would not get the score he or she truly deserves. On a different day the headache might be better and so too would performance, but not because of any change in underlying cognitive abilities. On a given measurement occasion, a person's health is not variable so it does not have an opportunity to emerge as a source of error on a measure of internal consistency reliability. Instead, its constant status makes it act like true score. On the other hand, test-retest reliability would count the health changes and other changes for individuals over time as error. The major point here is that a source of error

⁶ The measures need not be strictly parallel. Classical models that relax this assumption (e.g., domain sampling) merely assume parallelism or similarity in the random sampling sense, yet still arrive at similar conclusions and definitions of reliability (e.g., Nunnally & Bernstein, 1994).

only “counts” in classical theory if it can show variability for a particular individual across measurement occasions. Clearly, then, error is multidimensional and a means of capturing this multidimensionality provides a more powerful approach to estimating and controlling error. Generalizability theory provides that means.

Generalizability theory. The major advantage of generalizability theory (Brennan, 1992, 2001; Cronbach, Gleser, Nanda, & Rajaratnam, 1972; Shavelson & Webb, 1991; Shavelson, Webb, & Rowley, 1989) over the traditional classical approach is the ability to specify and estimate more precisely the multiple sources of error that can contaminate obtained scores. This is accomplished by specifying carefully the conditions of measurement and estimating the influence of those conditions of measurement as sources of error variance in the obtained scores. In generalizability theory the conditions of measurement are known as *facets*. A facet is simply a clearly defined way that measurement occasions can vary and so represents a potential source of influence on obtained scores in addition to true score variance. Different days on which a measure could be collected, for example, are a facet of measurement. Measures collected on one day could vary systematically from those collected on another day (an overall effect for everyone) or the relative standing of participants might differ across days (an effect that varies by person). In either case, scores could vary by day so that any one obtained score would not necessarily provide a dependable indication of a person’s standing on the construct being measured. Multiple items on a test, multiple recordings on the same day, and multiple judges of the same behavior are all examples of measurement conditions (facets) that could introduce variability into obtained scores and obscure the ability to detect true score differences. The list of possible facets of measurement potentially is very long and depends on the specific measurement problem. Accordingly, a key challenge in generalizability theory is the identification of important measurement facets for a particular problem or application.

Generalizability theory gets its name from the idea that the ability to generalize obtained scores across conditions of measurement requires explicitly specifying and testing the conditions of measurement that might affect obtained score variability. Unlike classical theory in which assumptions about the importance of measurement conditions are often handled with a wink and a prayer, in generalizability theory such assumptions are put to an empirical test. Generalizability theory links conclusions about reliability to well-defined measurement facets. Collectively these measurement facets define what is considered an acceptable measurement and identify the boundaries within which the investigator considers observations potentially to be interchangeable. That exchangeability, however, is an empirical question.

Using generalizability theory to solve measurement problems can be thought of as a two-step process that

requires specifying two kinds of measurement boundaries, or “universes,” of measurement. In the first step, a *universe of admissible observations* is defined, which identifies explicitly the facets of measurement and the particular way those facets are defined. For example, a researcher interested in measurement of systolic blood pressure might define the universe of admissible observations to include an examiner facet and a time of day facet. This would reflect the belief by the researcher that these two aspects of measurement are potentially important sources of obtained score variability that need to be taken into account when measuring systolic blood pressure. The magnitudes of these contributions are important to know so that claims about generalization can be made with confidence or qualified appropriately. Furthermore, if any pairing of examiner and time of the day in which a measurement is taken was deemed an acceptable measurement, then the universe would be *completely crossed* (other possible arrangements of facets, such as nested facets, will be described later). Implicit in the definition of the universe of admissible observations is a population of respondents. Indeed, the nature of the respondents (e.g., healthy children or college students performing a stressful experimental task) quite often guides the definition of measurement facets (e.g., the characteristics of acceptable examiners or the times of day that are considered appropriate for measurement). Once the universe of admissible observations is defined, the specific contributions of the facets of measurement to obtained score variability – called *variance components* – need to be estimated. This is accomplished in what is called a *Generalizability Study* (or *G study*), in which particular instances of the facets are selected, a sample from the population is evaluated, and the obtained score variability is decomposed into variance component estimates. These estimates then indicate the relative size of true score and error components.

The second major step in the application of generalizability theory uses the variance components from a *G study* to explore specific intended applications. In an application, multiple measurements across facet levels will be combined (e.g., averaged) to produce more reliable composites. The characteristics of these composites are the focus of this second step and require defining a second universe – *the universe of generalization*. This universe represents the particular facets and their arrangements, which will be used in a particular application. For example, a researcher may want to know how well systolic blood pressure is measured if the assessments of two randomly selected examiners each collecting measurements at three randomly selected times of the day are averaged. Using the variance components from the *G study*, this question can be addressed in what is called a *Decision Study* (or *D study*). Different *D* studies can explore the consequences for reliability of different measurement protocols (e.g., using a nested measurement design, difference in numbers of instances of the facets, or assuming a facet is fixed rather than random). According to generalizability theory, then, there is

no single reliability for a measure. Reliability depends on the conditions of measurement and there are potentially as many reliabilities for a measure as there are unique uses or conditions of measurement. Generalizability theory provides a systematic framework for exploring these multiple reliabilities.

Generalizability theory essentially defines true score and error more carefully than the traditional classical view. The somewhat nebulous idea of a true score is replaced in generalizability theory with the *universe score*, the expected value of all observations in the universe of generalization. This universe represents the particular arrangement of measurement conditions defined by the particular interest or problem of the investigator. Although this too is a hypothetical value, it at least is bounded by well-specified measurement conditions and no claims about reliability are made outside those boundaries. The unitary error score of the classical view is replaced by several error scores, which are defined by the conditions of measurement. Generalizability theory is designed to estimate these multiple components of obtained score variability and to use those components to explore the consequences of different sources of measurement error. In the discussion that follows, we will take a closer look at the two major parts of generalizability theory via some examples in order to highlight the substantial advantages this approach has over the traditional classical approach (for other examples, see Burgess & Gruzelier, 1996; Di Nocera, Ferlazzo, & Borghi, 2001; Wohlgemuth, Edinger, Fins, & Sullivan, 1999).

As an initial example, suppose that a researcher wished to explore the reliability of systolic blood pressure (SBP) measurement, perhaps because SBP is to be used in research on the cardiovascular effects of cognitive and physical challenges. The ability to detect changes in SBP relies on knowing a person's "true" or typical blood pressure, but that true value might be obscured by several kinds of error (e.g., García-Vera & Sanz, 1999; Llabre et al., 1988). The universe of admissible observations must be defined to include facets of measurement that could create variability in blood pressure readings such that those sources of variability can be estimated separately in a G study. Of course, one source of variability will be characteristics of the participants in the study. In generalizability theory, this component of variability is known as the *object of measurement*, and is not usually referred to as a facet. Variability for this component is desirable and corresponds to true score variance in classical theory. This is referred to as the *p* component for *persons* or *participants*. Another source of variability might be called *observer* (*o*) and represents fluctuations that depend on the person recording the blood pressure. Variability in the obtained scores that are due to observer differences would be an undesirable source because it obscures the underlying universe score. If this were the only facet of interest, if any observer meeting an appropriately specified definition (e.g., regarding training in blood pressure measurement)

were considered interchangeable with any other qualified observer, and if any observer could assess any member of the population, then we have defined a one-facet Person \times Observer universe of admissible observations. To estimate the variance components in this universe, we might have two observers record blood pressures from five people. The data collection design would look like that depicted in Figure 33.3. In practice, of course, many more people would be sampled and more observers would be desirable so that sources of variance are estimated with higher precision.

Figure 33.4 displays a Venn diagram depicting the unique sources of variance in this *po* design. The sources indicate an expanded view of obtained score variability:

$$\sigma_x^2 = \sigma_p^2 + \sigma_o^2 + \sigma_{po}^2 \quad (33.9)$$

The variance components in a G study are estimated from the mean squares provided by *analysis of variance*, which in this case, yields three distinct sources of variance: Person (*p*), Observers (*o*), and Person \times Observers (*po*) (for details on variance component estimation see Brennan, 2001; Cronbach et al., 1972; Shavelson & Webb, 1991). With one exception, the mean squares in analysis of variance are not themselves pure variance component estimates. For the simple *po* design, the mean squares have the following expected values:

$$EMS(P) = \sigma_{po}^2 + n_o \sigma_p^2 \quad (33.10)$$

$$EMS(O) = \sigma_{po}^2 + n_p \sigma_o^2 \quad (33.11)$$

$$EMS(PO) = \sigma_{po}^2 \quad (33.12)$$

where n_o is the number of observers in the study and n_p is the number of people whose blood pressure has been measured. These expected mean squares allow the following

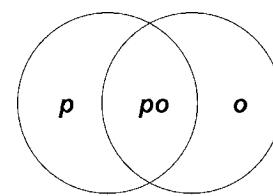

Figure 33.4. Sources of variance for a Person (*p*) \times Observer (*o*) G study.

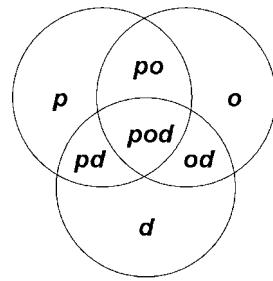

Figure 33.5. Sources of variance for a Person (p) \times Observer (o) \times Day (d) G study.

algebraic manipulation of mean squares to obtain variance component estimates:

$$\hat{\sigma}_p^2 = [MS_p - MS_{po}] / n_o \quad (33.13)$$

$$\hat{\sigma}_o^2 = [MS_o - MS_{po}] / n_p \quad (33.14)$$

$$\hat{\sigma}_{po}^2 = MS_{po} \quad (33.15)$$

Rules for generating variance components from more complicated designs are described by Cronbach et al. (1972), Shavelson and Webb (1991), and Brennan (2001).

The Person (p) component represents real differences in the systolic blood pressures of the participants. It is interpreted like any other variance, but in this case refers to the variance of scores representing the average of all recordings in the universe of admissible observations. The Observer (o) component represents systematic differences between the observers. For example, if readings were systematically lower for one observer, perhaps because of that person's calmer demeanor, then that would show up in the o component of variance and would affect scores for all individuals equally. The Person \times Observer (po) component reflects differences in the relative standing of participants for the two observers, plus any unaccounted for random sources of variability. The Person \times Observer interaction might represent, for example, systematically different ways that particular individuals react to particular observers. These effects, however, cannot be separated from the random errors of measurement in this design.⁷

It should by now be clear that the classical theory and generalizability theory view error in fundamentally different ways. In the classical view, random error is the only source of error. In generalizability theory, random error is a default category that represents error that could not be defined by conditions of measurement. Conditions of measurement reflect systematic ways that obtained scores can vary besides the object of measurement, that is, systematic error. Stated more strongly, in generalizability theory the presence of random error signals a relatively poor understanding of how measurement conditions affect obtained score variability.

Of course, the universe of admissible observations can be more complex. It might, for example, be completely

crossed and contain two facets: observers and days. On any given day, a person's blood pressure might be depressed or elevated for idiosyncratic reasons (e.g., a person attended a yoga class or had an extra cup of coffee). Those influences could obscure the detection of the person's true or typical blood pressure. The influence would be constant for a particular person on that day and so would be confused as true score, but from the standpoint of identifying typical blood pressure, a person would not get the value he or she deserves. The only way to separate this source of error is to include it explicitly in the measurement design. Adding a Day (d) component to the previous design and crossing it with the other components produces a completely crossed Person \times Observer \times Day design. A completely crossed random effects G study might then be conducted with two Observers and four Days. The analysis of variance for that design produces seven sources of variation (see Figure 33.5) that are estimated by mean squares. The expected values for those mean squares are listed in Table 33.1. As can be seen, each mean square (with one exception) is a linear combination of variance components. Accordingly, some simple algebraic manipulation can isolate each variance component for the generalizability theory analysis. Some hypothetical variance components are listed in Table 33.2. Also listed in Table 33.2 are the proportions of the total variance (the sum of all the variance components) accounted for by each component so that their relative size can be gauged more easily. The largest source of variance is for the Person (p) component indicating that much of the total variability is due to real differences in systolic blood pressure, at least as defined within this universe of

Table 33.1. Expected mean squares and variance component estimation for a completely crossed design (persons \times observers \times days design)

Expected Mean Squares

$$\begin{aligned} EMS(P) &= \sigma_{pod}^2 + n_o \sigma_{pd}^2 + n_d \sigma_{po}^2 + n_o n_d \sigma_p^2 \\ EMS(O) &= \sigma_{pod}^2 + n_p \sigma_{od}^2 + n_d \sigma_{po}^2 + n_p n_d \sigma_o^2 \\ EMS(D) &= \sigma_{pod}^2 + n_p \sigma_{od}^2 + n_o \sigma_{pd}^2 + n_p n_o \sigma_d^2 \\ EMS(PO) &= \sigma_{pod}^2 + n_d \sigma_{po}^2 \\ EMS(PD) &= \sigma_{pod}^2 + n_o \sigma_{pd}^2 \\ EMS(OD) &= \sigma_{pod}^2 + n_p \sigma_{od}^2 \\ EMS(POD) &= \sigma_{pod}^2 \end{aligned}$$

Estimated Variance Components

$$\begin{aligned} \hat{\sigma}_p^2 &= (MS_p - n_o \hat{\sigma}_{pd}^2 - n_d \hat{\sigma}_{po}^2 - \hat{\sigma}_{pod}^2) / (n_o n_d) \\ \hat{\sigma}_o^2 &= (MS_o - n_p \hat{\sigma}_{od}^2 - n_d \hat{\sigma}_{po}^2 - \hat{\sigma}_{pod}^2) / (n_p n_d) \\ \hat{\sigma}_d^2 &= (MS_d - n_p \hat{\sigma}_{od}^2 - n_o \hat{\sigma}_{pd}^2 - \hat{\sigma}_{pod}^2) / (n_p n_o) \\ \hat{\sigma}_{po}^2 &= (MS_{po} - \hat{\sigma}_{pod}^2) / n_d \\ \hat{\sigma}_{pd}^2 &= (MS_{pd} - \hat{\sigma}_{pod}^2) / n_o \\ \hat{\sigma}_{od}^2 &= (MS_{od} - \hat{\sigma}_{pod}^2) / n_p \\ \hat{\sigma}_{pod}^2 &= MS_{pod} \end{aligned}$$

⁷ In general, the highest order effect is confounded with random error.

Table 33.2. Hypothetical variance components for a completely crossed G study of systolic blood pressure measurement

Source of variance	Component of variance	Proportion of total variance
Person (<i>p</i>)	180.00	.40
Observer (<i>o</i>)	25.00	.06
Day (<i>d</i>)	15.00	.03
<i>po</i>	40.00	.09
<i>pd</i>	75.00	.17
<i>od</i>	10.00	.02
<i>pod</i>	105.00	.23

admissible observations. The remaining sources of variability are error, some of which are relatively large. For example, the Person \times Day (*pd*) component accounts for 17% of the total variability. This component reflects a shift in the relative differences of individuals over days. By contrast, the *o* effect is rather modest (only 6% of the variance) and indicates little variation across observers.

There is one other design variation that arises frequently in generalizability studies: *nested designs*. In the simple design with Observers as the only condition of measurement, it might not be possible to have the same observers test each participant. Instead, a different pair of observers might test each participant (perhaps this would occur if participants were patients being seen in different physicians' offices). In this case, observers are no longer crossed with persons, but are nested within persons. The universe of admissible observations is now defined differently than for completely crossed universe. The data collection design is shown in Figure 33.6 and is sometimes symbolized as *o*:*p* to indicate that observers (*o*) are nested (:) within persons (*p*). The major consequence of nesting is that some variance components, which can be estimated separately in a crossed design, are confounded in a nested design. As the Venn diagram in Figure 33.7 shows, the Person \times Observer (*po*) interaction cannot be separated from the Observer (*o*) effect. The overlap of the Observer component and the Person component (which defines the interaction *po*) is completely contained in the Observer (*o*) component. Only two components of variance can be estimated in this design: a *p* component and a combined component that contains both the *o* source of variance and the *po* source of variance.

Designs can have both crossed and nested features. For example, the Person \times Observer \times Day design might not be realistic. Although it might be possible to assess all participants on each day (Person and Day are crossed), it might not be possible for each observer to record the blood pressures of all participants. This creates a partially nested design (see Figure 33.8). With observers nested within persons, the Observer (*o*) source of variance is confounded with the Person \times Observer (*po*) interaction. As Figure 33.8 indicates, the *od* and *pod* sources of variance are also con-

founded. Consequently, only five sources of variance can be estimated from this design.

Generalizability theory makes one additional important distinction: *random effects* versus *fixed effects*. An effect is random if the facet levels are considered random samples from the population of all levels in the universe of admissible observations.⁸ By contrast, an effect is fixed if the levels used are the only ones of interest. When an effect is fixed, there is no intent to generalize to some larger population, either because there is no larger population (i.e., all facet levels are included) or because the ones included in the study are the only ones that the researcher cares about. This distinction between fixed and random effects is important for appropriate estimation of variance components (for a thorough discussion see Brennan, 2001). Two approaches have been recommended (see Shavelson & Webb, 1991). First, separate generalizability analyses can be carried out at each level of the fixed effect. This makes sense if each level of the fixed effect was selected because there was particular interest in that level. Second, if a researcher wants an overall average of the generalizability of the measure, then averaging across the fixed effects is another option (see Brennan, 2001; Cronbach et al., 1972; Shavelson & Webb, 1991). Large variance components for the fixed effect, however, would dictate caution using the averaging approach because it obscures an important source of variance.

Generalizability theory clearly provides a powerful way to determine the multiple sources of error in a measure. It provides an equally powerful way to estimate the consequences of those error sources so that future measurement efforts can be planned carefully. In generalizability theory, these forecasting and planning efforts are known as D studies. A D study uses the variance components from the G study to pose "what if" questions about future possible ways to collect data. Different D Studies can estimate the consequences of changing the number of facet levels (i.e., the aggregation principle), the way those facets are arranged (e.g., crossed versus nested designs), and the type of decision about the objects of measurement that the data will guide (e.g., whether an external criterion or cut-off score is used).

The essential difference between a G study and a D study is that data are collected and variance components are estimated in a G study; those variance components are then used in D studies to pose questions about alternative measurement and decision options. These latter questions exist within the universe of generalization. The difference between the two universes might be thought of as the

⁸ Ideally, effects would be randomly sampled from the population of possible levels. In theory this population would be infinite, but in practice it is usually very large. Furthermore, the levels actually used in a generalizability study may not be truly random samples; it is sufficient to assume that they are if there is no particular interest in the levels used and any other levels would work equally well. The distinction between random effects and fixed effects is crucial, affecting the estimation of variance components and estimates of reliability (see Brennan, 2001).

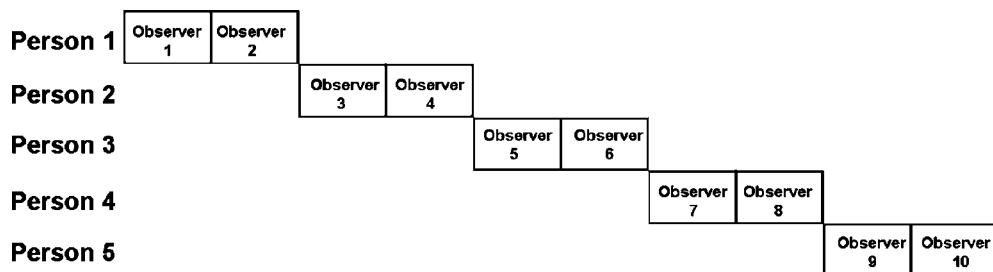

Figure 33.6. Data collection design with Observers (*o*) nested within Persons (*p*).

difference between defining what constitutes a meaningful or acceptable individual score (i.e., universe of admissible observations) and defining what constitutes a meaningful or acceptable aggregate (i.e., universe of generalization). In a D study, the number of facet levels and their arrangements are modified to determine how reliability of averages changes with different kinds of designs. It is important to recognize the critical link between the two universes. By using the variance components from a G study, any given D study is a commitment to the way individual scores and their facets are defined in the universe of admissible observations. If a researcher is unwilling to make that commitment for an intended application, then a new universe of admissible observations must be defined and a new G study must be conducted.

A key distinction in a D study is the kind of decision that will be made about the objects of measurement – a distinction that defines the nature of error and the estimation of reliability coefficients. There are two kinds of decisions that can be made. The first, known as a *relative decision*, reflects only the relative standing of the objects of measurement. The second, known as an *absolute decision*, takes the absolute value of the scores into account as well. In applied testing, these differences correspond to norm-referenced and criterion-referenced tests, respectively. Using a simple Person \times Observer design, Figures 33.9 and 33.10 display the nature of these two decisions and the influence of different error components on them.

The top panel of Figure 33.9 shows that the two observers provide the same relative rank ordering for the participants. If we wanted to identify the participants with the three highest blood pressures, we would get the same answer from either observer. This occurs despite the fact that all recordings are systematically lower for the second observer. This reflects an observer effect (i.e., the *o* com-

ponent would be large), but this source of error does not affect the relative decision. The bottom panel of Figure 33.9 depicts a different pattern. In this case, the relative standing of the participants is different for the two observers. This Person \times Observer interaction obscures our ability to identify the three people with the highest blood pressures. The *po* component then is a source of error for a relative decision. More generally, any interaction that involves the object of measurement will be a source of error for relative decisions. Such interactions indicate that across facet levels the differences between the objects of measurement shift in magnitude, making it difficult to consistently identify their relative standing.

Figure 33.10 displays the same two data patterns but now with reference to a criterion score. This criterion might represent an established cut-off score for defining high blood pressure. In other words, rather than defining high blood pressure as the three highest scores, an external criterion is used. Now the absolute values of the recordings are important. As the top panel indicates, the overall observer differences (i.e., the *o* component) influence whether a given participant exceeds the criterion. The bottom panel indicates that interactions involving the object of measurement affect absolute decisions as well. Absolute decisions are influenced by any source of variance that influences the value of the obtained score. That means that all sources other than the object of measurement will be a source of error for absolute decisions.

These rules generalize to other designs. Consider again, for example, the Person \times Observer \times Day design depicted

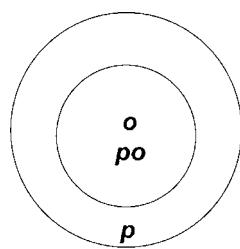

Figure 33.7. Sources of variance for a design with Observers (*o*) nested within Persons (*p*).

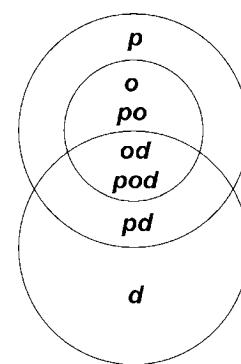

Figure 33.8. Sources of variance for a partially nested design in which Observers (*o*) are nested within Persons (*p*) and both are crossed with Days (*d*).

in Figure 33.5. For relative decisions, the *po*, *pd*, and *pod* sources all make it difficult to know with confidence the relative standing of participants. The *pd* component reflects changes in the relative standing of the participants between the different days on which recordings are made. The *pod* component reflects changes in relative blood pressure that vary simultaneously by observer and day. This component also contains other random sources of error. All of the variance sources other than *p* would contaminate absolute decisions.

Knowing the nature of the decision to be made is crucial for estimating reliability in generalizability theory. Just like classical theory, generalizability theory provides coefficients that gauge the reliability of measures defined by the universe of generalization. These coefficients, however, are calculated differently depending on the kind of decision that will be made about the objects of measurement. Reliability estimates for relative decisions, called *generalizability coefficients*, represent the proportion of obtained score variance that is due to universe score variance:

$$E\rho^2 = \frac{\sigma_p^2}{\sigma_p^2 + \sigma_\delta^2} \quad (33.16)$$

The term, σ_δ^2 , refers to the error variance for a relative decision and varies according to the type of design used

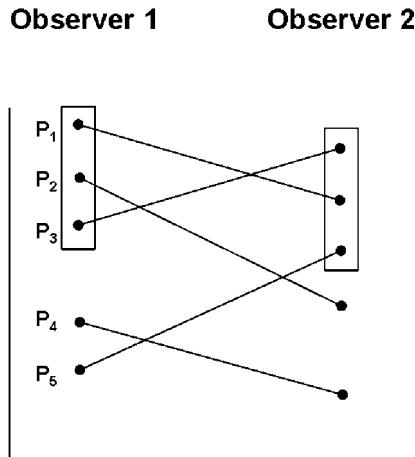

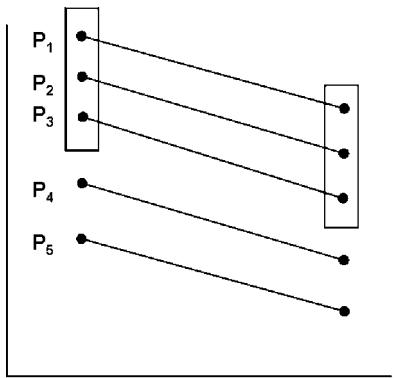

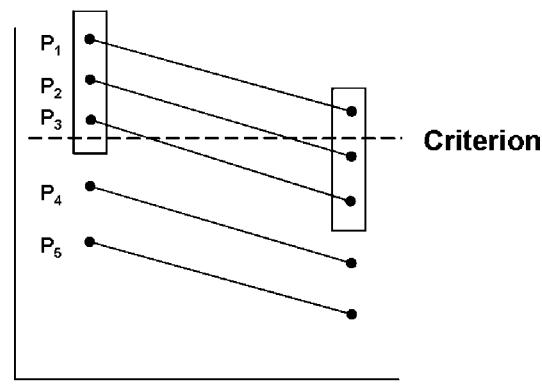

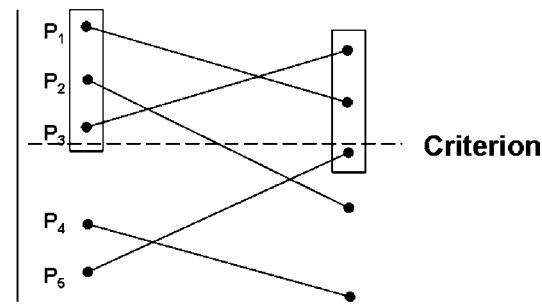

Figure 33.9. Sources of error for a relative decision.

Observer 1 Observer 2

Observer 1 Observer 2

Figure 33.10. Sources of error for an absolute decision.

in the D study.⁹ For the examples described previously, the error terms would be:

$$\text{Person} \times \text{Observer} (\text{po}): \sigma_\delta^2 = \frac{\sigma_{po}^2}{n'_o} \quad (33.17)$$

$$\text{Person} \times \text{Observer} \times \text{Day} (\text{pod}): \sigma_\delta^2 = \frac{\sigma_{po}^2}{n'_o} + \frac{\sigma_{pd}^2}{n'_d} + \frac{\sigma_{pod}^2}{n'_o n'_d} \quad (33.18)$$

Days \times (Observers within Persons) (d[o : p]):

$$\sigma_\delta^2 = \frac{\sigma_{o,po}^2}{n'_o} + \frac{\sigma_{pd}^2}{n'_d} + \frac{\sigma_{od,pod}^2}{n'_o n'_d} \quad (33.19)$$

in which n'_o and n'_d refer to the number of facet levels for observers and days respectively and the accent marks indicate that these numbers can vary and need not be the

⁹ Several links to the classical view should be noted. $E\rho^2$ is defined in the same general way as a ratio of “true” score variance to “error” variance (see Equation 33.3) and the symbol denotes a squared correlation between obtained scores and universe scores (cf. Equation 33.4). Also, for a simple one-facet design involving multiple items, $E\rho^2$ resembles Cronbach’s coefficient alpha (Cronbach, 1951). Finally, Equation 33.16 can be thought of as a generalized Spearman-Brown formula, allowing the same kind of forecasting but for a much wider range of designs. Other links are described by Brennan (2001) who notes some surprising results when traditional reliability estimates are considered within the generalizability theory perspective.

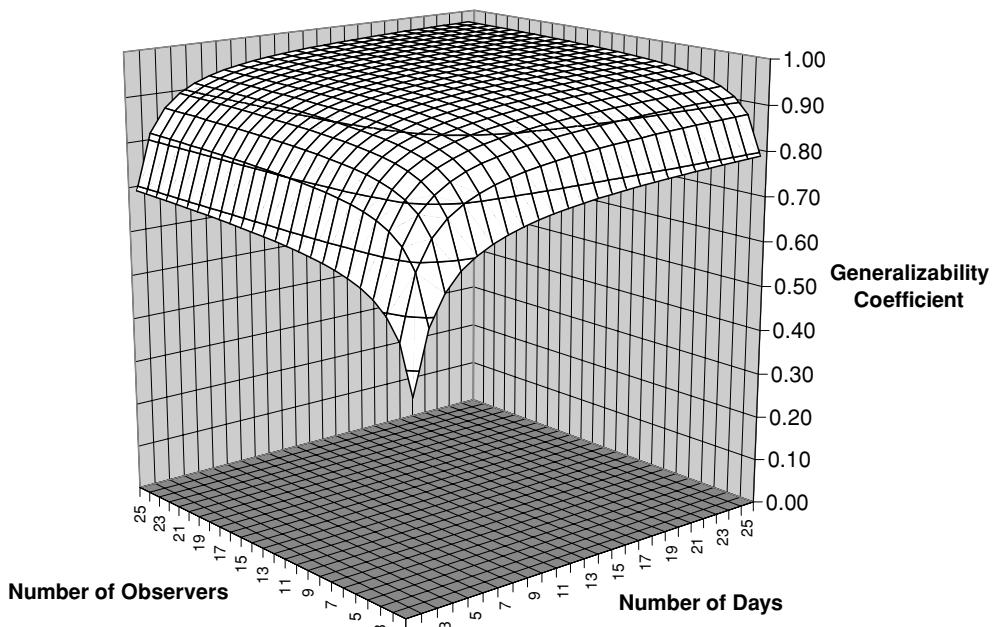

Figure 33.11. D study results for a completely crossed design using variance components from Table 33.2.

same as those that might have been used in a G study.¹⁰ The first term and the last term in Equation 33.19 reflect the fact that some variance components cannot be estimated separately in nested designs. For the example in Table 33.2, the generalizability coefficient is:

$$\begin{aligned} E\rho^2 &= \frac{\sigma_p^2}{\sigma_p^2 + \frac{\sigma_{po}^2}{n'_o} + \frac{\sigma_{pd}^2}{n'_d} + \frac{\sigma_{pod}^2}{n'_o n'_d}} \\ &= \frac{180}{180 + \frac{40}{2} + \frac{75}{4} + \frac{105}{2(4)}} = .77 \quad (33.20) \end{aligned}$$

Using the variance components from Table 33.2, Figure 33.11 illustrates the impact on the generalizability coefficient for a crossed design of varying the numbers of observers and days of observation. As expected, reliability increases as the number of observers and days increase, but the rate of increase is different for the two facets; increasing the number of days has a larger influence. This could have been anticipated from Table 33.2 in which the *pd* component is the largest source of error; that component will show the largest effect of aggregation. Nonetheless, Figure 33.11 also shows that aggregation over both days and observers will be necessary to achieve a modest reliability with modest cost.

¹⁰ D studies forecast expected results but are limited by the precision of the variance components from the G study. Confidence intervals can be placed around variance components (and around other parameter estimates) to provide an appropriate level of caution (e.g., Cronbach et al., 1972; Brennan, 1992, 2001). Sampling variability can be reduced by using large samples (e.g., people or facet levels). Also note that D studies can only investigate designs for which separate variance component estimates are available in a G study. A nested G study precludes D studies that require separate variance components that are confounded because of nesting.

Figure 33.12 represents the same information as Figure 33.11, but with reference to the standard error of measure (i.e., the square root of the error variance). The same conclusions would be drawn from this figure, but it represents reliability in the metric of the measure that will be used. This allows a better sense of the uncertainty researchers will have about a person's systolic blood pressure for different combinations of observers and days of observation.¹¹ For example, with two observers and two days of observation, the standard error for a relative decision will be 9.15. Using this to set confidence intervals reveals that the same universe score would be consistent with obtained scores that differ by as much as 37 points with 95% confidence (see Feldt & Brennan, 1989; Nunnally & Bernstein, 1994). This might be quite sobering and more informative to a researcher or practitioner than knowing that the generalizability coefficient under these conditions is .68.

The design is free to vary too, provided the appropriate variance components are available from the G study. For example, the G study might have been a completely crossed design, but different D studies could explore partially nested (e.g., *d[o:p]*) or completely nested (e.g., *o:d:p*) options. This allows careful planning that can optimize reliability while taking design cost into account (Marcoulides & Goldstein, 1990). If two designs produce essentially the same reliability the researcher can choose the one that is easier or is less costly to conduct. Alternatively, for a fixed cost a researcher can identify the

¹¹ Measurement error may not be equivalent for all score levels. Recent work has attempted to overcome this problem by providing conditional standard errors of measurement (Brennan, 1996, 2001; Feldt & Qualls, 1996; Kolen, Hanson, & Brennan, 1992). An extensive discussion is provided by Brennan (2001).

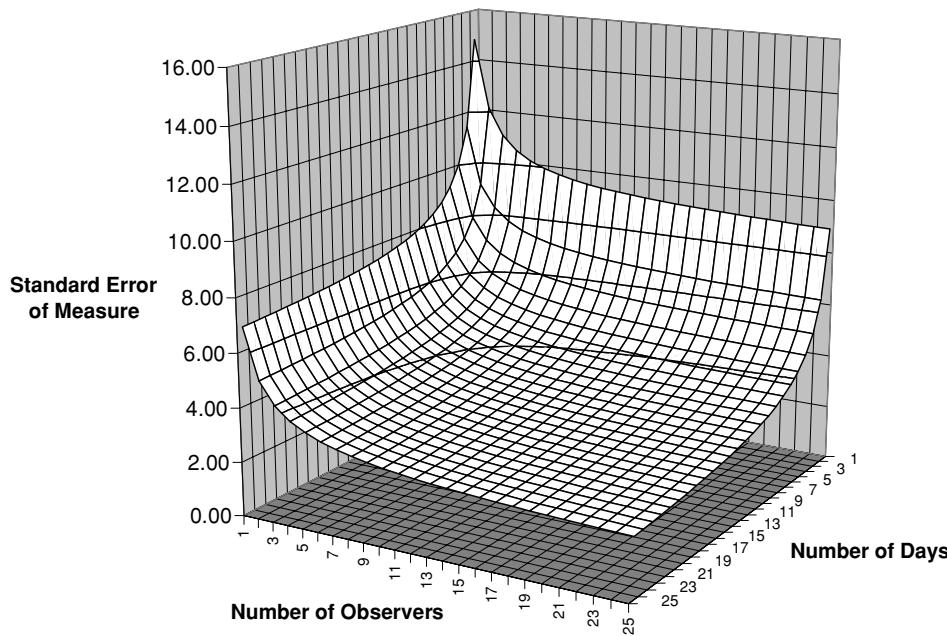

Figure 33.12. Projected standard errors of measure for a completely crossed design using variance components from Table 33.2.

design that maximizes reliability. It is usually fairly easy to specify costs on a “per observation” basis and to estimate any training or equipment costs. These can be linked to appropriate facet level indicators in the D study calculations, providing total cost estimates along with reliability estimates.

D studies can be used to ask “trade-off” questions within designs as well. We can ask, for example, what numbers of observers and days of observation will produce a reliability or standard error of a given amount. Figure 33.13 displays the results of asking this question for the design in Table 33.2 and a generalizability coefficient of .80, which is a common reliability benchmark. Clearly more than one day of observation will be necessary and the trade-off to limiting the number of days is a larger number of observers. Depending on the costs of training observers and collecting data over multiple days, a sensible combination of observers and days can be determined. If no combination will produce the desired reliability at a reasonable cost, then a different arrangement of facets (e.g., partially nested) might be considered. Also, efforts might be made to reduce error in other ways (e.g., standardization) or through inclusion of additional measurement facets. Nonetheless, any change in the measurement protocol that introduces new facets must be accompanied by a new G study to estimate new variance components.

The results in Figures 33.11, 33.12, and 33.13 assume that a relative decision will be made. If the blood pressure readings will be used to identify “at risk” individuals, then an external criterion will be used; the decision is then absolute rather than relative and subject to more sources of error. For absolute decisions, the reliability coefficient is called the *index of dependability* (symbolized as ϕ in Brennan & Kane, 1977) and is defined as follows:

$$\phi = \frac{\sigma_p^2}{\sigma_p^2 + \sigma_\Delta^2} \quad (33.21)$$

The term, σ_Δ^2 , refers to the error variance for absolute decisions. For the designs described previously, those error terms are:

$$\text{po: } \sigma_\Delta^2 = \frac{\sigma_o^2}{n'_o} + \frac{\sigma_{po}^2}{n'_o} \quad (33.22)$$

$$\text{pod: } \sigma_\Delta^2 = \frac{\sigma_o^2}{n'_o} + \frac{\sigma_d^2}{n'_d} + \frac{\sigma_{od}^2}{n'_o n'_d} + \frac{\sigma_{po}^2}{n'_o} + \frac{\sigma_{pd}^2}{n'_d} + \frac{\sigma_{pod}^2}{n'_o n'_d} \quad (33.23)$$

$$\text{d(o:p)} \sigma_\Delta^2 = \frac{\sigma_d^2}{n'_d} + \frac{\sigma_{o,po}^2}{n'_o} + \frac{\sigma_{pd}^2}{n'_d} + \frac{\sigma_{od,pod}^2}{n'_o n'_d} \quad (33.24)$$

Using Equation 33.23, the example in Table 33.2 yields an index of dependability of .72, smaller than the generalizability coefficient because of the additional sources of error that hinder absolute decisions (o , d , and od).

Several aspects of the reliability estimates provided by generalizability theory are clear from Equations 33.16 through 33.24:

1. Reliability estimates are design dependent.
2. Reliability depends on the number of facet levels (i.e., the aggregation principle).
3. Reliability depends on the type of decision that will be made.
4. Reliability depends as much on the universe score variance (σ_p^2) as it does on error variance.

This last point is especially important. Inadequate sampling of the objects of measurement can distort reliability estimates. This can occur because a restricted sample

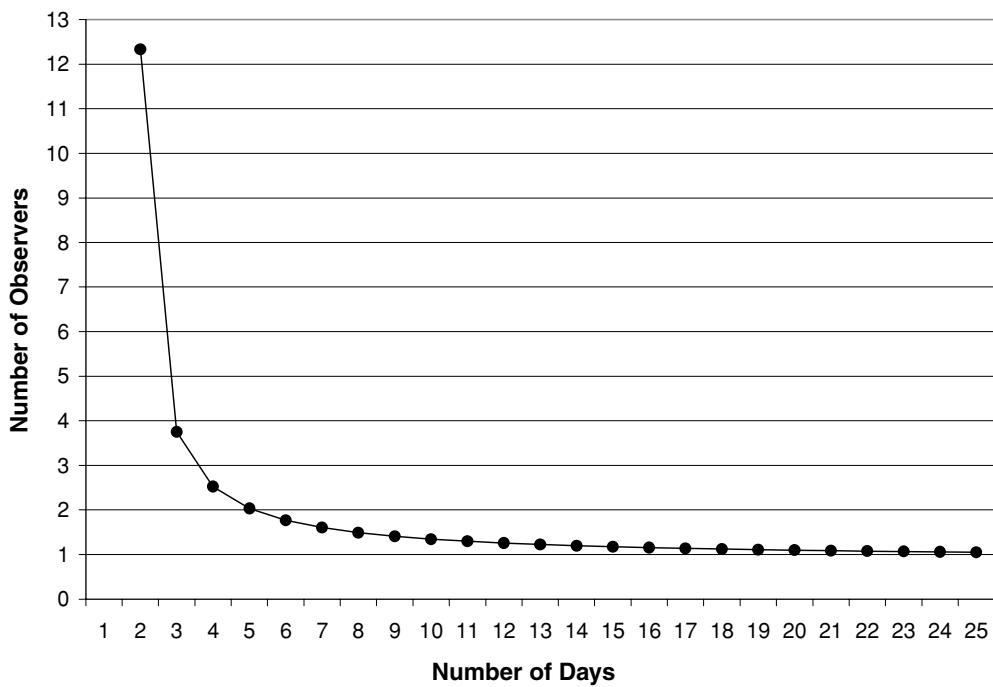

Figure 33.13. Combinations of observers and days that produce a generalizability coefficient of .80 (based on variance components from Table 33.2).

does not fairly capture the natural variation in the objects of measurement or because intentional sampling inflates the apparent variability of the objects of measurement. A fair sample represents a random sample from the population to which inferences will be made. All of these points underscore a comment made earlier that there are as many reliabilities for a measure as there are applications or conditions of measurement. In other words, there is an external validity to reliability estimation that is quite explicitly modeled by generalizability theory.¹²

¹² There are additional features of generalizability theory that cannot be described in detail here, but expand its potential range of application. For example, any facet can take on the role of objects of measurement (Cardinet, Tourneur, & Allal, 1976, 1981). A familiar example makes this clear. In a typical experimental design, persons are nested within groups ($p \in g$) and groups are the objects of measurement. That is, decisions will be made about groups (e.g., are they different?). The generalizability coefficient then refers to the reliability of group means (Brennan, 1995) and the standard error of measure is the familiar standard error of the mean (also see Brennan, 2001; Kane & Brennan, 1977). Generalizability theory does not apply to ranked data without modification (Vanleeuwen & Mandabach, 2002), which is a reminder that, like other statistical models, generalizability theory has assumptions that must be kept in mind. There is also a multivariate extension of generalizability theory that allows examining the influence of measurement conditions on the covariances between multiple outcome measures and exploring the generalizability of protocols or multiple measures (Brennan, Gao, & Colton, 1995; Cronbach et al., 1972; Hoyt, 2000; Marcoulides, 1994; Nussbaum, 1984; Webb & Shavelson, 1981; Webb, Shavelson, & Maddahian, 1983). Finally, some applications of generalizability theory may require an unbalanced design, with some facets varying in number of levels across other facets. This creates estimation complexities that are described well by Brennan (2001).

Identifying and controlling error. Generalizability theory emphasizes the estimation of separate error components, but that estimation hinges on correctly identifying those error components in the first place (for an excellent discussion of the general problem of error identification and correction see Schmidt & Hunter, 1996). One common problem is to ignore “hidden” facets (Brennan, 2001). For example, a researcher might administer multiple items to a group of respondents on one occasion and forget that occasion is a constant in the study, though it will be a likely source of variability and considered as error in application. The problem is that occasion variance, which Schmidt and Hunter (1996) call *transient error*, acts like a constant for each individual on a given occasion, and is counted as true score or universe score for each individual. For example, the systolic blood pressure of participants could be temporarily elevated or depressed on any give occasion in ways that are idiosyncratic (e.g., one person meditated that day and another person nearly had a traffic accident) or constant for all (e.g., a tornado warning was in effect on the day of examination). These sources exert a systematic effect that cannot be distinguished from the universe score on a single measurement occasion. Their status as error is only revealed through their variability over multiple measurement occasions. Brennan (2001) provides an excellent discussion of hidden facets and the complex problems they can create for interpretation of reliability.

Similarly, error specific to a particular test condition or mode of measurement, which Schmidt and Hunter (1996) refer to as *specific error*, can masquerade as universe score variance unless test condition or measurement mode is explicitly included in the measurement design and its

contribution to error is estimated (Llabre et al., 1988; Llabre, Spitzer, Saab, Ironson, & Schneiderman, 1991). The G study in the example could be expanded to include a standard mercury sphygmomanometer, a Dynamap automatic blood pressure monitor, and an ambulatory blood pressure monitor (Llabre et al., 1988). Variability because of measurement mode could then be estimated, although in this example it might be argued that measurement mode is a fixed effect.

A related problem is ignoring facets. Here the problem is not that a facet is held constant, but that a facet exists in a measurement problem and is not included in the statistical analyses. For example, in the blood pressure study, a time-of-day facet would exist if blood pressures were taken at various times throughout the day. Failure to include this source of variance could distort estimates of reliability. The general principle here is simple: Universe score variability, error variability, and estimates of reliability depend on the conditions of measurement and the conditions of application. Very careful attention must be given to what should count as error and, then, the measurement design must be constructed so all sources of error are given a fair opportunity to emerge and be estimated correctly. Stated differently, the measurement model must be defined correctly or the resulting measurement characteristics will be estimated incorrectly.

There is, of course, another option for the control of error other than aggregation: *standardization*. Rather than letting an error source be free to vary and harnessing that error through aggregation, the error source can be controlled effectively through standardization. Standardization is simply the attempt to control the measurement conditions carefully so that no extraneous sources of error are allowed to influence scores. For example, the same instructions delivered in the same way should precede a measure. Otherwise individuals' obtained scores might vary slightly in response to differences in instructions and that would be an additional source of error that obscures the ability to detect the true score. Similarly, environmental conditions should be the same for all respondents otherwise respondents' scores could vary depending on temperature, humidity, or ambient noise. The important point about standardization is that when measurement conditions are standardized, potential sources of variance become constants and cannot influence the variability of obtained scores. When is an error source a constant and when is it a hidden facet? It depends on the intended application. Conditions that will be free to vary in an application must be free to vary and their influence estimated in a generalizability study. Indeed, generalizability theory underscores the responsibility of a researcher to carefully mimic the intended application parameters when modeling variance components in G studies and D studies. This might seem to fly in the face of conventional wisdom that all sources of error should be controlled. If D studies are to provide informative forecasts, however, the conditions likely to be present in the application need to be present in the forecasting model.

Three additional points about error are pertinent. First, reliability of measurement does not ensure sensitivity of measurement. A poor choice of measurement instrument may preclude detecting the phenomenon of interest even though what is detected is done so reliably. For example, verbal reports of physical symptoms may be quite reliable, but they are notoriously insensitive to specific visceral reactions (Pennebaker, 1982). Second, reliable measurement alone will not insure a correct causal inference. Reliability increases the maximum possible correlation that can be detected between two operational definitions (Equation 33.5), but this does not imply that a causal relation exists between those operational definitions. Additional requirements for inferring causality must be considered (i.e., internal validity, see Shadish et al., 2001). In fact, reliable measures may fail to reveal associations between variables because other statistical assumptions are not met (i.e., statistical conclusion validity, see Cook & Campbell, 1979). Finally, standards of reliability should be recognized as arbitrary and crude benchmarks for the control of error in measurement. To be sure, with reliability, higher is better. However, attempting to achieve a particular reliability value may provide only a crude approximation to the real goal of keeping measurement error at a known level or achieving an acceptably sensitive test for an effect of known size. Accordingly, concerns about statistical power (see Bollen, 1989; Fleiss & Shrout, 1977; Humphreys & Dasgrow, 1989; Kopriva & Shaw, 1991; Williams & Zimmerman, 1989; Zimmerman & Williams, 1986) and the setting of confidence intervals should guide the choice of a reliability value to achieve.

VALIDITY

Validity is defined traditionally as the extent to which a measure assesses what it purports to measure (Kelley, 1927). Perhaps a better way to think about validity is the appropriateness of the label that is applied to a given application for a measure (Messick, 1989). This reminds us that, as was true with reliability, there are as many validities for a measure as there are applications for it. State differently, numbers are just numbers until they are put to some use.

The basic problem of invalidity can be viewed as an extension of our previous discussion of reliability. In classical theory an obtained score is conceptualized as being composed of a true score plus a random error score. In generalizability theory, this idea was expanded to include multiple error sources in which some of them are systematic. That is, in generalizability theory, some components of variance exert a predictable influence on the scores of individuals, but those variance sources have nothing to do with the true or universe score. If those sources (e.g., observers) influence the obtained variability to a great extent, then the labeling of the measure as an indication of stress could be inappropriate, particularly if the universe score variability is quite small. In this sense, generalizability theory is appropriately described as blending the concepts

of reliability and validity (Shavelson & Webb, 1991; Brennan, 2001). It suggests as well that the two concerns of psychometrics – reliability and validity – each addresses aspects of measurement error. Invalidity represents the erroneous labeling of an operational definition.

More generically, the conceptualization of an obtained score might be displayed simply as:

$$X = t_1 + t_2 + e \quad (33.25)$$

in which t_1 represents the true score of primary interest and t_2 represents the true score for another construct (e , as before, represents random error). If the variability in x is due to t_1 being substantial, then a label (based on t_1) applied to x is appropriate, that is, it is valid. If, however, the variability in x is primarily due to t_2 , then a label based on t_1 will be invalid. For example, heart rate would be a relatively poor measure of sympathetic nervous system influence because it is affected by both sympathetic (t_1) and parasympathetic (t_2) systems.

Strictly speaking, then, a measure is not validated; rather the interpretation or purpose for which the measure will be used is validated. Accordingly, the number of validities for a measure can vary considerably (Fahrenberg et al., 1986). The ways that measures can be validated can vary widely. Indeed, it could be accurately said that most of science is a process of validation. Nonetheless, there are several well-defined approaches to validation that emphasize some useful points.

Content validation. Content validation is a consensual approach that relies on expert agreement about the content universe or domain, the degree to which a given indicator or item represents that domain, and the degree to which a collection of indicators adequately represents all facets of the domain. Representation here might include issues about the appropriate measurement circumstances and the particular profile or patterning of responses over time or situation (cf. Cacioppo & Tassinary, 1990). The question is essentially whether a given operational definition is a good proxy for the underlying construct, that is, the extent to which most experts agree that it “stands for” the construct. Broadly speaking, content validity refers to consensus on the universe of admissible observations.

There are two distinct types of content validation. The first and more common approach is to assess expert agreement about representativeness after the measure has been developed. For example, if the intent were to assess cardiovascular function, the researchers could propose a set of indicators (e.g., systolic blood pressure, diastolic blood pressure, pulse transit time, forearm blood volume, and heart rate) and measure expert agreement concerning suitability of each indicator and the representativeness of any set of indicators. This might be accomplished by having a group of experts rate each indicator, indicator profile, and their measurement circumstances (e.g., on a seven-point scale) according to their appropriateness given the construct definition and then assessing expert agreement

using generalizability theory (see Crocker, Llabre, & Miller, 1988).¹³

A second, more preferred, approach is to use expert opinion in the measurement development phase. Each expert would generate indicators or measurement conditions believed to be appropriate given the construct definition. Then those indicators or measurement conditions generated by a sizeable majority of the experts would be selected for inclusion (e.g., parallel-panels approach, see Ghiselli et al., 1981). For example, experts could be queried about the times of day, testing conditions, and other situational influences that should be covered to insure adequate sampling of the blood pressure domain (cf. Pickering et al., 1982). These facets of measurement can affect the obtained scores and potentially challenge the preferred labeling of those obtained scores. Similarly, expert opinion can be sought about the appropriate response dimensions to use (e.g., amplitude or frequency), the correct profile to construct, or the appropriate ways to represent a measure statistically. Accordingly, it is more appropriate to speak of content-oriented measurement development than of content validation (Guion, 1978).

Not surprisingly, content validation is easiest when constructs are simple and well defined. In this case the body of content is clear and there is a greater likelihood of agreement among experts. But even for relatively concrete constructs the content validation approach is not without problems. One crucial decision is selection of experts. They should possess technical competence, have adequate knowledge of the field, and be unbiased in their research and theoretical orientations. An aggressive attempt should be made to prevent the kind of confirmatory bias that can so easily enter into validation attempts as a function of the critical choices made in structuring the research setting (Greenwald 1975; Greenwald, Pratkanis, Leippe, & Baumgardner, 1986).

Content validation is easiest when the “distance” from the construct to the operation is fairly short. When the construct is more abstract, the identification of an adequate sample of operational definitions is more difficult. In this case, the content validation approach can be thought of as an initial quality check on the operational definitions with the need for additional construct validation.

Criterion-related validation. A second approach to validation – the criterion-related approach – is essentially based on the desire for a measure that can be substituted for the criterion. In other words, there is an agreed upon “gold standard,” but (a) the criterion is too difficult or costly to assess, (b) the criterion has not yet occurred but a measure that can predict its likely occurrence is desired, or (c) the criterion has occurred in the past but is no longer

¹³ Agreement in categorical judgments could be assessed using Cohen's kappa to guard against capitalization on chance agreement (Cohen, 1960, 1968; Conger, 1980; Fleiss, 1971; Hsu & Field, 2003; Janson & Olson, 2001, 2004; Kraemer, 1980; Li & Lautenschlager, 1997; Schuster, 2004; Schuster & Smith, 2005; Uebersax, 1982, 1987, 1988).

directly accessible. These three conditions are referred to respectively as *concurrent validity*, *predictive validity*, and *postdictive validity*. An example of concurrent validity is the substitution of x-rays for the more costly but more accurate surgical detection of tumors. An example of predictive validity is the search for cardiovascular markers of future hypertension and coronary disease. An example of postdictive validation is the use of electrocardiography to determine past occurrence of myocardial infarction.

Criterion-related validation is common in psychophysiology because of the cost, invasiveness, and difficulty of measuring physiological variables for certain samples or under specific conditions. Examples include the substitution of self-reported sleep for physiologically documented sleep (Hoch et al., 1987), development of an efficient measure of sleep parameters for use in the home (Helfand, Lavie, & Hobson, 1986) or in clinical studies (Huupponen, Himanen, Hasan, & Värrti, 2004), investigation of an indirect measure of beat-to-beat change in blood pressure (Shapiro, Greenstadt, Lane, & Rubinstein, 1981) or heart period (Giardino, Lehrer, & Edelberg, 2002), examination of practical means for assessing psychophysiological markers of stress (Diaz, Vallejo, & Comeche, 2003), and development of a measure of neonate blood pressure (Hall, Thomsas, Friedman, & Lynch, 1982). In other cases, it may be easier to standardize the administration of an alternative measure or protocol compared to the gold standard (Moretti et al., 2003) or to use an alternative measure as an efficient screening device (Kovatchev et al., 2001; Yamada et al., 2000).

In choosing the criterion-related approach to validation, researchers need to be aware of some potential dangers. First, selection of a criterion may be quite arbitrary and no more representative of the construct than the proposed predictor. The criterion is ideally the most appropriate operational definition from a theoretical standpoint that has itself been validated rigorously. Accordingly, the criterion-related approach should not become a mindlessly empirical effort in which any measure is correlated with the criterion in order to find a suitable substitute but without regard for the theoretical appropriateness or meaning of the predictor. To be sure, for some applied problems there is often little interest in the nature of the predictor so long as it provides a statistically reliable means of assessing the past, current, or future presence of the criterion. This is not necessarily inappropriate if one's interests are purely functional. More care is necessary, however, if advances in conceptual understanding are to be gained. Note, as well, that a purely empirical search for predictors places one at the mercy of correlations that are inflated because of chance or dependent on unknown moderator variables.

A second danger is the assumption of an isomorphic relation between the criterion and the proxy. Their consistent and perhaps high association does not necessarily warrant the conclusion that they have a one-to-one relation (see Cacioppo &, Tassinary 1990). Although a proxy vari-

able might be highly associated with a criterion, the proxy could well have a different pattern of relations with other constructs and these relations would alter the meaning of the proxy. This problem highlights that, although linking a measure to an existing criterion is a valuable validation tool, it is not a complete validation exercise. Additional evidence is needed to establish firmly the correct label for the measure.

The practical utility of the criterion-related approach is limited in that it presupposes that a carefully validated and reliable criterion has already been established (cf. Cole, Howard, & Maxwell, 1981). In one sense, then, the criterion-related approach to validation represents a somewhat later phase in a complete validation program: (a) an important construct is identified and defined, (b) an operational definition of that construct is developed (perhaps via content validation), (c) the link between construct and operational definition is validated (via construct validation), and (d) a decision is made to find additional operational definitions that are easier to obtain than the original and that can be used in future theory-based and applied research. The validity of these additional operational definitions is examined via the criterion-related approach with the original operational definition as the criterion (see Ghiselli et al., 1981 for a discussion of additional statistical issues that can arise with the criterion-related approach), and the validity of that criterion-based label is verified further via construct validation. A good example of a criterion-related substitute measure is the use of glycosylated hemoglobin (HbA_1) as an indicator of recent compliance with a blood glucose control regimen (e.g., Bann, 1981; Kennedy & Merimec, 1981; for comments about the validity of a biochemical index of smoking behavior see Bliss & O'Connell, 1984).

Construct validation. Although content validation and criterion-related validation are important parts of the measurement labeling process, more convincing evidence for an interpretation of an operational definition derives from *construct validation*. The hallmark of the construct validation process is the placement of a construct within a network of logically and theoretically justified constructs and construct relations with specifications as to how these translate into observable operational definitions (i.e., a nomological network, Cronbach & Meehl, 1955; Messick, 1981; Westen & Rosenthal, 2003). The validation of a construct then entails the validation of the multiple operation-level relations that are derived. The network or theory surrounding the constructs informs and guides the researcher as to the operational definitions that should and should not be related as well as to the direction and magnitude of those relations. For example, if we were attempting to validate systolic blood pressure as a measure of stress, our theory might dictate that stress occurs in response to control loss (i.e., Figure 33.2). Accordingly, establishing an empirical relation between control loss and systolic blood pressure provides *partial validation* of systolic

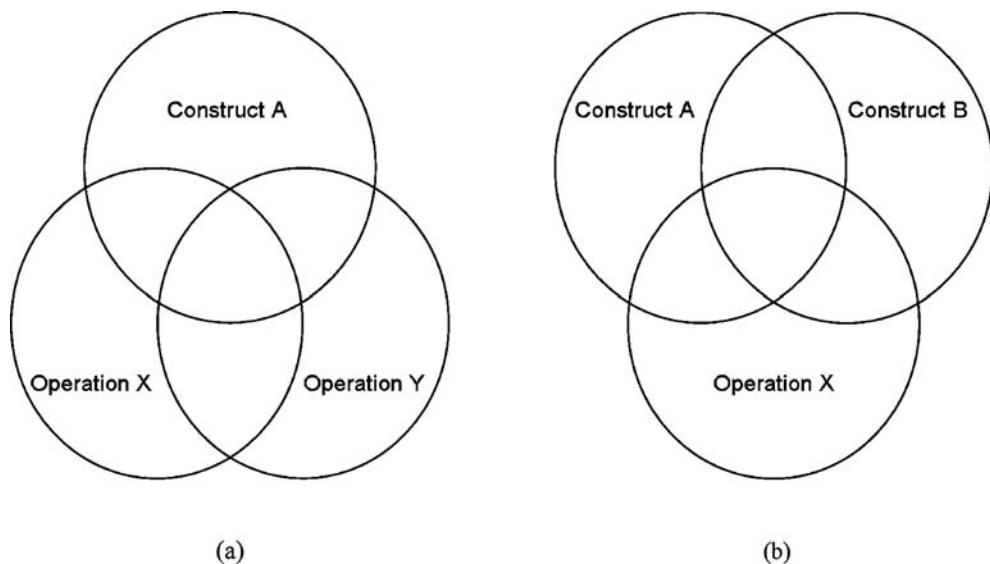

Figure 33.14. Two problems with operational definitions: (a) incomplete representation of a single construct and (b) representation of multiple constructs.

blood pressure as a measure of stress. Other empirical relations (e.g., correlations with other validated measures of stress) would add to or detract from our confidence in this interpretation depending on their magnitude and the conditions under which they are obtained. So too would relations with nonstress-related measures; these relations would challenge the appropriateness of the label.

Demonstrating construct validity is typically hampered by two common characteristics of operational definitions: (a) any one operational definition may capture only part of the underlying construct and (b) operational definitions are multidimensional and may represent two or more constructs. These relations are depicted in Figure 33.14 (see also Shadish et al., 2001; Fiske, 1987). Note that the claim that a construct is poorly represented at the operation level assumes that the construct is clearly defined in the first place. Consequently, construct invalidity can be seen to arise from problems with methods or operations (this point is argued in a very compelling fashion by Fiske, 1987; but see Shadish et al., 2001).

The dangers of incomplete representation are two-fold. First, it is possible that a particularly crucial aspect of the construct has been missed. For example, the full range of a construct may not be included in an experimental manipulation. Failure to find an empirical relation between the operational definitions might then lead to the inference that the constructs are not related when in fact an adequate test has not been performed. In psychophysiology, exclusive use of verbal reports to measure stress or emotion may lead to the conclusion that a stimulus has no long lasting effects on behavior. But this may be incorrect, as Zillmann (1978) demonstrated in his work on excitation transfer. Zillmann found that residual arousal from a prior stimulus (e.g., physical exercise) can influence later behavior (e.g., aggression) despite reports by participants that they are no longer aroused. Second, if only part of

the construct has been tested and an empirical relation is found, there is no guarantee that the results generalize to the more complete construct. Additional work may, in fact, suggest the need for a narrower construct (Fiske, 1987).

Operational definitions may also represent more than one construct (Figure 33.14). This situation often reflects the actual state of affairs: Most behaviors are multiply-determined and can be expected to be influenced by more than one source of variance. Indeed the ease with which researchers can come up with alternative explanations for internally valid empirical relations speaks to the complex and multiple constructs tapped to varying degrees by incomplete or inaccurate operational definitions. An example is the skin conductance response, which has long been recognized as being affected by widely varying stimulus conditions, across sense modalities, with interpretations including an index of specific emotions, a measure of motivation, a measure of attention, and a personality index. A not so obvious danger to multiple construct representation is the assumption that obtained relations between operational definitions imply an isomorphic relation, a point to which we will return.

The construct representation problems indicate that reliance on any one operational definition could lead to seriously distorted conclusions and that the validity of any one operational definition depends on convergent and discriminant evidence. The solution to both problems is *multiple operationism*, that is, to specify a set of correspondence rules that serve to associate a single concept with multiple operations. Only when empirical relations replicate across multiple operations can any confidence in construct relations be attained and the proper interpretation of an operational definition be made confidently. The logic of multiple operationism, depicted in Figure 33.15, is based on the simultaneous collection of convergent

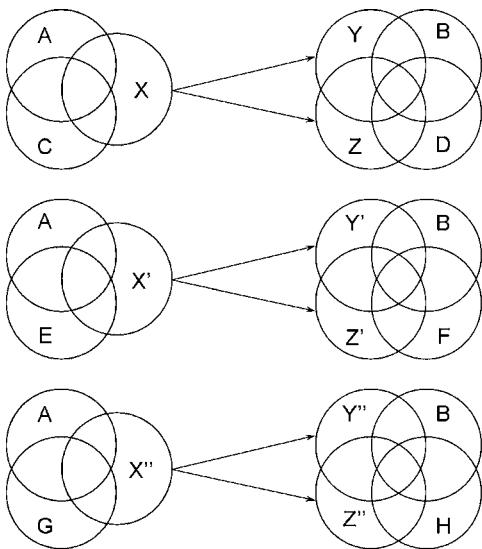

Figure 33.15. The consequences of multiple operationism.

and discriminant validation evidence. Each hypothetical study in Figure 33.15 tests the same conceptual hypothesis: $A \rightarrow B$. In each study, however, a different set of operations is used. Across studies, the “excess” representation varies, whereas the relation between constructs A and B is constant. Likewise, across studies, the incomplete construct coverage in any one study is compensated for by different coverage in other studies. Based on supportive and consistent empirical relations, the most parsimonious explanation for the entire set of results is that Construct A is causally related to Construct B. Although it is not possible to rule out entirely the conclusion that, for example, Construct C caused Construct D in Study 1, Construct E caused Construct F in Study 2, and Construct G caused Construct H in Study 3, such a complex model is less parsimonious and becomes less plausible as additional supportive studies are added. Ordinarily, of course, many more such conceptual replications are necessary to establish firmly the appropriate label for a measure.

Multiple operationism actually refers to two distinct tasks. First, any one construct will give rise to many possible operational definitions (e.g., the many ways that arousal can be operationalized physiologically). The relations among these operations must be examined for their internal consistency. This *monoconstruct* multiple operationism provides information about the validity of interpreting any given operation as representing the construct. Second, relations between constructs must be tested by examining the interrelatedness of different sets of operations. For example, if researchers investigate the hypothesis that arousal increases vigilance, they would want to examine relations between multiple measures of arousal (e.g., heart rate and skin conductance) and multiple measures of vigilance (e.g., reaction time and event-related potentials). This *multiconstruct* multiple operationism speaks to the validity of the proposed construct linkages.

Both validation tasks are crucial to model testing and both are represented in Figure 33.15 in which monoconstruct multiple operationism is represented within each study for dependent variables and multiconstruct multiple operationism occurs across studies.

An additional word of caution regarding multiple operationism is in order. The power of using multiple operations is greatest when they diverge substantially from each other. There is little to be gained from using two self-report measures, or two nearly identical modes of physiological assessment. Any correlation between the operations might reflect their similarity in method rather than any common underlying construct. Stated differently, a construct should not be method bound, unless one is taking a particularly narrow view of a construct. The only way to demonstrate the independence of method and construct is through multiple operationism. The importance of avoiding method artifact has led to the development of the multiattribute-multimethod matrix procedure (Campbell & Fiske, 1959; Fiske, 1987; Hammond, Hamm, & Grassia, 1986; Kenny, 1995), a technique for identifying the degree to which operational relations are contaminated by method variance. This approach can be combined with structural equation modeling to provide concomitant control of measurement error (Marsh & Grayson, 1995; Wothke, 1996).

An example might make some of the preceding discussion clearer. Expanding the previous example in Figure 33.2, we might propose that the following conditions are representative of *control loss* and will bring about an increase in *stress*: (a) failing a driving test, (b) unexpectedly losing a job, (c) getting caught in a traffic jam, (d) having someone cut in line just as you near the ticket counter, and (e) getting caught in the rain without an umbrella. In successive investigations we could devise operational definitions and examine their relation to our operational definition of stress: systolic blood pressure (perhaps measured using an ambulatory monitor). We could also include in each study additional measures of stress. Taken together, this type of evidence would provide convergent validation that systolic blood pressure measures stress. On the other hand, our model might also predict that stress is not related to (f) simple physical exertion or (g) chemical stimulation. Accordingly we would not predict empirical relations between operational definitions of these variables (e.g., treadmill test, ingestion of caffeine) and systolic blood pressure. That these relations would most assuredly be found would indicate a lack of discriminant validity.

In our previous discussion of reliability we noted that aggregation is an important principle for the suppression of error. Over repeated measurement occasions, random errors have an increasing chance of canceling out and leaving true score more apparent. A similar aggregation principle operates for validation via multiple operationism. Over repeated studies using multiple operations, errors because of construct mislabeling can be identified and corrected.

The process of construct validation. As might be clear by now, construct validation is an iterative, evolving, programmatic process, which can be highlighted by examining the logic involved in making inferences based on data-level relations more closely (see Nunnally & Bernstein, 1994). Consider again the original diagram of the basic inferential task (Figure 33.1). All that we have to base our inferences on is a relation between operational definitions X and Y; perhaps this is a causal relation, $X \rightarrow Y$. Any inference that we make, however, involves three other relations: (a) the extent to which X is a valid representation of construct A, (b) the extent to which Y is a valid representation of construct B, and (c) the extent to which A is causally related to B. In any one study we cannot simultaneously make inferences about all three of these relations. Rather, we must first assume two of them to be true, and then allow the empirical relation $X \rightarrow Y$ to inform us about the plausibility of the remaining relation. For example, if our intent were to make inferences about $A \rightarrow B$, then we have to assume that X and Y are valid representations of constructs A and B, respectively. In other words, if we wish to make inferences about construct relations, then we must assume that the operational definitions have construct validity. Likewise, if we wish to make inferences about the construct validity of Y, then we must assume A and B are causally linked and that X is a valid representation of A. Our assumptions about the truth of the relations in our conceptual model is based on research (our own or previous research conducted by others). If our ultimate goal is making causal inferences, then we must proceed by first generating empirical evidence for the construct validity of our measures. This is a necessary first step because we must assume construct validity is present when causal hypotheses are tested and without such evidence, lack of empirical support for the causal hypothesis is uninterpretable. Furthermore, past research must be able to support considerable confidence in such assumptions because the appropriate interpretation of positive or negative empirical results hinges on the validity of those assumptions. An incorrect assumption can alter the direction of subsequent research and make the construct validation process inefficient if not completely misleading. This incremental view of construct validation returns us to a point made at the beginning of this chapter: Research must be guided by a very clear view of what one intends to infer from the data.

Several final comments about construct validation are in order. First, the construct validity of both the independent and dependent variables require careful attention. Psychophysiological research tends to emphasize the construct validity of physiological signals as dependent measures. But the construct validity of the eliciting conditions for those signals is equally important. For example, work on the physiological markers of stress has used a wide variety of stressors (e.g., physically demanding tasks, mental arithmetic, and cold pressor task). The conceptual equiv-

alence of those tasks is an important consideration that influences the labeling of the physiological signal. Second, conceptual models should be responsive to empirical findings. A conceptual hypothesis is only an educated guess about how things work. If the evidence indicates a need for revision, it behooves researchers to let their models evolve rather than fall prey to confirmatory bias. Although it may be obvious, it is important that model revisions be tested on new samples. In a similar fashion, researchers should test their models aggressively, that is, provide empirical tests of hypotheses that are not immune to falsification. Researchers should assume that their measures and models contain errors and then set out aggressively to find and correct those errors rather than assuming measures and models are true and finding ways to protect that fragile perception. Finally, researchers should realize that construct validation is a slow, methodical process. The building of a conceptual model should be taken one sure-footed step at a time.

Psychological labels for physiological signals. Whenever labels are attached to numbers there is a danger of assuming an isomorphic relation between the measures on which the labeling is based. This is particularly a problem in psychophysiology, in which the "label" attached to a physiological signal is quite frequently a psychological state or process (Cacioppo & Tassinary, 1990; Sarter et al., 1996). As Cacioppo and Tassinary point out, an important goal of psychophysiological research is to specify the functional relation between elements in the psychological domain (Ψ) and elements in the physiological domain (Θ): $\Psi = f(\Theta)$. Often this functional relation is investigated by manipulating some element in the psychological domain and measuring the consequent response in the physiological domain. It is tempting to conclude that corresponding signal differences can be labeled with the psychological element that produced them. As Cacioppo and Tassinary (1990) remind us, however, "simply knowing that manipulating a particular psychological element such as emotional arousal leads to a particular physiological response such as electrodermal activation does not logically enable inferences about the former based on observations of the latter" (p. 24). The problem here is that the relations between elements in the psychological domain and elements in the physiological domain may not be one-to-one. Consequently, the probability of a physiological response given a psychological event, $P(\Theta|\Psi)$, is not necessarily equal to the probability of the psychological event given the physiological signal, $P(\Psi|\Theta)$. More than one distinct psychological event could produce the same physiological signal, for example (what Cacioppo and Tassinary call a many-to-one relation). The problem is perhaps clearest in cognitive neuroscience (Sarter et al., 1996). Cognitive operations are manipulated (e.g., using memory tasks or naming tasks) to determine the effect on brain images in order to isolate brain structures

that may be responsible for the psychological process. Finding such associations (e.g., $P[\Theta|\Psi] > 0$) does not justify labeling the structure a particular cognitive center in the brain and inferring that a change in that structure would produce the psychological event (e.g., $P[\Psi|\Theta] > 0$). It certainly does not justify the isomorphic inference that $P(\Psi|\Theta) = P(\Theta|\Psi)$. Such invariant relations are a noble goal, but they require more evidence than is usually gathered in any single investigation.

The lessons to be learned from the inferential pitfalls identified by Cacioppo and Tassinary (1990) and Sarter et al. (1996) are that (a) strong inferences should not be assumed when the empirical relations do not justify them, and (b) one's research strategy should be planned to achieve strong inference when possible. The latter goal can be achieved through careful attempts to transform many-to-one, one-to-many, and many-to-many relations between the psychological and physiological domains into one-to-one relations. This may require thinking of the "elements" in those domains as sets or profiles of responses, that may have a temporal nature to them, and that might require restricting the circumstances under which they are measured. This brings us back to a theme that has been emphasized throughout this chapter: the characteristics of operations (e.g., reliability, validity, and relations) are not ordinarily invariant. They depend on the circumstances of measurement, broadly defined. Striving for such invariance requires increasing specification that might seem to limit the utility of the measures and defeat the goal of broad generalizability. It is, in fact, in the spirit of the kind of error-reduction that has been emphasized throughout this chapter.

A return to theory. We began this chapter by noting that measurement starts with a clear conceptual model that describes causal relations among constructs and operational definitions. This causality-based view of measurement is common in discussions of measurement (e.g., Boorsboom, Mellenbergh, & van Heerden, 2003; Edwards & Bagozzi, 2000; Embretson, 1983), but its full implications are often lost, and as a consequence, efforts to develop good measures can get sidetracked. The point is perhaps made most forcefully by Boorsboom, Mellenbergh, and van Heerden (2004), who argue that current validation work emphasizes correlation over causality and often amounts to little more than seeking validity after the fact rather than building validity into measurement. As they put it, "the problem of validity cannot be solved by psychometric techniques or models alone. On the contrary, it must be addressed by substantive theory" (p. 1062). We would not paint as stark a picture as Boorsboom et al. (2004) regarding the current state of affairs in measurement nor would we dispense with some of the approaches in common use (e.g., criterion-related validation and the nomological network) that they find objectionable. Used properly, these validation tools can help refine measurement considerably. We are in complete agreement, how-

ever, with their statement that "no amount of empirical data can fill a theoretical gap" (p. 1068). In our opinion, science and measurement will always be a winnowing process that seeks to strip away error to reveal some meaningful truth. That process is streamlined considerably when informed by clearly reasoned theory.

CONCLUSION

The psychometric principles discussed in this chapter lie at the very heart of scientific progress. Although most researchers have a rudimentary understanding of these principles, their importance and specific application are often ignored. This arises, perhaps, because psychometric principles are most often associated with the classic psychometric traditions of intelligence, ability, and personality assessment. Yet, as has been stressed throughout this chapter, attention to psychometric principles is crucial no matter what form measurement takes. Whether one is attempting to map the physiological structure of mood, to identify stable physiological markers of future disease risk, to develop procedures for determining the physiological concomitants of cognitive function, or to demonstrate the practical utility of physiologically based lie detection, psychometric principles provide essential "rules of evidence" that are used to judge the adequacy of our conceptual and applied conclusions.

Science is aptly described as a truth-seeking enterprise, but it perhaps is best described as an error-correction enterprise. After all, scientists rarely find the truth staring them in the face. Instead, it emerges grudgingly after careful trimming and winnowing of the numerous error sources that obscure the view. Careful attention to psychometric principles can make that winnowing process more efficient and effective.

34 Methodology

J. RICHARD JENNINGS AND PETER J. GIANAROS

Science is a method. We observe and then compare observations to find regularities in nature. The method of observation determines what we see and should determine how we interpret our observations. Consider two hypothetical experiments on the same topic. Both ask whether the pupil of the eye dilates during exposure to loud white noise (80 dbA). The first exposes six research participants to five minutes of relative quiet (40 dbA white noise) followed by five minutes of loud noise. The second experiment exposes six participants to five minutes of relative quiet and a different six participants to five minutes of noise. Both experiments measure pupil size and compare data collected under conditions of relative quiet and relative noise. Analyses show that noise influences pupil size, in one experiment, but not in the other. Why the discrepancy? We should suspect that the difference in the method of observation caused the discrepancy. We will discuss this particular discrepancy below when we suggest that the sensitivity of measuring the same subject under different conditions is typically higher for psychophysiological measures than sensitivity of measuring different participants under different conditions.

This chapter addresses salient issues that occur more frequently in psychophysiology than in psychological research in general. General treatments of methodology can be found in Keppel (1991), Kirk (1995), Kerlinger and Lee (2000), and Maxwell and Delaney (2004). Abelson (1995) offers an enjoyable and wise perspective on statistics and methodology, which we recommend highly.

Our emphasis will be on experimental design and its relationship to statistical analysis, although we shall also discuss issues of data collection and response representation. Methodological issues that are specific to particular measures will not be covered. Such coverage is available in measurement-oriented handbooks, for example, Martin and Venables (1980) and Hugdahl (1995). A series of publication guidelines on specific measures have been

published in the journal *Psychophysiology*: skin conductance (Fowles et al., 1981), heart rate (Jennings et al., 1981), electromyography (Fridlund & Cacioppo, 1986), EEG (Pivik et al., 1993), impedance cardiography (Sherwood et al., 1990), blood pressure (Shapiro et al., 1996), respiration (Ritz et al., 2002), event-related potentials (Picton et al., 2000), startle blink (Blumenthal et al., 2005), and assessment of heart rate variability (Berntson et al., 1997). Loewenfeld (1993) covers measures of the pupil of the eye. Further information on event-related potential methodology is in a special issue of *Behavioral Research Methods* (van Boxtel, 1998). Basic issues of experimental control are addressed in chapters by Johnson and Lubin (1972) and Stemmler and Fahrenberg (1989).

PLANNING THE RESEARCH

Designing the observations

The key principle of methodology is as simple to state as it is difficult to implement. The methods must be chosen to answer the primary question posed by the research. Implementing this principle requires stating the experimental question concretely, assessing the means available for response measurement, identifying factors that could confuse the answer of the question, and employing statistics that answer the question precisely.

The psychophysiologist typically starts with a psychological concept of interest, assesses the concept with a physiological measure, and observes the correlation between the measure and the concept across an experimental manipulation or across a relevant dimension of individual differences. We will leave the choice of psychological concept to the reader. The choice of a physiological measure typically poses the first major challenge to the apparent simplicity of fitting the methods to the question. Often the experiment is conducted to see if measure x acts like a measure of a psychological concept. The basis for this expectation must be carefully reviewed. If a good basis exists, then it may also be possible to identify measures that are similar to measure x that either should or

(in preparation). Salient Method, Design, and Analysis Concerns. Chapter to appear in Cacioppo, J. T., Berntson, G. G., & Tassinary, L. G. (Eds.), *Handbooks of Psychophysiology*, 3rd Edition. New York: Cambridge University Press.

should not covary with variation in the psychological process. Drawing a complete picture of the expected mapping between concept and physiological measures should yield optimum convergent and discriminant validity for the measurement methodology. Cacioppo and Tassinary (1990), as well as Jennings (1986), provide a detailed, more formal discussion of how psychological and physiological concepts can be appropriately related to each other. Once this conceptual exercise is completed, then a number of practical concerns must be weighed against the value of obtaining convergent and divergent measures.

An example should clarify the conceptual and pragmatic issues that must be addressed. Consider an investigator interested in impulsive behavior in children. She wishes to show that positive reward induces greater impulsive behavior in children classified as impulsive on a scale of impulsivity. Positive reinforcement (a nickel) is contrasted with negative reinforcement (loss of a nickel). A visual, two choice reaction-time task is presented requiring a left hand response to the appearance of a left pointing arrow and a right hand response to the appearance of a right pointing arrow. A hundred ms before each arrow stimulus, however, a tone is presented to one of the two ears. Seventy-five percent of the time the tone is presented on the same side of the body as the side of the correct response to the upcoming arrow. On the remaining 25% of the trials a miscue is presented (i.e., a tone is presented on the side of the body opposite to the direction that the upcoming arrow is pointed).

How is the investigator to use psychophysiological measures? First, note that the investigator seems to have the modest, but hardly simple, goal of validating a scale/dimension of impulsivity. Impulsivity is operationalized as responding prior to the receipt of complete information. Behaviorally, responding is pushing a button. However, physiologically, responding includes preparatory adjustment of posture and competing motor activity, activation of motor cortex of the appropriate laterality, transmission to peripheral motor units, and electrochemical activation of the myofibrils resulting in flexion sufficient to make the button switch closure. The question of what is responding now appears more complicated. After considering the possible sources of variance in the button press initiation (e.g., nerve conduction differences and motor strength) the investigator begins to wonder how many measures could possibly be required. Some reading may convince the investigator that conduction time and motor strength differences are not likely to be a major contributor to the reaction speed, but that inhibition can stop a response even after activation of the motor cortex. At this point, the investigator may decide that impulsivity may arise both from aberrant central processing and the coupling of this with peripheral response mechanisms. Measures of motor cortex would seem useful as would measures of different aspects of the peripheral response.

At this stage, pragmatic measurement factors may be appropriate to consider. Without losing the fit between the

measures and concept of impulsivity, it would be preferable that the measure is simple to use and analyze, inexpensive, not prone to noise, acceptable and ethical to apply to human participants, and capable of being understood from previous experience (or, at least, can be understood in the time one has during pilot work). Such considerations might push us, for example, toward the use of surface electrodes for electromyography rather than needle electrodes, or toward electroencephalography rather than magnetic resonance imaging.

Investigators can weigh pragmatic factors too much or too little in their considerations. The investigator who places too much weight on practicality may choose a measure already operational in the laboratory (e.g., electrocardiography), rather than a conceptually relevant measure that may not yet be operational (e.g., electromyography). The investigator who places too little weight on pragmatic factors will waste time and money, and may also incur more subtle costs. Most seasoned investigators believe that it is easier to collect data than to analyze and interpret data. Collecting 64 channels of EEG when the conceptual question only requires 4 channels may mean that each channel will receive some 1/16th of the analytic and interpretive time that the investigator would have placed on one of four channels. Although this numerical argument is specious, it seems reasonable to ask the investigator to consciously consider the trade off between understanding a small number of variables quite well and understanding a large number of variables less well. The tradeoff can also occur during data collection if too many technically difficult measures are attempted. Most investigators would not purposefully violate such common sense considerations, but most have collected data that were not analyzed or lost data from an entire measure because of an unforeseen technical failure. Some problems may be avoided if the investigator collects and completely analyzes pilot data from a few participants, which might include the investigator as a participant.

In the case of our hypothetical experiment on impulsivity, a practical set of response measures might be the lateralized readiness potential, surface electromyography, and response initiation, force, and completion measures. Briefly, a rationale can be cited, although it is not necessarily the best rationale – this is, after all, a hypothetical experiment. With surface cortical electrodes over bilateral motor sites and bilateral comparison sites, the degree of motor activation related to a response on one hand can be identified (see review; Coles, 1989; Coles, Gratton, & Donchin, 1988). Surface electromyography over muscles subserving a selected response, in this case each hand, can detect activation that may not result in an overt response (Lippold, 1967; van Boxtel, van den Boogaart, & Brunia, 1993). Finally, initiation of a response, the force of that response, and time of completion (standard RT) provide converging information on the intensity of any impulsive response (cf., Zahn & Kreusi, 1993). Our measurement choices would not be adequate if the investigator had different goals. If,

for example, the investigator wished to explain impulsivity as a result of heightened midbrain activation, then convergent measures of cortical and autonomic activation indices might be required.

Design: Repeated measures versus between subject

Should we compare the influence of a variable between different groups of participants or use a single group and expose them to all levels of the variable? Our initial example of the influence of noise on pupil size compared exposing the same participants to noise and quiet with exposing different subject groups to noise and to quiet. In the first design the mean of pupil size under the noise condition is compared to the mean in the quiet condition; and in the second, the mean of one group in noise is compared to the second group in noise. Most psychophysicologists use some form of within-subject design. Why? And what problems does this create?

Similar to most psychophysiological measures the range of differences between individuals in pupil diameter is larger than the range of expected changes as a result of stimulation. The result is that pre- and postmeasures of, for example, pupil diameter, will be highly correlated. For example, three participants could have pupil diameters of 3, 4, and 5 mm. A dilation for each might yield diameters of 3.2, 4.3, and 5.1. The correlation between pre- and post-stimulation values is high despite the variability among the subject in the size of change, .2, .3, and .1 mm. Consider the statistical result if identical values for pupil size were obtained from one group of subjects for the baseline values and another for the stimulated values. Such values would be independently collected in the two groups (uncorrelated). A t-test can be computed for illustrative purposes using a t-test for dependent values for the within-subject comparison and an independent groups t-test for the other (see statistics text, e.g., Hays, 1994) (Kerlinger & Lee, 2000; Maxwell & Delaney, 2004). In both cases the mean difference between baseline and stimulated pupil is .2 mm. This value is divided by the estimate of the standard error of the mean for the between-participants design (.52) or for the within participants design (.01). The t-value of .4 for the between-subject comparison is dramatically smaller than the 20.0 for the within-subject comparison. Because of the strong correlation between baseline and test values within subject, the within-subject test statistic is markedly more sensitive than the between-subject test (Hays, 1994; Keppel, 1991). This difference in sensitivity is the primary argument for use of a within-subject design in psychophysiological research.

The primary problem of within subject designs is dependency (carryover) between conditions (see below for discussion of temporal dependency within the response measure). Serial dependency is created when our participants behave differently depending upon the condition they initially (or previously) received, for example, performing

differently in a quiet condition when it has been preceded by a noise condition rather than being the initial session of an experiment. Serial dependency seriously challenges the interpretation of research results. This problem has been discussed most thoroughly by Poulton (1973, 1982; Poulton & Freeman, 1966; Poulton & Edwards, 1979).

A recent set of experiments directly assessing carryover effects may illustrate the issue well. Altmann (2004; see also Loftus 1994), was interested in how preparatory time influenced the ability to shift efficiently from one task to another (e.g., switching from responding based on the height of objects to responding based on widths). He was concerned that if the same subject experienced both a longer and shorter preparatory time that learning to prepare with one time interval would alter how participants prepared during the other time interval (i.e., a carryover effect). To test this possibility he ran the same experiment manipulating preparatory time from trial to trial (within subject) and by having one group of participants exposed to the shorter preparatory period and one exposed to the longer (between subject). The results were strikingly different. When the manipulation was performed within subject, the longer interval enhanced the efficiency of switching between tasks; when the manipulation was performed between participants, no evidence of such an effect was found at all, despite careful attention to the statistical power of the experiments.

This demonstration and Poulton's methodological arguments, clearly warn the investigator that a validity check is important when using a within-subject design (see Osterhout, Bersick, and McKinnon (1997) for a psychophysiology example). Investigators should first adhere to the general methodological advice to avoid within-subject designs when differential carryover between conditions is likely, and to isolate conditions experimentally as much as possible. We also share Poulton's recommendation: ideally, a study would be run with both within- and between-subject designs. More practically, within-subject designs should vary the order of treatments so that the first treatment received can be analyzed as a between-participants comparison. If the design per se is not altering the results, then the mean difference is due to the treatment and should be comparable regardless of whether the comparison is between- or within subject. If the direction or magnitude of the mean difference is inconsistent, then diagnostics should be initiated to understand any carryover effect present in the experiment.

The number of participants, power and determining effect size

Studies should be large enough to detect the differences that are sought (if present), but not significantly larger; studies should have adequate power. Power is the probability of rejecting the null hypothesis when it is false, and it complements the more familiar probability of accepting the null hypothesis when it is false, often termed alpha. Power is determined by the ratio of the expected mean

differences as a result of the independent variable (the effect) and the error variance. Therefore, any parameter affecting the effect size or the error variance plays a role in increasing the power of an experimental design. This means that power can be increased not only by increasing the number of participants, but also by using the appropriate design, planning specific contrasts (Abelson & Prentice, 1997), using covariates or blocking factors, and selecting the most appropriate statistical analysis. Power analysis has been introduced in some degree to psychology by Cohen (1977, 1992).

General power computation software is now commercially available as part of program packages such as Statistica, SPSS, and SAS (Borenstein, Cohen, & Rothstein, 1997), but most do not specifically address repeated-measures designs. A general linear model approach for computing power has been successfully applied to repeated measures (Muller & Barton, 1989, 1991; Muller, LaVange, Ramey, & Ramey, 1992). The PASS program provides specific routines to calculate the power of repeated-measures designs based on the Muller approach (Hintze, 2004). A means for using SPSS to compute power for a number of complex designs has also been presented (D'Amico, Neilands, & Zambarano, 2001). See Algina and Keselman (1997) and O'Brien and Muller (1993) for further discussions of approaches to power for repeated measures.

Measurement scales

The novitiate to psychophysiology is often impressed with the technical equipment and the continuous data flowing from this equipment in objective units such as volts and siemens. This impression can conceal the important measurement issues that psychophysiology shares with the rest of psychology (and most of science). Glancing at a polygraph or computer screen, four signals might be displayed: EEG, EKG, blood pressure, and photoplethysmograph. All have been translated to voltages so they can drive a polygraph or computer display, but each is very different. Despite common appearance, these signals do not share any underlying measurement characteristic.

Common metrics with appropriate scale properties that permit the direct comparison of individuals are desired. We will consider here only scale properties of individual measures that may permit comparison between and within individuals rather than scaling techniques that compare individuals using more than a single measure. Physical measures, such as time, have equally spaced units and ratio properties so that arithmetic operations performed on the measures are meaningful (e.g., an interbeat interval of 1200 ms is twice as long as one of 600 ms) (see Stevens, 1951). Often we are, however, not really interested in the observed measure. Voltage measures have good properties. Assume that the investigator is interested in blood flow, and does not know how a voltage output from a photoplethysmograph is related to blood flow. A photoplethys-

Relationship between mv scaling and scale of personality aspect varying reactivity

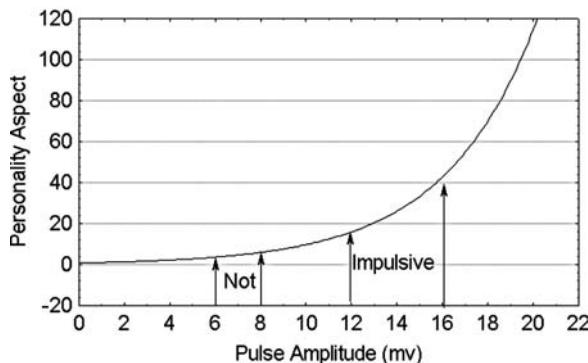

Figure 34.1. Illustration of how difference scores fail to resolve scaling issues that arise because our scaling is not linearly related to the true scaling. The x-axis is our scaling mv, of a photoplethysmograph signal, and the y-axis is the true scale value on the dimension of interest, sympathetic nervous system influences on the vasculature as driven by impulsivity. Mean data from impulsive and nonimpulsive groups under rest and task conditions are shown and the continuing distortion of the difference scores illustrated.

mographic output of 5 mv is half of one of 10 mv. If one does not know the translation to blood flow, however, the blood flow associated with the higher voltage could be 10 or 1.1 times as large as that associated with the lower voltage.

Taking this point further, physical measures with excellent scale properties do not necessarily support psychological inferences. If one is interested in impulsivity and a person has a mean pulse amplitude of 3 mv and another an amplitude of 9 mv, it can be said that the amplitude of the former is one-third less than that of the latter. It cannot be said, though, that the former has one-third more (or less) impulsivity than the latter because the investigator does not know how impulsivity alters pulse amplitude. Difference scores do not necessarily help. Assume that the mean pulse amplitude of the impulsive participants goes from 16 to 12 mv during mental arithmetic, while the mean of the nonimpulsive participants goes from 8 to 6 mv. It is tempting to think a difference score may adjust for the basal differences and put the individuals on the same scale. The difference score is -4 mv for impulsive participants and -2 mv for nonimpulsive participants. Presume, though, that pulse amplitude has a nonlinear relationship to the personality aspect relevant to the mental arithmetic response. Figure 34.1 depicts the relationship of the true scale for this aspect relative to the millivolt scoring used. If the change is read in "true" units from the graph, the impulsive change is from 42 to 17 (-25 units); while the nonimpulsive change is from 8 to 3 (-5 units). The difference scores clearly did not resolve the nonlinearity of the scaling, although the influence of the difference in pulse amplitude levels between groups was reduced.

One solution for assessing measures with unknown properties is to abandon statistical procedures based on the assumption of ratio measurement and use statistics

based on ordinal or categorical scaling (Siegal 1956), or use bootstrapping to either check the significance of obtained statistics or to provide the key test statistic (Efron & Tibshirani, 1991; Wasserman, 1989). The cost of using nonparametric (ordinal or categorical) tests is a loss of power (i.e., less likelihood of detecting differences that are truly present) for specific comparisons and loss of other advantages of parametric statistical tests, for example, use of covariates and testing of the whole design of an experiment. Incurring this cost may be appropriate if scaling is truly ordinal or less, but in the case of psychophysiological measures most might argue that the scaling is more than ordinal even if ratio, equal-interval scaling has not been established. Short of conducting the considerable work to prove that appropriate scale properties are present, the best procedure may be to use parametric statistics to identify potentially significant effects and then use nonparametric statistics to confirm the statistical significance of the identified effects. Applying bootstrapping involves a slightly more complex statistical procedure. Bootstrapping may, however, not impact power as much as the application of nonparametric tests and would not require application of both parametric and nonparametric tests. The most important concern though with either method is interpretation. For example, statements of magnitude about impulsivity require a conceptual or empirical scaling that accurately places individuals on an equal interval continuum. In the absence of such scaling, only ordinal conclusions are appropriate, i.e., statements similar to "individuals with higher impulsivity scores are more likely to show earlier EMG response onsets."

Sampling: Time is sample in within subject designs

Prior to the initiation of the research, consideration should be given to data scoring and analysis. Psychophysiologists invariably sample physiological signals that are always present. An experimental psychologist must convince a subject to emit a reaction, but living participants continually produce brain potentials, heart rate, and skin conductance in the absence of volition. To collect psychophysiological data we must sample an ongoing signal extracting a time series of data points spanning the course of the time the subject is in the laboratory. Care must be taken to sample these time points without bias and in a fashion that can be replicated by other scientists. As with any sampling, the measures will be more stable and less susceptible to random error if the investigator can collect more time samples from periods sharing the characteristics of interest to us. If the investigator asks a person to do mental arithmetic for five minutes, then blood pressure collected from that period will be estimated better by three samples at 90 s intervals than by a single sample. Samples should be spaced at equal intervals unless there are good reasons to sample differently. A psychometric rationale can be offered for this advice. If one assumes that blood pressure measures have a true component, random

error component, and that the same true component is being sampled throughout the measurement period, then the true variance in the measure will increase n times as fast as the error variance when the number of measures is increased, where n is defined as the ratio of the increased number of measures taken over the original number, or in other words, the Spearman-Brown prophecy formula (see Guilford 1954). Kamarck and colleagues (1992) provide an example of increased measurement stability resulting from applying sampling ideas to the study of cardiovascular reactivity.

An important, but simple, consideration in sampling is whether the research hypothesis refers to the tonic level of a variable (e.g., heart rate levels throughout a five-minute task), or the phasic response of a variable (e.g., transient increase in heart rate following a specific stimulus). Counting r-wave spikes for the five-minute task period is an excellent sampling strategy for heart rate level, but will not be adequate to resolve the response of the heart in the five seconds following a stimulus. The count of heartbeats uses all the data available in the interval, and is more reliable than sampling the counts for only a portion of the time period. Sampling must differ for detecting the response to an environmental stimulus. The timing of each individual heart beat relative to the preceding heart beat must be saved (ideally, to millisecond accuracy), for example, five seconds preceding and following the stimulus. Tonic and phasic are relative terms, but exhaustive sampling within those timeframes should yield the most reproducible data, despite differences in sampling time frames.

Some scoring practices are questionable when viewed from the perspective of sampling. Samples of equal length should be compared to ensure the central tendency and variability of the samples are likely to be estimated equally between samples. For example, consider the response at the surface of the cortex to a flash of light. The EEG is sampled for 2 s surrounding the flash and ensemble averages are computed across multiple flashes. The event-related potential following the flash could be analyzed and graphed solely for the 1 s following the flash. This would not, however, establish that a cortical response occurred that differed from ongoing EEG activity. The 1 s prior to the stimulus should be considered. The ensemble averaging of this time sample should not yield a waveform comparable to the 1 second following the light flash. Statistical comparison could verify the existence of a waveform, and graphical presentation of pre- as well as poststimulus activity can illustrate the presence of a waveform not present in ongoing EEG.

The scoring of complex waveforms can also be biased from a sampling perspective. A biphasic heart rate response (e.g., deceleration followed by acceleration) can be scored as the difference between the heart rate at stimulus onset and the minimum heart rate following the stimulus within a 10 s window. Could the score be used to say that a reliable response to the event occurred? Not really, the scoring scheme is highly biased toward a positive

difference, and significant “responses” would likely be found in the majority of random samples of heart rate. A further problem is that the minimum heart rate is a single, extreme sample value that is likely to be an unstable estimate of the size of any response and this minimum is compared to a single heart rate at stimulus onset. Stability could be increased by comparing response values to a prestimulus mean of, for example, 10 seconds of heart rate. Such a measure would remain biased though as single points are differenced from a mean value. Adequate scoring requires that the sampling be comparable for pre- and poststimulus periods. This can be done by including all heart rate values per- and poststimulus for 10 s in a single analysis (see Wilson, 1967), or by scoring maximum and minimum from smoothed data for equivalent samples of pre- and poststimulus heart rate and using these in analyses.

Response definition and intermeasure dependencies

Many psychophysiological investigations are directed at the responsivity of the person to an environmental event or a psychological process initiated by such events. Responsivity should be defined objectively prior to starting the study. What is our primary measure of responsivity? How will the onset of the response be defined? How will electrical noise influence these definitions? In our example we chose as one response measure the lateralized readiness potential of impulsive children. This measure requires bilateral (usually over C3 and C4) scalp electrodes subject to electrical noise, which is likely to obscure the readiness potential on any single trial. This will force us to use multiple trials so that the results can be ensemble averaged by aligning time samples with the stimuli and then averaging over trials to yield a mean waveform. The obtained potentials must then be assessed in some way. Are potentials examined from stimulus onset to 100 ms poststimulus? From 100 ms before the stimulus to 299 ms after? From the stimulus to when maximum negativity is reached within 500 ms? Answers to these questions define the response for your research and can also guide the design of filters and software scoring systems. An efficient, accurate, and ideally automated response scoring procedure can save hours of tedious work. As our example implies, response identification and scoring issues are largely specific to the psychophysiological measure studied. Law, Levey, and Martin (1980) provide a relatively general orientation to response scoring. After reading this chapter, more recent measure-specific articles should be consulted.

Psychophysiological responses must typically be defined by exclusion criteria as well as inclusion criteria. Physiological measures respond to many events, not only the events that are the subject of our research. A cortical negativity just after stimulus onset may meet most criteria for a readiness potential, but still be suspect if it is associated with eye movement, which could elicit an electrical nega-

tivity in the absence of any stimulus, or a particularly high voltage at an occipital (or other sensory) site. Note that these possible exclusion criteria require the investigator to collect additional measures, for instance, an eye movement index and additional scalp sites. Adequate experimental design requires the identification of all factors other than the factor we seek to manipulate that may influence our dependent measure.

The application of this dictum is not always clear. Our scientific question determines what is “artifact” and what are relevant data. In the case of the impulsive children we are examining the lateralized readiness potential to find out whether premature responses occurred more frequently in these children than in controls. However, eye movements might also index impulsivity. An eye movement toward the source of the irrelevant stimulation may reliably precede a (inappropriate) response to that stimulation. The eye movement may even produce a frontal negativity that contributes to negativity at central electrodes. The eye movement in this scenario can be seen as an index of impulsivity, and not as an “artifact.” The eye movement negativity will summate with any readiness potential yielding an “amplification” of the lateralized readiness potential. In this case we may have a very sensitive index of impulsivity, but a contaminated measure of the readiness potential.

Signal processing. Psychophysiological investigations typically use some form of instrumentation to isolate, amplify, and record physiological changes. The typical choice is a combination of electronic amplifiers designed for biological signals and a personal computer with components for analog to digital conversion. This results in a measurement system that flexibly meets a variety of needs.

Physiological signals collected noninvasively result in an electrical signal that is amplified, filtered, and digitized. Amplification poses few problems with current equipment, but frequently students are concerned with the influence of filtering and the rate of sampling. Thorough and elegant treatments of these topics can be found elsewhere (Cook & Miller, 1992; Kamen, 1987; Stearns & David, 1993; Thede, 1996), but here a few very elementary points may be useful. Biological signals should be collected without distorting the features of primary interest to the investigator. Any system used to collect biological signals and digitize them for computer processing will have a sampling rate and filter characteristics. Filtering and sampling can, however, distort the signal of interest to the investigator. Filtering refers to the electronic or analytic selection of the signal of interest as typically defined by a frequency range. Frequency is the number of times per second (i.e., hertz) that a signal cycles around its mean value. In the United States the voltage in a typical house cycles around a mean of zero volts 60 times per second or 60 Hz (50 Hz is the voltage in a typical house in other countries). When delivered to a home the voltages will contain not only variation at 60 Hz, but also very small voltages at other frequencies

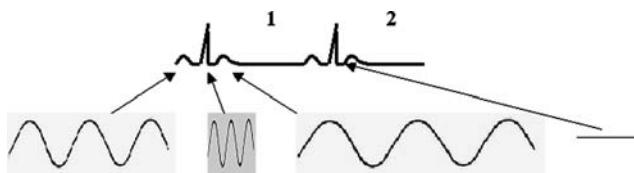

Figure 34.2. Diagram of how different segments of a physiological signal can be conceptualized as portions of a sine-cosine wave of a particular frequency.

(e.g., frequencies used by radio transmitters. An electrical filter could be designed to ‘purify’ the frequency). Typically this filter would taper, the amplitude of variations away from 60 Hz (i.e., reducing the amplitude of frequencies close to 60 Hz more than those at greater distance).

Filtering of biological signals works in the same way, but the change of voltages over time is not as symmetrical or continuous as household voltage, and investigators almost always want to reject or filter out 60 Hz ‘noise.’ Figure 34.2 shows two complexes of an electrocardiogram signal. It varies over time, but it is flat much of the time and then a complex waveform appears. Filter electronics or software views the waveform as if it were a set of simple, continuously varying waveforms. The figure illustrates this by extracting four portions of the electrocardiogram waveform and then imagining that they continued to vary in the same way over time. When this is done, the sharp (r-wave) portion of the electrocardiogram might produce a waveform with a frequency of about 30 Hz, the p-wave that precedes it will yield a waveform with a slower frequency of around 10 Hz, and the t-wave following it at an even slower frequency. The portion of the waveform between the s- and t-wave may be essentially flat (i.e., yield a frequency of less than .001 Hz).

What will happen to this signal when a low-pass filter is applied,¹ that reduces voltages in the signal with frequencies above 25 Hz? The result will be a reduction in amplitude of the r-wave. Given that the r-wave is typically used to determine the time between heartbeats, the investigator may want to shift from a 25 Hz low-pass filter to a 50 Hz low-pass filter. What will happen when a high-pass filter is applied that reduces signals below 1 Hz? The very slow frequencies will be damped, which will likely eliminate any change in the segment between S and T. This will be fine if the investigator is only measuring interbeat interval, but not when trying to see if heart disease has altered the voltage level of the segment of the signal between the s- and t-waves. The prudent investigator should estimate the interesting frequency components in the signal and then ensure that filtering via either the amplifier settings (hardware filtering) or computer programming (software filtering) does not influence the signal components. An empirical way of doing this prior to an experiment is to run an artificial signal through the entire measurement system

from a waveform generator similar to the signal of interest and note whether particular frequencies are attenuated by the system.

An analog to digital converter transforms a continuous signal into a series of numbers corresponding to the voltages sensed at a particular instant. The investigator will likely re-represent the signal as if it were continuous. The converter will make the continuous signal a series of discrete dots of voltage that hopefully will be sufficient to recreate the signal when the investigator “connects the dots.” The sampling rate of an analog to digital converter, under ideal conditions, must be at least twice the frequency of the highest frequency of interest in your signal. In practice sampling at four or more times the highest frequency is advisable. The signal is missed or distorted when the sample rate is too low. This is illustrated in the top of Figure 34.3.

An EEG signal is shown and the result of sampling at two frequencies is illustrated graphically. On the left, the analog to digital converter is shown as sampling at a rate of 100 Hz and, on the right, sampling at a rate of .5 Hz. The data on the left does a reasonable job of recreating the signal, whereas the data on the right loses the waveform. When the dots are connected an apparent signal is formed, which appears to be a slowly decreasing voltage, the original signal has been distorted (i.e., aliased). The bottom of Figure 34.3 shows a complication arising from oversampling. A slow respiratory-like signal is shown with a good signal-to-noise ratio (i.e., the slowly changing component of the signal is visually very clear and does not contain much noise). On the left the signal is sampled at an appropriate low rate (e.g., 5 Hz), and the signal is recreated accurately. On the right, one breath is diagrammed as sampled at a high rate, 1000 Hz, which results in about 300 sample points for a 300 ms interval and incidentally creates large data files. The resulting data is amplified to show that the result of the high sampling rate for the 300 ms segment and reveals a fine structure of peaks and valleys in the signal (i.e., noise from the investigator’s perspective). Computer programs designed for respiratory detection may find cyclic high and low points in the data

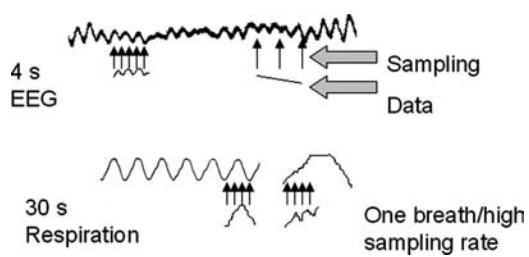

Figure 34.3. Illustration of how sampling rate will alter the obtained signal. The upper portion illustrates how distortion can occur from sampling a relatively high frequency signal with too low a sampling rate. The bottom portion of the figure illustrates how a relatively high frequency sampling rate may emphasize high frequency noise in a signal potentially obscuring the low frequency component of interest.

¹ This wording frequently confuses students: a low-pass filter rejects or filters out frequencies above its cutoff point and passes frequencies below its cutoff point.

for this small segment and call them “respiratory breaths.” It will find about 3 breaths in this noise. This problem can be circumvented by creating “smarter” software and filtering the signal. Sampling at a lower frequency and filtering may be easier on a computer program, and permit it to do an adequate scoring job with less data storage required of the computer. A frequent, practical approach to filtering and sampling is to low-pass filter the signal electronically and sample the signal at five times the frequency of the filter cutoff frequency (Stearns & David, 1993). Further software and digital filtering may also be useful for noise that is close in frequency to the signal of interest.

The choice of gain, sampling rate, and filtering rate should be checked throughout the experiment by visually monitoring the output of the hardware and software collection system. Ideally, this would be done as the data are collected by displaying the signal at one or more points in processing as well as displaying the digitized data as it is stored. A display that shows a relatively “raw” signal and concurrently shows the digitized, processed signal will show how sampling and filtering have altered the signal. Filtering also can cause time delays; so, a comparison of when an event occurs relative to the signal in raw and processing displays is also important. Some software programs will alter the data by excluding points assumed to be invalid. For example, cardiac interbeat intervals shorter than 300 ms or greater than 1750 ms might be coded as missing data. It is useful to know immediately or, at least, after individual participants have completed their session whether such automatic editing has been done for a large or small amount of the data. The investigator should know when and how data are being transformed, and ideally be able to control such transformations (e.g., adjust the high cutoff for interbeat interval duration to 2000 ms for an athlete with average interbeat intervals in the range of 1750 ms). When hardware data displays are not available, software can be written to check on data transformations in a number of ways (e.g., box plots or stem and leaf displays on raw and less raw data) (Tukey, 1977). Also, see statistical issues concerning transformations below. Any time spent is worthwhile if it ensures that data collection is functioning as the investigator planned. Typically, psychophysiological data requires as much or more processing time as collection time. Collecting good data will make the processing time worthwhile and usually considerably shorter.

We undertook a survey of instrumentation available to psychophysiolists to see how available systems meshed with our technical needs. A questionnaire was developed that asked about the characteristics of data collection in hardware and software, analysis software, and customer service. Eleven instrumentation suppliers participated out of the 18 that had been exhibited at the annual meetings of the Society of Psychophysiological Research between 2000 and 2004. Exact comparability is not present because some suppliers emphasized EEG and ERP measures, oth-

ers autonomic measures, or ambulatory data collection or analysis.

Table 34.1 lists features that varied between suppliers and the reason why the user might be interested in this feature. We have chosen to only report on items that showed considerable variation among suppliers. We queried other areas (e.g., gain control and number of data channels available) but do not report the items that were essentially invariant across suppliers. The tables are intended to provide users with a set of items to check on as they decide upon systems. The results are from December 2004 and changes to the systems described are likely to have occurred already. For this reason, we did not specifically table characteristics of specific suppliers or cost comparisons. Both the requirements of the individual psychophysiolist and the specific features of the systems that might fit individual needs are too complex and variable to pick an ideal vendor for all applications. Readers may find useful a recent chapter by Curtin et al. (*in press*) on design of a psychophysiological laboratory system.

DATA COLLECTION AND REDUCTION

Data quality control

Once the design is set the experiment should be run exactly as designed. Nonetheless, the results from the first few participants should be scrutinized carefully to ensure that the assumptions made in designing the study are reasonable (e.g., the investigator should examine whether a ten minute baseline truly permitted a return of blood pressure to the approximate normal values. If data from the design based on the researcher's original assumptions indicate that the assumptions are flawed, then redesigning the experiment at this early point is more efficient than completing research with an inappropriate design.

The other task that continues during data collection is data quality control. Psychophysiological data are characteristically fallible, large in quantity, individualistic in quality, and low in intrinsic interest (in their raw form). Studies of the event-related potential, for example, would typically sample data at 100 Hz and might, in a small study, accumulate 100,000 data points per subject. Although averaged electroencephalographic data presented graphically may hold some fascination, the 100,000 numbers constituting the raw data are likely to be low in intrinsic interest. Editing irrelevant values that result from head and eye movement is necessary to maintain the integrity of the data. The massiveness and low interest value of the data pose a severe challenge to visual data editing. Graphical and statistical techniques combined with human judgment are generally required for appropriate editing. Editing techniques are somewhat specific to different measures and have been discussed by others (Cheung, 1981; Bernston, Quigley, Lang, & Boysen, 1990; Gratton, Coles, & Donchin, 1983). We will provide a brief overview of approaches in order to emphasize the importance of editing for data integrity.

Table 34.1. Features varying among suppliers of psychophysiological data collection and analysis systems

Varying item	Reason for possible concern
Data collection	
Availability of direct current recording	Level of signals, e.g., S-T segment of electrocardiogram, can be important.
Filtering: analog vs digital and pre- vs post-collection	All configurations offered are functional, but you may have a preference.
Sampling rates differ by channel	Can be important if you study signals with varying frequency characteristics.
View data pre- and post-filtering	Checks on what filtering does to your data.
Specific amplifiers required	Primarily an issue if you already own amplifiers.
Direct data output from system available to user	Important if standard data processing by packages is not acceptable.
Ability to add code/routines to software	Important if your needs don't fit the collection/analysis stream of software.
Data scoring	
Amplify post-collection	Accurate visual checking may be facilitated.
Aspects of waveform scored	Slight variations in whether slopes or other features are scored may be important to certain applications.
Artifact rejection/replacement choices	User may prefer flexibility or a particular technique not offered.
Facilitated outlier detection	Graphical/coloring schemes can aid identification.
Intermediate files directly available to user	Further specific processing may be aided.
Limited to specific hardware	Important if you already own amplifiers.
Routines may be added by user	Facilitates specific/novel analyses.
SUPPORT	
On-site support	On-site support at purchase and later can be useful.
Charges for support	Most phone/email/web support free, but a few suppliers charge.
Staff devoted to support	Ratio of support to other staff varied between 11 and 50%. Check with other users to ensure satisfaction.

Note: Participating suppliers were: AD Instruments Pty Ltd., Biopac Systems, Inc., Contac Precision Instruments, Cortech Solutions, LLC, Coulbourn Instruments, EGI, Mindware Technologies, Source Signal Imaging, Thought Technologies, UFI, and Vivo Metrics, Inc. Questionnaire and spreadsheet of responses are available on website www.pghmbc.org under the Biological and Biomedical Measurement Core.

A number of useful books are available to assist in the graphical presentation of raw data. These will assist the investigator in presenting individual data so that outliers can readily be detected. Tukey's classic volume (1977), *Exploratory Data Analysis*, is a useful starting point in that graphical techniques are presented that permit rapid assessment of entire data sets; also see Greenhouse and

Junker (1992). Techniques of particular relevance are box plots and stem and leaf displays, as well as the usual plotting of the frequency distribution of the data. Box plots, for example, typically display the data as a box centered on the median and extending to the first and third quartiles. Extending beyond the box are lines to the minimum and maximum values present in the data set. The

investigator can quickly assess whether the data show the appropriate range of value, central tendency, and balance around the median. Fortunately, many statistical package programs (e.g., Statistica and SPSS) provide programs to efficiently display raw data in box plot and stem and leaf formats.

Once outliers, or unusually distributed data, are detected, what is to be done? Data can be transformed, outliers can be eliminated, or nothing can occur. Levey (1980) provides a thorough, well-written discussion of the various options. Little absolute advice can be offered except that the investigator should first try to understand why a data point is an outlier or why a distribution is distorted. An examination of laboratory notes might lead, for example, to an investigator finding out that a low heart rate outlier was from a child with impulsive behavior who did not meet study inclusion criterion because medications had been administered just before the study. Such data should be deleted, as it is an error that it was collected and analyzed at all. More typically, heart rate values (e.g., 10 beats per minute) or changes (e.g., an 85 beat per minute change between heartbeats) will have occurred that are physiologically impossible. Investigation may reveal computer software "bugs" or data collection errors that might be correctable or require data deletion. Similarly, distributional characteristics can identify factors, such as sampling bias, which initially escaped detection by the investigator. The investigator would then have to judge whether interpretation is possible given the bias. If not, then the data set must be discarded, as transforming data that are systematically biased will not render data interpretable. If no reasons are apparent for the outliers and the sampling or manipulations cannot be faulted, then transformation can be considered.

Transformation is indicated when outliers or the distributional pattern will inappropriately lead to a disproportionate effect on the results because of a small percentage of the observations. Appropriateness and disproportionateness are difficult to define; they remain dependent on the investigators judgment. The disproportionate influence of outliers or clusters of points can be checked by calculating descriptive statistics with and without these points. Distributions can be examined before and after a transformation to ensure that the rescaling produces conceptually reasonable results. For some investigations outliers may be theoretically expected and the most interesting outcome of the study. The weight that is given to these outliers by the original metric may be appropriate. Given the robustness of common statistics to moderate departures from assumed statistical distributions (for a discussion see Levey, 1980), transformation may frequently not be necessary if little disproportionate influence exists. As with many statistical problems, outliers and distributional problems are frequently solved by increasing the sample size.

It is necessary to be cautious when transformations are applied. Transformations necessarily make it more diffi-

cult to understand how the original measures responded to manipulations or individual differences. This problem is particularly acute when data are scaled on an individual-by-individual basis, for example, for range scores in which a skin conductance response is scored as a proportion of the individual's range of responses (Lykken, 1972). A reader interested in the size of skin conductance change in microsiemens will likely be unable to find out this number unless the investigators have taken care to provide this information.

Transformations can change the mean results more than many investigators would expect. Levey (1980), as well as Cacioppo, Tassinary, and Fridlund (1990), have provided numerical examples in which a usual transformation changes the mean difference from favoring one condition to favoring another condition. A brief excursion into sympathetic and vagal effects on the heart can illustrate the influence of the metric. Assume that interbeat interval increases 60 ms (because of a fixed vagal activation) from a baseline during which the heart beats once every 1000 ms as well as 60 ms from a baseline during which the heart beats every 500 ms (with the same vagal stimulation and with the baseline altered because of sympathetic stimulation). There is no interaction; the vagal change is identical despite a difference in sympathetic level. Transforming to the reciprocal measure, heart rate, there is a change from 60 bpm to 56.6 bpm and a change from a 120 bpm baseline to 107.1 bpm. A 3.4 bpm change compared to a 12.9 bpm change is consistent with accentuated antagonism between vagal and sympathetic systems. Statistically, an interaction is present: heart rate changes more from a higher level of sympathetic background than from a lower level. Note, however, that no interaction or "accentuated antagonism" exists if we use interbeat interval scaling.

Which transformation is correct? Berntson and colleagues (Quigley & Berntson, 1990; Berntson, Cacioppo, Quigley, & Fabro, 1994; Berntson, Uchino, & Cacioppo, 1994) have used the interbeat interval metric as well as developed and provided supporting data for model in which no accentuated antagonism exists. Levey and colleagues (Levey, 1977; Levey & Martin, 1984) used heart rate and animal stimulation data, and developed a detailed physiological model that predicts accentuated antagonism. The metric is intertwined with the theoretical views of these investigators. The correct metric may be revealed once one completely understands the detailed mechanisms of how vagal and sympathetic stimulation combine to alter heart rate (or interbeat interval).

We have already advocated the limited use of a transformation (moving to nonparametric statistics to check parametric results) when the scale properties of the measures are unknown or suspect. Nonparametric statistics convert the original scale to either rank orders or categories. The rescaling of the data to ordinal or nominal categories does provide the investigator some insight into whether the original scale may give disproportionate weight to

certain observations. Significant discrepancies between parametric and nonparametric tests are a signal to the investigator to look closely at the scaling and distribution of the data. Another rescaling is frequently done but rarely discussed: a continuous measure, for example, weight, is converted to an analysis of variance factor by splitting values at the mean or median. Scale values have been converted to a nominal scale (e.g., greater weight and lesser weight). The potential loss of information relative to using a statistically equivalent testing procedure (e.g., regression analysis) has been argued elsewhere thoroughly (Cohen & Cohen, 1975; Levey, 1980).

Bush, Hess, and Wolford (1993) have provided an interesting simulation study that addresses the influence of certain transformations as well as outliers on the power of statistical outcomes. These investigators specifically examined within-subject transformations using randomly generated normal and skewed distributions. Varying sample sizes were drawn per subject (i.e., samples within a condition) as well as varying the number of participants and effect sizes. One thousand or more "experiments" were carried out for each set of parameters tested. All experiments involved a single baseline condition and a single treatment condition with the baseline-to-treatment manipulation done within each subject. Transformations examined were the arithmetic mean of a subject's data within condition (i.e., averaged over observations within that condition for that subject), log of that mean, a Z score based on the mean and standard deviations for all observations of that particular subject, a range-corrected score, and a ratio score, which expresses score as a fraction of the highest score of that subject. The Z score measure performed the best overall across variations in sample size, number of observations per subject, skewness, and percentage of data with outliers.

The Z score continued to do well relative to using medians as well as the other scores across different methods of eliminating outliers. The combination of Z scores and trimming (i.e., eliminating an equal percentage of extreme scores from all participants) performed the best when outliers were added to the simulation data. Performed "best" was defined by the ability to detect the real difference in conditions that had been added by the experimenters. Very few instances were found in which transformation yielded anomalous results (e.g., baselines higher than treatment that differed from the original data). Overall this simulation study suggests that transformations are useful when subjects vary in the degree of variability across observations.

REPRESENTATION OF RESULTS

The results of the research must be presented such that their meaning is evident not only to investigators, but one's peers, students, and, ideally, the general public. A number of books on scientific graphics are available. Most of these are rightfully critical of the modal scientific illus-

tration. Cleveland (1985), for example, found that 30% of the graphs presented in *Science* in 1980 had significant problems: features that were not explained, data points or lines that could not be discriminated, errors in construction, or reproduction so poor that the graph was illegible. Even in the absence of such significant problems it is common for graphs to obscure rather than highlight the primary feature of the results, have gridlines that overpower the results, axis numbers or legends that obscure data points, or to be excessively complex. The history of graphical presentation is used to derive principles for good graphing in the richly illustrated contributions of Tufte (1983, 1990, 1997). A number of excellent guides focusing more closely on the illustration of typical scientific data are also available (Cleveland, 1985; Wainer & Thissen, 1981, 1993). We found the Cleveland volume to be a particularly useful "hands-on" guide for graphical representation. His volume, like a number of others, provides ample illustrations of poor graphic representation with the correction of the identified faults. A recent book by Jacoby (1997) offers a pocketbook-sized condensation of graphic advice. Specific information on the plotting and analysis of residuals in regression illustrates the importance of graphing techniques for analyzing as opposed to representing results (Cook & Weisberg, 1994).

Graphical presentation of statistical results raises a specific issue. Medical and biological journals frequently ask that error bars be included in graphs so that the statistical differences between groups or conditions can be visualized. Typically, standard deviation or standard error of the mean provides the error bar for each group or condition plotted. One issue with such plots is that parametric analyses typically estimate error from the entire experiment rather than for individual groups or conditions. Furthermore, the presentation of standard deviation or standard errors for a condition varied within subject presents an estimate that is computed across participants when the analysis examined the condition effect within subject. Presentation of confidence intervals based on the statistical error term used to test an effect is an alternative. Loftus and Masson (1994) suggest this and provide a guideline for using appropriate error bars in graphs portraying within subject effects.

ANALYZING DATA

The methods that a psychophysiological uses to analyze data should be those that are best suited to the research design and the characteristics of the dependent measures. For better or worse, however, the most common method of data analysis in psychophysiology is some form of analysis of variance. To illustrate this point, we reviewed every journal article published in *Psychophysiology* from 2000 to 2004, excluding review articles and computer simulation studies. By reading the Methods and Results sections of each article, we categorized the primary data analysis method of the article under one of the headings as listed

Table 34.2. Percentage of articles in Psychophysiology that used different methods of data analysis

Analysis method	Year				
	2000	2001	2002	2003	2004
Analysis of variance or covariance	71.1	76.7	72.1	75.8	84.4
T-tests	17.1	19.8	23.3	22.0	31.3
Multiple regression/correlation	15.8	27.9	25.6	19.8	27.1
Multivariate analysis of variance	26.3	26.7	22.1	9.9	13.5
Nonparametric analysis	6.6	9.3	5.8	7.7	8.3
Factor analysis, Principle components analyses, Multidimensional scaling, Path analysis, or Structural equation modeling	3.9	4.7	7.0	4.4	3.1

Note: Other methods of data analysis (e.g., add-mixture analyses, statistical parametric mapping of functional neuroimaging data, signal detection methods, and partial least squares tests) were not included in the above percentages because they comprised less than 1% of the approaches used in Psychophysiology from 2000–2004. The percentages for each year do not sum to 100% because the same study may have used more than one method of data analysis.

in Table 34.2. We then tallied the total number of journal articles using data analysis method in a given year, and divided this number by the total number of articles appearing in *Psychophysiology* that year. As shown, psychophysicists, like other behavioral scientists, continue to use analysis of variance as the dominant method of data analysis – most likely at the expense of not using other methods of analysis that may prove more appropriate to the research designs and types of data that are most common to psychophysiology. As researchers, rather than statisticians, we will review the analysis of variance approach in addition to other approaches to data analysis.

Sequential time samples are statistically dependent

Most psychophysiological data take the form of sequential observations in time from the same subject. The methods that are used to analyze such repeated observations must take the correlation between observations into account. We have already discussed the enhanced power of repeated-measures designs for psychophysiological data and their inherent concerns. A remaining issue is the degree to which available methods of data analysis for such designs provide valid statistical inferences. Unfortunately, the characteristics that make repeated measures desirable are precisely those that make analyzing such data a challenge. Namely, most psychophysiological measures do not typically meet the requirements of a standard repeated-measures analysis: Correlations occurring between the successive measurements of each subject reduce error variance, but violate assumptions of unre-

lated errors and homogeneity of the variance/covariance matrix (Huynh & Feldt, 1970; Jennings & Wood, 1976; Keselman, Rogan, Mendoza, & Breen, 1980).

The repeated-measures ANOVA assumes that differences between the correlations of any set of pairs of the within-subject treatment are due to chance and there is an underlying constant correlation (Lavori, 1990). Violation of this assumption leads to using a critical test statistic that is too small or to Type I error inflation (Box, 1954). A conservative correction for the violation was developed by Greenhouse and Geisser (1959) and a more liberal one by Huynh and Feldt (1976). These adjusted (reduced) degrees of freedom work well as long as the design employs equal group sizes (Greenhouse & Geisser, 1959; Keselman & Keselman, 1990; Keselman, Keselman, & Lix, 1995). Both of these procedures are available in most statistical software packages (e.g., Statistica, BMDP, SAS, SPSS).

Multivariate tests do not carry the assumption of equivalent correlations among measures, and thus they do not require the epsilon correction factor. They do, however, carry assumptions of normality and independence of observations across subjects. Furthermore, certain situations do not favor multivariate analyses. For example, multivariate analyses can be less robust than corrected univariate analyses for unbalanced designs (Keselman et al., 1995). And, if the number of variables exceeds the number of subjects, or the study is designed with a small sample size, then the repeated-measures univariate approach with the corrected degrees of freedom may be the more appropriate choice. However, with designs that incorporate large sample sizes, a multivariate analysis is more sensitive than the univariate test (Algina & Keselman, 1997; Davidson, 1995). Because repeated-measures observations are

correlated, they can essentially be viewed as a multivariate design (Cole and Grizzle, 1966). The MANOVA estimates all possible correlations of pairs of the within-subject treatment, does not assume they are equal, and, therefore, allows the influence of the covariation of the pairs to act on the analysis rather than calling it unexplained variability and increasing the error term. The MANOVA test of differences does not say how the multiple dependent measures may differ, just that they differ. Additional close examination of planned contrasts is still required (Lavori, 1990). As Russell (1990) notes, these subsequent contrasts are not completely protected from inflated experiment-wise error.

Other test statistics for repeated-measures designs are available in addition to the two salient choices: univariate or multivariate analyses. The Welch-James test for completely randomized designs (James, 1951, 1954; Welch, 1947, 1951) has been extended to work with unbalanced multivariate designs by Keselman, Carriere, and Lix (1993). This statistic employs nonpooled variance techniques and corrected degrees of freedom. Lix and Keselman (1995) also provide an easy to use SAS (Cary, 1989, 1996) and IML program. We recommended that this be the statistic of choice when there is an unbalanced design and unequal group covariances. This procedure does require a relatively large sample size: three to four times the number of within treatments minus one for main effects, and five or six times the number of within treatments minus one for interaction effects (Keselman, Kowalchuk, Algina, Lix, & Wilcox, 2000).

Analysis of covariance

An analysis of covariance is applied in psychophysiology for many reasons. A common reason is to control for factors that are not central to an experiment, but that might modify the results. For example, a characteristic of the individual, such as trait anxiety, may not be of primary interest, but may influence a psychophysiological variable. In a separate section below we discuss the use of analysis of covariance as a means to "correct for" baseline effects. To treat covariates accurately, the psychophysiologist must ask whether each subject has a single covariate value or multiple values and whether the covariate terms will be pooled across groups. If the analysis of covariance is being applied to "correct for" differences between groups, it most likely is inappropriate as clearly explained by Miller and Chapman (2001). In addition, most covariate approaches assume homogeneity among covariate relationships across treatments. In other words, across treatments all extraneous variables covary in the same way and to the same degree with the dependent variable.

Two examples that differ in their analytic approach illustrate the covariate assumptions that are unique to these approaches. In the first, a single covariate is used for each subject. In psychophysiology, this would correspond to the common design in which values from a single baseline period are used as a covariate in the assessment of values

obtained from one or more tasks, for example, mental arithmetic. The covariate in this situation is a between-subjects variable. In the second situation, the covariate is measured multiple times within each subject. For example, a brief baseline period might be used prior to each of a number of tasks. The value for each of these baselines could be paired (as a covariate) with the value from the task immediately following the baseline. The covariate in this situation is a within-subject variable. In the first case, a between subject covariate results in three computational alternatives that yield comparable power, but that vary in the assumptions about error variance. The simplest approach may be to use a regression approach, which can be implemented readily in SAS (Khattree & Naik, 1995). In the second situation different approaches yield markedly different results. No simple analytic approach can be offered, but Judd, McClelland, and Smith (1996) provide guidance for analyzing such designs.

Regression alternatives to ANOVAs for repeated measures

Analysis of variance can be considered as a special case of regression analysis by using dummy variables to express the factor levels. Cohen and Cohen (1975) have developed this approach, and it is used frequently in the general linear model programs. The regression approach provides considerable flexibility that ideally would help model the data with the desired statistical approach. At a basic level, serial measurements (e.g., a repeated-measures time series) can be analyzed as a univariate regression analysis of responses with correlated errors (Ware, 1985). This is discussed further below. At the other end of the spectrum are autoregressive approaches, such as ARIMA, which essentially fit periodic components to the data (Box & Jenkins, 1970). The strength of the regression approach can also be considered as disadvantageous. A regression model that closely fits a particular set of sample data may be fitting the variance specific to the quirks of that sample. Thus, the population parameters could be estimated inaccurately. This concern makes independent replication of regression models particularly important.

Regression analyses can be a useful tool for psychophysiological studies as they allow for specific modeling of the inherent correlations of a repeated-measures design. It provides an intra-individual look at data, as well as an inter-individual perspective, that is provided by repeated-measures ANOVA. Conducting these analyses using several different regression analysis strategies leads to the construction of a more accurate picture of the data. These strategies include individual regression analysis, hierarchical and stepwise regression techniques, and random regression analysis. Appropriately applied, regression techniques can resolve problems that result from missing data or unbalanced designs, serial correlations, and time-varying covariates (Gibbons et al., 1993; Petrinovich & Widaman, 1984).

A primary concern with regression analysis techniques is the problem of collinearity. If alternative predictors of the dependent variable are highly correlated, then the one chosen by the analysis as the primary predictor will be dependent on the particular sample in use. In other words, it is governed by the quirks of the samples. Particularly in this situation, the investigator must guard against a literal acceptance of a statistical outcome, believing, for instance, that depression predicts school grades, but that anxiety does not because of the initial selection of depression by the analysis. For a more complete description of benefits and cautions of these techniques see Cohen and Cohen (1983) and Hays (1994).

We will briefly discuss two forms of regression analysis that may prove most applicable to psychophysiology: individual regression analysis and random effects analysis. Individual regression analysis, also known as growth curve analysis, is a statistical technique that detects a pattern of change in a variable across time within a particular treatment or condition (Sidani & Lynn, 1993). The temporal pattern detected by regression analysis provides a qualitative look at relationships that would otherwise be represented as difference scores at different time points by a repeated-measures ANOVA. An individual unit of analysis can be a single subject, group, or condition. The linear model, employed in the regression technique, assumes that a subject's score on one measure is a function of the score on another level, and subsequently results in a trend line for each individual, unlike a repeated-measures ANOVA that assumes one common intercept of a trend line for the within-subject variable at each time point (Gibbons et al., 1993). When an individual regression approach is applied to a repeated-measures design, the variable of interest is regressed on the time variable. The functional relationship is depicted in the form of a regression line and the slope of this line provides the magnitude and the direction of change over time. A t-test of the slope compared to a slope of zero tests the difference. This method is useful for describing and evaluating individual differences. Furthermore, comparisons between groups can be examined by finding the regression line for each individual in the sample and testing for group differences with a t-test or an ANOVA of the intercept or slope. A significant difference between groups on the intercept indicates a baseline difference, and a significant difference between groups in slope indicates different patterns of change among the groups. Gianaros and colleagues (Gianaros et al., 2003) illustrate an application of this analysis. Gianaros et al. fit linear regression models to each individual's minute-by-minute level of respiratory sinus arrhythmia while they were exposed to a rotating optokinetic drum, a stimulus that provokes nausea. The authors found that those individuals who showed greater decreases in respiratory sinus arrhythmia over time, as defined by more negative respiratory sinus arrhythmia-by-time slopes, also reported more severe nausea. We encourage other investigators to use such individual-level approaches to quantify their psy-

chophysiological data because the approaches offer opportunities to assess experimental effects at the individual and group levels of analysis.

There are also some advantages of using an individual regression analysis over a repeated-measures analysis of variance. First, individual regression analyses clearly delineate patterns of change across time in terms of magnitude and direction, and they allow for the examination of individual change while still permitting group analysis. In addition, required assumptions are kept to a minimum. Missing data are not as crucial to the identification of the pattern and, when a nonlinear relationship is suspected, polynomial or logistic functions can be added to the regression equation to allow an accurate description. There are two practical limitations to consider before adopting individual regression analysis, however. If the variable under study, such as EEG frequency, reacts differently over time, (e.g., in different sleep stages regression will not be valid because the differences cannot be depicted in a single line. Also, values that change drastically and in different directions require a technique other than linear regression. For a more detailed description of individual regression analysis see Rogosa, Brandt, and Zimowski (1982).

Random regression models (Gibbons, Hedeker, Waterman, & Davis, 1988), also known as random effects models (Laird & Ware, 1982; Ware, 1985), or hierarchical general linear models (Bryk & Raudenbush, 1987), provide an estimation of random person-specific effects similar to individual regression analysis. Random regression analysis goes a step beyond individual regression analysis by incorporating information about the population trend across time and providing an estimate of within-subject time trends given the individual's data (Gibbons et al., 1993). In other words, information about other subjects with similar characteristics provides support or reinforcement for a better estimate of an individual's trend. Similarly, missing data estimation in random regression models is derived from the trends of all other like-individuals in the study. These missing data points are not simply interpolated data. They are produced by the model and are consistent with the observed data of the subject, but they also differentiate between treatments to the same extent as do individuals with complete data. In addition, measurement at the same time points or for the same number of times is not required of each subject (Gibbons et al., 1993). Examples of random regression-produced estimates of missing data are depicted in Gibbons et al. (1993). A more detailed discussion of this handling is available in Ware (1985).

In random regression modeling, person-specific estimations are achieved through the use of empirical Bayesian procedures (Casella, 1985). These procedures use a weighted average based on the individual data and data from the entire sample. A subject with the most data receives a weight that is mostly influenced by the individual data. Weights of subjects with less information are more influenced by the group mean. In addition, the variance around a single person's trend is available, resulting in an

estimation of the population variance-covariance matrix of person-specific effects. This is not possible with other repeated-measures analyses (Bryk & Raudenbush, 1987; Gibbons et al., 1993).

Covariates also receive distinctive treatment within a random regression model. While in repeated-measures models time-varying covariates can be a problem (as opposed to time-invariant variables that are adequately handled with a repeated-measures approach), they are easily included in a random regression model. The covariance relationships assessed by this model include (a) the overall relationship between the variable of interest and the covariate across time, (b) how this relationship changes over time, and (c) how within-subject change of interest is related to the within-subject change of the covariate (Gibbons et al., 1993).

Related to the issue of covariance is the treatment of unexplained nonrandom errors. Some examples of non-random errors, such as autocorrelated errors, are allowed in the random regression model; in particular, first-order nonstationary autoregressive errors (Chi & Reinsel, 1989). As this is the process in which a subject's response at one time point is influenced by the immediately preceding response, it is especially important for psychophysiological data. Repeated-measures analyses typically employed by psychophysiologists are biased when this is the situation.

Several weaknesses of the random regression modeling technique are evident. The theory from which random regression is derived requires large sample size. This creates an area of caution for psychophysiologists. In addition, a linear trend is assumed, which may not always be the case. Assumption of a linear trend also influences the estimation of missing data points used in the analysis because missing data would not occur in a linear fashion. Also, as in most other statistics, a normal distribution, to some extent, is expected. Lastly, these models are not appropriate for dichotomous variables, including transformed dummy variables (Stiratelli, Laird, & Ware, 1984).

As with any decision researchers must make, the influence of positive and negative factors are present. To decide which is the preferable analysis, a regression approach or an analysis of variance approach, ask two questions: 1. What aspect of change is of interest? (That is, do you want to know if there is change or how big a change there is or what does the change look like and what is the rate of change?) and 2. What is the unit of change that will be analyzed? (Or is it important to look at individual differences?). For general guides that include understanding and selecting regression as the analysis of choice please refer to Schroeder, Sjoquist, and Stephan (1986) and Hays (1994).

Other time series approaches

Spectral analyses of time-series data have been introduced to psychophysiology largely through their application to

the analysis of heart rate variability by Porges and others (see Porges & Bohrer, 1990). The rhythmic, usually sine-cosine, functions present in a sequence of second by second heart rate values are identified using frequency (Fourier) or period (ARIMA) analyses. For example, if a sample of five minutes of heart rate per second values is examined, then rhythmic fluctuations might be identified at the frequency of respiration (about .2 Hz), which is around a frequency related to vascular fluctuations (about .1 Hz) as well as less well-defined lower frequency fluctuations (See Porges & Bohrer, 1990; Jennings & McKnight, 1994). Porges (1995) has related the power (variance at these frequencies) of these components to normal and abnormal early development; while later in life the power in these components is related to vulnerability to heart attack (see review; van Ravenswaaij-Arts et al., 1993).

Interpreting interactions

The interpretation and testing of interaction effects often puzzles students. Psychophysiologists cannot afford to be confounded by interactions because their primary interest is often in the interaction term of an analysis of variance. Typically, responses are represented within an analysis of variance by a Time factor with levels corresponding to the time series representing the response, which is often a mean value for a baseline and one for a response level. We expect this Time factor to be statistically significant. That is, we expect a response level to differ from a base level. Here, our primary interest is in the interaction of this Time factor with another factor in the experiment, such as impulsivity group or item content.

Although there are multiple ways to depict interactions, typically interactions are interpreted as cell means reflecting a difference between the differences, which is a simple effects test (Keppel, 1991). Figure 34.4 illustrates the difference-between-differences interpretation and contrasts the residual interpretation, which is discussed next.

With difference-between-difference approaches, Note that different means occur for a particular factor when utilizing difference-between-difference approaches, but this difference depends on the concurrent level of an additional factor. When interactions are examined with this approach, a meaningful interaction requires qualifying the meaning of the main effects (Kirk, 1995). For example, EMG onset could be earlier for affectively charged items than neutral items, but only among the impulsive group of the earlier example. This difference-between-differences approach would suggest that the Item Content-by-Impulsivity grouping interaction could be interpreted as EMG onset times being dependent on the affective content of an item, but only for children who are impulsive. Simple effects of task could then be analyzed. That is, investigators could statistically compare affect and neutral items only for children with impulsive behavior and

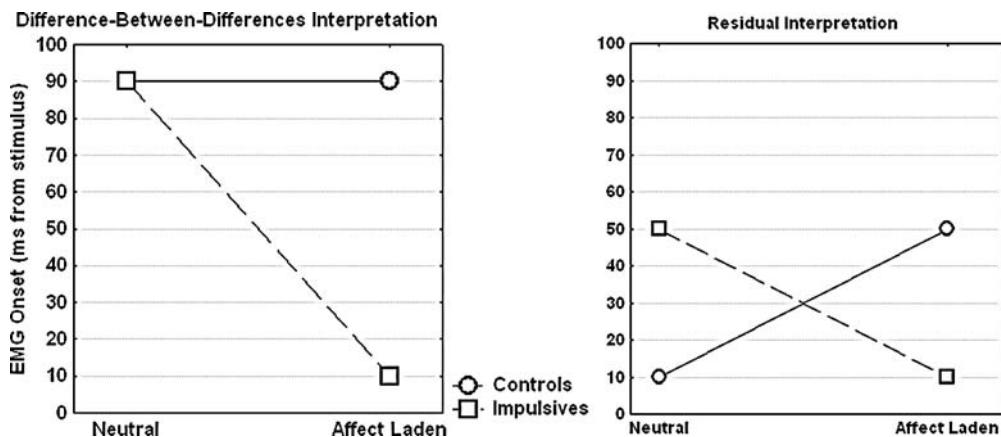

Figure 34.4. Contrast between difference between differences and residual interpretation of an interaction term. Mean results are shown either with the mean of the individual main effects removed (residual) or without this adjustment (difference between differences).

separately from children in the control group (Meyers, 1991).

An alternative approach to interpreting interactions emphasizes removing main effects so that the residuals representing the interaction can be directly examined (Rosnow & Rosenthal, 1989a, 1989b, 1991, 1995). This approach is supported by the fact that a cell mean representing an interaction also contains the influence of all lower level factors (i.e., potential main effects) (Rosenthal & Rosnow, 1991; Zuckerman, Hodgins, Zuckerman, & Rosenthal, 1993). Therefore, interpretation of the cell mean also reflects main effects. To continue with the above example, a residual representation of the Item Content \times Impulsivity interaction for EMG onset could be interpreted as showing that children in the impulsive and control groups react in an exactly opposite directions for affectively laden and neutral items.

Both of these approaches, difference-between-differences and residual, result in the same interaction variance (Keppel, 1991; Rosnow & Rosenthal, 1989b), but they lead to different and, sometimes, conflicting conclusions (Petty, Fabrigar, Wegener, & Priester, 1996). The difference-between-differences approach interprets children with impulsive behavior have a different EMG onset, which is dependent on the content of the stimuli, and the residual approach interprets the children in the control group and children in the impulsive group have completely opposite reactions to the content of the stimuli in terms of EMG onset. By subtracting the main effects from the means forming the interaction, the residual approach can be compared to the difference-between-difference approach to see if one of the interpretations fits better with the conceptual issue addressed by the research.

Planned contrasts and multiple regression:

Analyzing the interaction

Up to this point only the interpretation of an interaction has been discussed. Another issue is the consideration for the best statistical test. Alternatives to interaction

terms from standard analysis of variance packages exist. Contrasts are comparisons of two or more cell means, and seem to be an appropriate choice. When constructing contrasts, cell means are orthogonally weighted to correspond to the hypothesized order of their effect. This allows a focused examination of the data (Rosenthal & Rosnow, 1985; Abelson & Prentice, 1997), which is more focused than an interaction term from a standard omnibus F test. For example, the investigator could predict that the children in the impulsive group would only respond prior to a stimulus for which there is an affective item content. The investigators would then have more and less children with impulsive behavior performing under high and neutral affective content conditions with proportion of early responses as the dependent measure. A contrast could be constructed and tested by assigning equal weights to less and more impulsive children in the neutral affect condition: for example, -2, -2, and weights of 1, 3, to the children with less or more impulsive behavior in the high affect condition. The weights would directly test the hypothesis rather than depend upon the standard weighting that is assigned for an interaction in an omnibus F test. Indeed, the interaction term could be significant even if the groups differed under neutral affect conditions, but not high affect – an outcome directly opposed to the hypothesis.

Note that in the contrast test of the “interaction,” the variance of the main effect was combined with the interaction variance, while the standard ANOVA F statistic would use only the interaction variance. Therefore, different results could be obtained. A match between the hypothesis and the statistic is required for appropriate testing. If an interaction is expected, a contrast may not be appropriate because the statistic will include the variance of the main effect. If there is an expectation that both a main effect and an interaction effect will be present in the data, then a contrast reflecting this is appropriate because it can incorporate the variance of each. However, if only the main effect contributes a meaningful variance, it will not

be identified with the contrast because an interaction did not occur.

A multiple regression approach can also be used to implement the testing of specific patterns of interaction. First, nonorthogonal contrasts can simultaneously be tested (with the orthogonal contrast) via a multiple regression analysis. Second, several orthogonal contrasts could be specified and simultaneously entered into a regression analysis to determine the partial variance that the alternative contrasts account for (Aiken & West, 1991; Rosenthal & Rosnow, 1991).²

Explaining interactions with an ANOVA model is appropriate when the variables under study are discrete or if the expected relationship between the independent and dependent variable appears as stepped (Kenny, 1979), but even these instances (e.g., impulsivity groupings above) can be handled with multiple regression techniques (Aiken & West, 1991; Cohen and Cohen, 1975). Multiple regression interactions are critical when predictor variables are continuous. An interaction, as described by a multiple regression equation, states that variable Y regressed on X will have a particular slope for each individual value of Z. This provides a regression line for every point of Z. Each member of this family of regression lines is a simple regression line and the effect of X on Y is a conditional effect (Darlington, 1990).

To examine the interaction once it has been identified as such, then plotting the interaction and conducting post-hoc tests are the appropriate steps. Aiken and West (1991) thoroughly discuss ways to interpret multiple regression interactions. An example of this approach to analyzing and presenting interactions within the context of a regression analysis is available in the Study 4 analysis in Graziano, Smith, Tassinary, Sun, and Pilkington (1996).

Debatable statistical issues in psychophysiology

The principle of initial values. Baseline activity in a given physiological function (e.g., heart rate) could be related to the degree, and sometimes direction, of change in that function in response to experimental manipulations. More precisely, higher baseline levels of a given function (e.g., of heart rate) might result in a limited increase in that function and lower baseline levels might result in a limited decrease in that function. A response system might well be built so that it will respond less when it is operating at a higher output level than at a lower output level. If this were true, then the investigators should certainly take baseline level of function into account when measuring change from that level. This is the so-called "law of initial

values" (Wilder, 1958). However, it is probably more appropriately termed the "principle of initial values" (Stern, Ray, & Quigley, 2001). Does such a principle exist? When a baseline level or change correlation does appear, what should be done? Levey (1980) suggests that baseline level dependency and data transformation are two issues akin to a bit of sand inside the shell of psychophysiology. At the time of his writing, a lustrous pearl should have formed or the irritation should have killed the area, but he notes that neither has occurred. Rather these issues, along with arousal and inverted U functions, seem to haunt the field: psychophysiologists do not believe in ghosts, but cannot stop thinking about them.

Myrtek and Foerster (1986) analyzed widely used correlation techniques to see if change was related to baseline level. They pointed out that the calculations were biased toward finding the negative correlation expected by the law of initial values. They proposed a test to eliminate this bias and found that baseline to change, if it showed anything, it showed a positive not a negative correlation. Greenen and van de Vijver (1993) arrived at the same conclusion, but provided a simpler test statistic that was largely equivalent to the Myrtek and Foerster (1986) statistic. Conceptually, the baseline to change relationship can be accurately assessed as negative (e.g., the law of initial values) if baseline variance is substantially larger than response level variance. Myrtek and Foerster found it more likely that a positive relationship is present if baseline variance is smaller than response level variance. Interestingly, Bush, Hess, and Wolford (1993) tested the sensitivity of baseline-adjusted scores in the simulation study previously discussed. The Z-score difference scores performed well when baselines changed over time within a subject's data. This Z-score difference performed slightly better than the range score, which was designed to address law of initial values issues. However, covariance adjusted scores were not tested. The primary point, however, is that statistical reasons, as well as empirical reasons, exist to discard the law of initial values.

We summarize our review by suggesting that investigators interested in psychophysiological responses carefully assess how response values might be conceptually and empirically related to basal values for their measures. A statistical or conceptual model of the relation of change and basal state should provide the best response measurement (cf. Stemmler & Fahrenberg, 1989). The conceptual assessment should consider the original design decision on choice of baseline and the degree of baseline stability present in the results. Jennings, Kamarck, Stewart, Eddy, and Johnson (1992) review the importance of baselines and suggest procedures for designing and assessing baselines. As a statistical part of this assessment the presence of an association between baseline and response could be assessed following the Greenen and van de Vijver (1993) technique. If a significant relationship does not exist, no correction should be done. If a relationship exists, then another attempt should be made to conceptualize

² Contrasts are especially useful when a relationship between more than two factors or levels has to be explained, for example, in a main effect composed of 4 levels. In addition, they are useful in providing further ways to discuss a linear contrast when the residuals are not significant. Significant residuals would imply the linear explanation was not an adequate one. Further contrasts can be performed on the residuals to identify quadratic trends (Abelson, 1995; Abelson & Prentice, 1997).

the relationship. Lacking this conceptualization, covariance adjustments for baseline influences could be done, analyzed, and compared to either raw or transformed difference scores. Reporting only the noncorrected results is preferable, if there are not differences in outcome between corrected and noncorrected. Presentation of both analyses may be wise if corrected and noncorrected measures yield different results (see similar guidelines in Stemmler & Fahrenberg, 1989). Llabre and colleagues (1991) provide a nice overview of the statistical issues involved in using difference scores versus covariance corrected scores, which provides further depth on the issues we have just discussed and extends them to the reliability and ability to generalize results.

The null hypothesis debate. Most journals publishing psychophysiological work will review statistical results to see if they are "significant." The analysis of variance approach as well as the testing of regression coefficients implies the use of the null hypothesis to test hypotheses using a fixed probability (e.g., $p < .05$) to reject the hypothesis. This approach has been criticized widely for its arbitrariness, blindness to the size of the effect assessed, and failure to estimate the likelihood of an empirical claim (Chow, 1996; Kline, 2004; Cohen, 1977, 1994; Harris, 1991; Loftus, 1994; Loftus & Masson, 1994; Rozeboom, 1960; and a special section in *Psychological Science*, 1997 vol. 8 (1)). Alternative approaches to statistical testing have not, however, supplanted null hypothesis testing. Frick (1996) and Greenwald, Gonzalez, Harris, and Guthrie (1996) have argued that the continued popularity of null hypothesis testing is due to the appropriate fit between much of our research and the answers provided by this statistical approach. In practice, null hypothesis testing has proved rather robust in the face of critiques. The critics of the null hypothesis also have sound advice, however, which we also recommend following (Rosenthal, Rosnow, & Rubin, 2000). Cohen (1994) advises, for example, close attention to measurement, careful understanding of data using graphical techniques, attention to effect sizes, reporting of confidence intervals, use of replication of experiments, and employment of meta-analytic techniques when possible. As the critics point out, null hypothesis testing cannot establish the validity of hypotheses, null or alternative. Null hypothesis testing only estimates the chance that your findings would have occurred, given that the null hypothesis is true. In reality the conclusions must be based on thoughtful interpretation in the context of the empirical literature, available concepts, reliability within and across experiments, and available statistical indicants (see Abelson, 1995).

CLOSING COMMENT

We have attempted to highlight methodological concerns relevant at different stages of a psychophysiological research project. Psychophysiology has a traditional

and continuing interest in methodology, most immediately in the technology of noninvasively acquiring physiological signals, but also in the general methodology of performing research and drawing appropriate inferences from the research. We have detected no signs of declining interest or flagging of expertise in methodology and statistics. Psychophysiologists remain methodologically sophisticated. Nonetheless, we share methodological problems with other areas of psychology, for example, a relatively blind reliance on null hypothesis testing and a rapidly expanding number of statistically significant results that fail to coalesce into conceptual advances.

The major obstacles to the use of appropriate scientific methodology may be societal rather than intellectual. An initial stage in working with a conceptual problem is exploring different measures, trying out manipulations, and generally spending time to explore methods that both follow from the conceptual question and have good measurement properties. Good hypothesis generation should precede the hypothesis testing around which much of the science is structured. A number of factors have led to a virtual disappearance of exploratory laboratory time: (a) competition among peers for positions and promotions based on research productivity, which is often defined numerically; (b) research grants awarded on a similar basis and evaluated in terms of power to confirm existing hypotheses; (c) bureaucratization of human use procedures making it impractical to vary any aspect of a research project; and (d) greater rewards for producing research articles rather than reading them. In general, the current system seems designed to produce data and reports rather than concepts and explanations. In addition to instilling greater idealism in peers and editors, a solution may be to incorporate exploratory measures and manipulations into larger hypothesis testing research. This procedure, called "leap-frogging" by some, permits the authors to get necessary exploration done while continuing to comply with current societal requirements. In the long run, exploratory results should provide the basis of solid hypothesis testing research.

Having recognized the pressures against good methodology, we would nonetheless urge psychophysiologists to use the best methods. In particular, we would urge greater time spent on the conceptualization, initial design, and piloting of projects. Care must be taken to ensure that response definitions, measures, and planned statistical analyses follow directly from the concept of the research. The almost universal dependence of psychophysiological research on within subject designs implies that we should be particularly wary of carry over effects, which are defined as the influence of one assessment upon other assessments. Designs should counter and check such effects. Once a design is established, care should be taken to use adequate sample sizes. Our success in conceptually replicating our work has not been borne out of the hope that principles can be uncovered with sample sizes of single digits per cell. Pilot work may help investigators decide whether

they need double or triple digits per cell of their designs. Results should be examined graphically and numerically until the investigator understands the characteristics of the data and how the statistical analyses are expressing those characteristics. Ideally, a graphical presentation and corresponding analysis would be found that would convey the same understanding to a reader. Such a presentation should convey the amplitude and conceptual importance of a finding as well as its statistical significance. The process of analyzing the data may reveal that a "hypothesis-testing" outcome is, in fact, a poor representation of the results. It seems likely that most reports in psychophysiology should show a mixture of hypothesis testing and hypotheses generating outcomes in the process of data analysis. Ideally, our standards would change toward quality over quantity and replications of hypotheses- generating results would occur prior to publication. In practice, the field should be advanced by acknowledging the quasi-hypothesis testing of much of our work and evaluating this work, not on its post hoc value, but on the conceptual importance of the finding.

35 Biosignal Processing

GABRIELE GRATTON

1. INTRODUCTION

This chapter reviews issues related to the analysis of psychophysiological data. It focuses on general questions, which are relevant to a variety of techniques, rather than specific issues related to individual methods. Another chapter in this book (Jennings & Stine, this volume) also deals with statistical issues in psychophysiology, and focuses on issues of inference and data interpretation.

1.1. Stages of data processing

In describing the procedures used in analyzing psychophysiological data, it is useful to distinguish among different stages of analysis. The **first stage** is *signal-enhancement* and elimination of observations that are artifactual or can be considered outliers. This stage, sometimes called “signal-conditioning,” involves, at least in part, techniques that are specific to each type of physiological measure.

The **second stage** involves *data reduction* (sometimes called “quantification” or “parameter extraction”). Most psychophysiological experiments include a large number of observations per subject (i.e., dependent variables). Whereas this provides data sets that are rich in information content, it also increases the probability of spurious or noisy observations. In general, one of the main objectives of signal processing is maximizing the signal-to-noise ratio. A large number of observations may contain many different signals to study, but may also contain a large amount of noise. It is advantageous, therefore, to select information that is relevant and to minimize redundancy between the dependent variables entered in the statistical analysis. Redundant dependent variables will not necessarily increase the signal, yet they may generate additional opportunities for noise to be present. An important step in signal processing is to reduce the data set to the smallest possible number of dependent variables (each variable affected by the smallest possible amount of noise) while preserving the information content of the original data set as much as possible. However, a moderate degree of redundancy may be useful in distinguishing random noise from systematic noise, thus making it possible to derive a valid and reliable estimate of the “signal.”

The **third stage** of data processing is *statistical analysis*, which may include hypothesis testing, model fitting, parameter estimation, and so forth. As mentioned earlier most psychophysiological experiments are multivariate in nature – that is, they involve repeated observations from the same subjects. The multivariate nature of psychophysiological measures is one of their greatest assets: it allows for the experimenters to view phenomena from different “points of view,” thus affording a more complete and detailed picture of bodily phenomena. However, it often introduces special types of problems in the statistical evaluation of data sets. Two general approaches can be considered: the *univariate approach*, which considers one dependent variable at a time, and the *multivariate approach*, which considers all dependent variables, as well as their covariation, together (see Huberty & Morris, 1989). Each of these approaches has advantages and disadvantages. In general, when there is a limited number of subjects in the study (relative to the number of dependent variables), and the dependent variables tend to be correlated with each other across conditions (or groups) in the same manner as within conditions (or groups), the univariate approach is more powerful. The multivariate approach is preferable when there is a large number of subjects in the study (relative to the number of dependent variables), and the within- and between-condition (or group) correlations among dependent variables add important information, as it is the when the dependent variables tend to go in opposite directions. (The statistical analysis stage is treated in the chapter by Jennings and Stine, and will not be considered in detail here).

In concluding this section, it is important to remind the reader that the output of an analysis is only as good as its input (this is captured by the well-known aphorism “garbage in, garbage out”). Complex and sophisticated data analyses in no way can be substituted for clear experimental hypotheses, elegant experimental designs, or accurate data collection procedures. However, they can

complement these steps by providing clear and convincing data.

1.2. General issues

Psychophysiological data vary along a number of dimensions, and different types of data propose different types of analytical problems and solutions to the investigator. However, there are a few overarching themes that are valid for most types of measurements. Some general issues are particularly important and worth mentioning early in this chapter. **First**, *psychophysiological measures are typically indirect*. In other words, they are measures of events occurring outside the human body, which are related to events that occur inside the body. For instance, measures of the electrical activity produced by the body (such as the electrocardiogram (EKG) or the electroencephalogram (EEG)) are in fact measures of the difference in potential between two electrodes located on the surface of the body. Another example is positron emission tomography (PET), which measures the arrival of high-energy (gamma) photons to particular detectors located at some distance from the body, which, in turn, is related to the concentration of radioactive substances in various areas of the body. In general, psychophysiological measures are subject to some transformation with respect to the original signal generated within the body because of physical, physiological, or psychological reasons. This transformation may partially distort the signal (as well as its statistical properties) and may occasionally generate artifacts that need to be recognized and eliminated from the data before the statistical analysis is performed.

Second, most of the *data are sampled in a discrete fashion* both temporally and spatially. The transformation of analog parameters into discrete measures may distort the signal and require specific solutions to statistical problems. One of the major problems is obtaining a representative sample of the variable of interest, both over time and space. In addition, some techniques (e.g., measures of heart rate acceleration or deceleration) may be based on the observation of internal events (e.g., the occurrence of an R-wave in the EKG) whose spacing is variable (and, in the case of heart rate changes, is a function of the variable of interest). This may make it more difficult to compare observations across trials and subjects. Investigators using these measures have developed special approaches to address this problem (see the chapter on autonomic measures).

Third, most *psychophysiological measures are “multiply determined.”* In other words, measures are determined by the interaction of a variety of factors. Some of these factors may be extraneous to, and uncorrelated with, the experimental manipulations and, therefore, will contribute to the statistical noise. On the other hand, other factors may be related to the experimental manipulations in ways that are different from those intended by the researcher, which will contribute to both the statistical noise and the systematic effects. The latter type of factors are particularly insidious

and difficult to eliminate. One of the most important characteristics of good experimental methodology is the use of appropriate control procedures that distinguish between signal and systematic noise.

Fourth, most *psychophysiological measures are inherently noisy*, which make it difficult to distinguish between signal and noise in raw (single trial) observations. Several techniques have been developed to extract the signal from the noise. One of the simplest is signal averaging: a measure is repeated several times and the individual responses are then averaged together. Signal averaging is based on the central limit theorem, and can, therefore, be expected to provide reasonable estimates of the expected central tendency of the population in a large number of situations, provided that enough trials are used. Note that for signal averaging to work appropriately, it is important that the expected value of the noise be equal to zero across trials. Although this is a reasonable assumption in many cases, there are certainly situations in which it is not true. For instance, as we will see in section 3.2.2, frequency analysis (such as the Fourier transform) can be used to estimate the “power,” or variance, associated with a particular frequency. Because this value cannot be less than zero, the average of the power values for a particular frequency obtained in different trials (or in different subjects) will always be greater than zero, even if no systematic activity exists at that frequency.

A problem with signal averaging is that it eliminates potentially relevant information about the trial-to-trial (and in some cases subject-to-subject) variability of the signal. This variability is entirely attributed to stochastic phenomena. However, in most cases the variability of the signal is not entirely random, but depends on the influence of intervening variables. For instance, in an experiment that evaluates the size of the visual evoked potential as a function of stimulus intensity, the size of the response may also be influenced by subjects' variables (e.g., allocation of attention or emotional factors), contextual conditions (e.g., stimulus sequence or noise in the environment), or other factors. When signal averaging is used, all of these intervening variables are treated as contributors to stochastic noise and are ignored. This may lead to loss of information or to systematic errors when contingencies exist between the experimental manipulations of interest and any of the intervening variables. Similar problems have been described with respect to other types of measures (see Estes, 1956; Siegler, 1987).

Another problem with signal averaging is that the signal may vary along dimensions other than intensity. In some cases, the latency of the phenomenon or its spatial location may vary from trial to trial (partly because of the reasons outlined above). In these cases signal averaging may produce systematic distortions, the most typical of which is a “smearing” of the response across different data points (or spatial locations). The effect of smearing is more intense for signals with a steep gradient. In cases of electrophysiological signals that vary quickly over

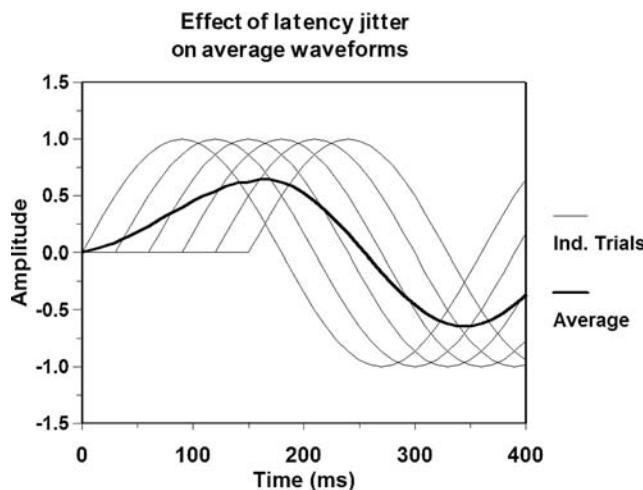

Figure 35.1. The effect of trial-to-trial variations in latency (latency jitter) on the amplitude of a an averaged psychophysiological activity. In this example, the latency of the first positive peak varies systematically in latency between 90 and 270 ms. Although the amplitude of the peak on single trials (indicated by thin lines) is always equal to one, the amplitude of the peak of the average waveform (indicated by the thick line) is considerably smaller (slightly larger than 0.5). The duration of the activity also appears prolonged.

time, smearing leads to the phenomenon of “latency jitter”: the size of an evoked electrophysiological activity may be underestimated when using signal averaging because the activity “peaks” at different latencies on individual trials. A similar problem exists when data from different subjects are pooled together (for a discussion of this problem and some solutions, see Möcks, Köhler, Gasser, & Pham, 1988). Interestingly, the development of brain imaging methods, which have strong gradients in the spatial domain, has led to the recognition of a similar smearing problem in which average spatial maps are computed across subjects because of intersubject variability in brain anatomy. The effect of latency jitter is illustrated in Figure 35.1. Note that this problem is not specific to psychophysiological measures. For instance, investigators in psychology have long recognized that apparently smooth, speed-accuracy functions may result from the mixture of distributions of fast responses with a low level of accuracy and slow responses with a high level of accuracy in which the two distributions have some degree of partial overlap in response time (Yantis, Meyer, & Smith, 1991).

In order to address the smearing problem, several investigators have proposed to measure psychophysiological phenomena on single trials (or subjects). A critical step of this procedure is the development of techniques for identifying target features on single trial records. These techniques, although quite varied, can be grouped under the label of “pattern-recognition” algorithms. Some of them are based on visual inspection of individual data, and are most useful when the target features are much larger than the noise. Other techniques are “computer-controlled,” and based on statistical approaches such as

cross-correlation, auto-correlation methods, as well as other automatic methods. The individual records may then be aligned along the target feature and averaged together. Alternatively, some measure of the single record distribution other than the mean can be used. An example of an alignment methodology in the time domain is the Woody filter (Woody, 1967), which is a general-purpose statistical method; an example in the spatial domain is the alignment method proposed by Talairach and Tournoux (1988), a special purpose approach, which has become standard practice in brain imaging.

2. GENERAL CLASSIFICATIONS

Psychophysiological measures are usually defined as non-invasive measures of bodily functions taken with the intent of addressing issues that are relevant to psychologists and cognitive neuroscientists. This broad definition encompasses a large variety of measures that differ along a number of dimensions. Of these dimensions, some are important for the purposes of the present chapter because they result in different types of signal processing problems. I will pay particular attention to three of these dimensions.

2.1. Fast versus slow measures

As mentioned above, psychophysiological measures reflect bodily changes that are related to psychological phenomena. These changes occur over time. Some of them evolve very quickly (within a few milliseconds) and others quite slowly (over seconds, minutes, or even longer times). Indeed, it is possible to consider a parameter that will indicate the speed at which the activity evolves for each type of psychophysiological measure used. We can refer to this parameter as the “time constant” of a particular physiological measure. This time constant depends on three factors: (a) the rate of change of the relevant psychological phenomenon; (b) the time required by the physiological event being measured to track changes in the underlying psychological phenomenon; and (c) the time required for the measurement.

By and large, it is possible to consider individual time-delay functions for each of these steps, although in some cases interaction terms should also be considered. Note that each step may itself comprise several substeps. Each step can be considered as having an input, which comes from the previous step, and an output, which influences the next step. However, a delay will usually occur in the operation of translating an input into an output. An example of a function expressing this delay can be the following:¹

$$O_t - O_{t-1} = (I_t - OI_{t-1}) * (1 - e^{-1/tc}) \quad (35.1)$$

¹ Note that this formula may not apply to all cases, and is only provided as an example of the typical influence of delaying factors on the time course of physiological measures. In fact, not only the time course but also the intensity of the output with respect to the input may vary from case to case.

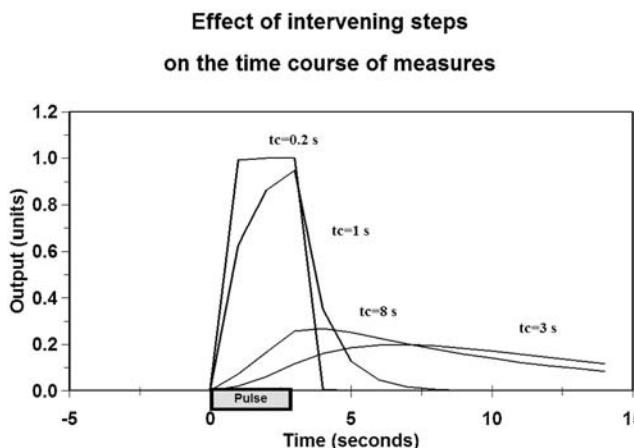

Figure 35.2. Simulated example of a series of individual steps between an input (pulse) and a final output measure. The input is a 3 second pulse (this may simulate a short duration stimulation). Each step introduces a delay, which is described by a parameter called time constant (see text). Four steps were simulated, with time constants, respectively, of 0.2, 1, 8, and 3 seconds.

In this function, the change in the output ($O_t - O_{t-1}$) of a particular step is a delayed function of the difference between its input I_t and its previous level O_{t-1} . The delay is determined by an exponential function whose critical parameter is tc , which is the *time constant* of that particular step. When several steps are involved, the total time-delay function is determined by a convolution of the individual functions. That is, the total time constant of a measurement is related to the integration of the time constants of each individual step. An example of this cascade, and of its effect on the final output measure, is illustrated in Figure 35.2. In this example, the initial input is a 3 second pulse (which is intended to simulate a brief stimulation). Four steps were simulated, with time constants of 0.2, 1, 8, and 3 seconds, respectively (for each step, the output serves as the input for the next step). Note that the final output is substantially delayed with respect to the input, and actually peaks well after the termination of the pulse (i.e., of the stimulation).

The steps contributing most to the total time constant are called “rate limiting” steps (step 3 and, to a smaller extent, step 4 in the example). Although all factors determining the measurement time constant (i.e., rate of change of the psychological event, delay of the physiological phenomena, and measurement time) are always present to some extent, there is often one (or a few) “rate limiting” factor. The nature of the rate limiting factor and the measurement time constant vary between different physiological measures. I will label measures with a long time constant “slow” measures and measures with a short time constant “fast” measures.

The following can be considered examples of slow measures: (a) measures of the electrodermal activity (EDA) in which the psychological or the physiological phenomena evolve slowly over time; (b) functional magnetic resonance imaging (fMRI) in which the physiological event

under study (e.g., a change in blood oxygenation) evolves slowly; and (c) PET (in which, in addition to a delay in the hemodynamic or metabolic response with respect to the triggering event, the actual measurement time is also relatively slow. Fast measures include (a) event-related brain potentials (ERPs); the magnetoencephalogram (MEG); (c) the electromyogram (EMG); and (d) the event-related optical signal (EROS). In all these cases, all three factors mentioned above are fast measures. Some other measures, for instance, heart rate and pupil diameter, are intermediate between these two extremes.

Measures with a short time constant have a good temporal resolution (i.e., the effects of two different psychological or physiological events occurring in rapid succession can be distinguished), whereas measures with a long time constant have a poor temporal resolution (i.e., events in rapid succession cannot be separated easily). This is illustrated in Figure 35.3 in which the time courses of the effect of two stimuli presented in rapid succession on measures with short and long time constants are compared.

Measures with a slow time constant provide few independent observations per unit time. In contrast, measures with a fast time constant provide a large number of independent observations over the same time unit. The processing of psychophysiological data usually requires transformation of the data into a series of numbers sampled over time (i.e., a time series). Then an issue arises: what is the optimal temporal sampling strategy for each type of measure? This sampling strategy must preserve the information contained in the signal as much as possible.

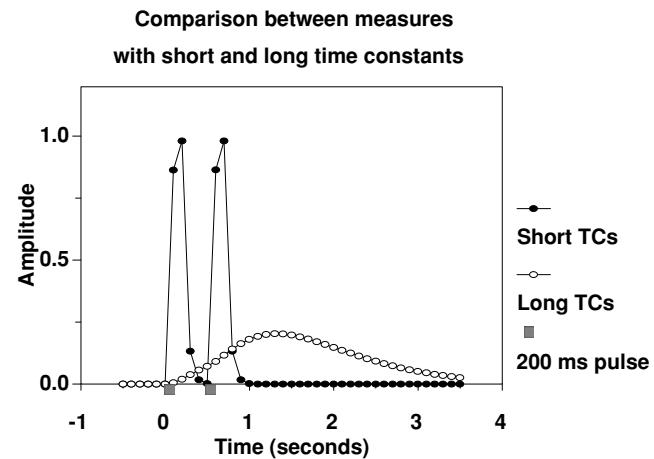

Figure 35.3. Simulated example of the response of output measures with short and long time constant to two stimulations in rapid succession. Two 200 ms stimulation pulses were presented, separated by an interval of 300 ms. This is intended to simulate two independent psychological events. The closed-circle line is obtained by assuming a cascade of three intervening steps between the stimulation and the measurement system, each introducing a delay characterized by a time constant of 200 ms. The open circle line is obtained by assuming a cascade of three intervening steps with time constants of 5 seconds. Note that short time-constant measure affords easy separation of the two pulses (i.e., psychological events), whereas the effects of the two pulses on the long time-constant measures are lumped together.

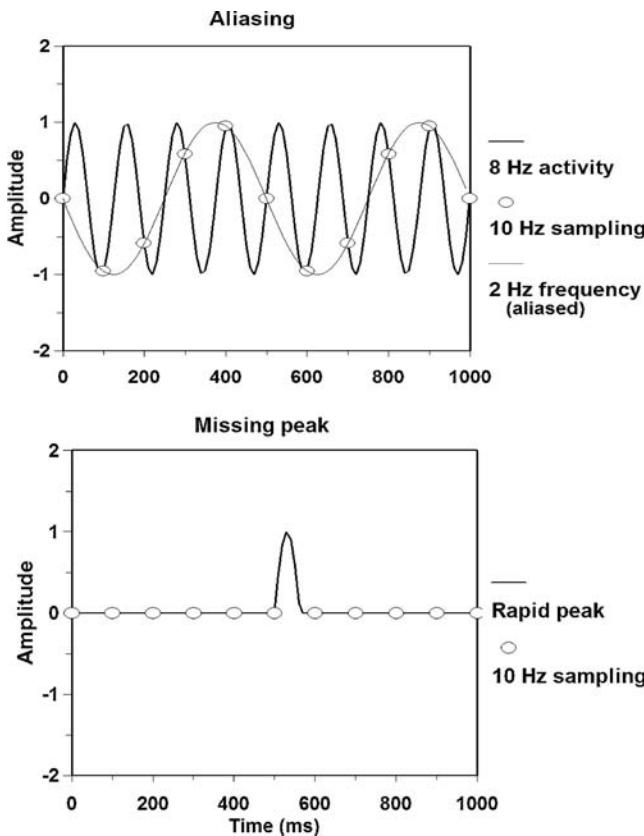

Figure 35.4. **Top:** The effect of sampling at a frequency lower than the Nyquist frequency (aliasing). The signal (indicated by the thick line) is sampled at 10 Hz (indicated by the open circles), which is less than the Nyquist frequency of 16 Hz. The result is an apparent 2 Hz signal (indicated by the thin line). **Bottom:** A rapid activity (duration = 62.5 ms) is measured using a 10-Hz sampling rate. In this particular case, the activity occurs in between two sampling points (open circles) and the peak is not detected by the measurement system.

The minimum sampling frequency at which information is maintained is twice the frequency of the signal, which is called the “Nyquist frequency.” At sampling rates slower than the Nyquist frequency, aliasing causes a high frequency signal to manifest itself as a lower frequency signal. This phenomenon is illustrated in the top portion of Figure 35.4. Also, a sampling frequency that is too slow may completely miss the occurrence of a very fast, transient phenomenon. This is illustrated in the lower portion of Figure 35.4. To avoid the risk of aliasing, investigators may wish to sample at the highest possible frequency. However, it should be remembered that, because each observation will contain both signal and noise, it is important to minimize the number of data points (i.e., dependent variables) entered into the statistical analysis. This may be achieved conveniently at the data reduction stage. Finally, some recording systems impose limitations on the maximum sampling rate. However, the issue of aliasing should always be considered when studying physiological variables. This problem is likely to occur when fast phenomena are studied using a relatively slow sampling rate (e.g.,

when EEG is measured at <20 Hz, EKG at <2 Hz, and respiration at <0.5 Hz).

2.2. Direct versus indirect measures

Psychophysiological measures also differ in the number of intervening steps that occur between the physiological phenomenon, which is the “real” target of the study (e.g., neuronal activity, sympathetic, or parasympathetic activation), and the actual physiological measure that is taken (e.g., scalp electrical activity, increased blood flow, increased heart rate, or increased EDA). The “indirect” nature of these measures may have several consequences. **First**, as we mentioned earlier, it may introduce a lag between the psychological event of interest and the observed changes. **Second**, each of the intervening steps may introduce distortions in the size or shape of the observations compared with the original signal.

A particularly important issue related to the indirect nature of psychophysiological measures is that of the “linearity” of the relationship between the measure and the underlying phenomenon of interest. A measure M is linearly related to an inferred psychophysiological variable θ if the following formula is valid:

$$M = k^* \theta + \text{offset} \quad \text{with } k \neq 0 \quad (35.2)$$

For all practical purposes, it may be sufficient that this formula is valid (at least approximately) for an interval of values of M and θ , provided that this interval contains the typically observed values of the measure and the expected range of the psychophysiological factor. Note that in order for the linearity assumption to be valid, two terms must remain constant across conditions in this formula: the proportionality factor k and the measurement *offset*. The proportionality factor k depends on variables such as the relationship between the psychophysiological phenomenon of interest and the physical phenomenon actually measured, which includes the propagation of the physiological measure to the surface, the recording and analysis procedures employed, and so forth. An example of a potential change in the proportionality factor is a change in the way neuronal signals are transformed into a hemodynamic phenomenon in young and old adults, which depends on the health of the subject’s cardiovascular system. Similarly, increases in neuronal activity at occipital and frontal locations may result in different increases in the scalp electrical signal measured over these areas because of different thickness of the skull in frontal and occipital regions. The offset factor may also depend on the effect of variables other than the physiological phenomenon of interest. For instance, an apparent increase in the amplitude of the ERP at frontal electrodes may be the consequence of an increase in the ocular artifact. Similarly, head movements may result in apparent large changes in the fMRI signal.

Another interesting example for psychophysologists is the difference between measures of EDA. Two such

measures are possible: (a) measures of the electrical *conductivity* between two locations on the skin, and (b) measures of the electrical *resistance* between the same locations. These two measures are inversely related to each other. However, the physiological phenomenon of interest (e.g., increase in conductivity associated with the activity of the sweat glands) is directly proportional to conductivity and inversely proportional to resistance. Therefore, in this example, conductivity is a linear measure of the physiological phenomenon, whereas resistance is not. Quigley and Berntson (1996) have pointed out that a similar case can be made for measures of heart rate compared to heart period, which are reciprocal to each other. Heart period, but not heart rate, appears to vary linearly with basic autonomic activation.

Linearity is useful because it allows for linear transformations of measure M (such as additions, subtractions, multiplications by a constant, and averaging), as well as the physiological variable θ , to be considered valid. Linear manipulations of the observed measures are commonly performed in the analysis of psychophysiological data. However, if the relationship between M and θ is nonlinear (i.e., if k or the offset are not constant), these types of operations, which are performed on the dependent variable, may not be valid with respect to the psychophysiological variable. Therefore, inferences should not be drawn because they may be misleading.

Lack of linearity may occur whenever any of the intervening steps between the observed measure and the psychophysiological construct of interest involve some form of nonlinear transformations. For example, consider the steps occurring between the onset of neuronal activity in response to a stimulus and the subsequent increased O_2^{15} -PET response. These steps may include the release of some chemical by the active neurons, subsequent local vasodilation, increased regional blood flow, and, if a radioactive tracer is introduced in the blood flow, increased radioactivity in a particular volume of the head. In principle, the relationships between causes and effects that exist at each step may be nonlinear or even nonmonotonic. In other words, it is not necessarily the case that a certain percent increase in neuronal activity is followed by an equal percent increase in vasodilation. Therefore linearity needs to be assessed on a case-by-case basis. In the case of PET responses, Fox and Raichle (1984) observed a nearly linear relationship between frequency of visual stimulation (within a range between 0 and 7.8 Hz) and changes in blood flow in primary visual cortex as estimated using O_2^{15} -PET method (see Figure 35.5). The presence of linearity was considered critical for the application of “subtraction” methods during the analysis of hemodynamic responses.

If the linearity assumption is not met, it is still possible that the relationship between the dependent variable and the physiological phenomenon is monotonic. Although a monotonic relationship may limit the use of linear transformations and of parametric statistics,

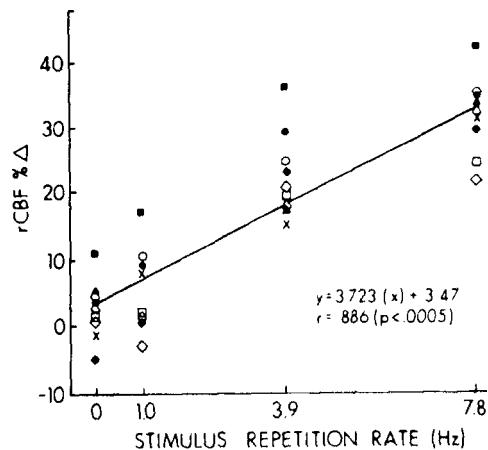

Figure 35.5. From Fox & Raichle (1984): the linearity of the relationship between stimulation frequency and blood flow measures obtained with O_2^{15} -PET.

it is still sufficient for the application of nonparametric statistics based on qualitative judgments about effect sizes. Finally, relationships that are nonlinear, but follow a more complex function, are susceptible of transformations that can make them linear (e.g., the transformation of electrodermal resistance measures into conductance measures).

So far I have discussed the linearity of the relationship between the observed measures and the physiological parameter they intend to measure. To the extent that psychophysiological measures are used to make psychological inferences, it is also important to consider the type of relationship that exists between the physiological parameter and the underlying psychological concept being investigated. For instance, the purpose of measuring neuronal activity in a certain brain area may be the investigation of memory or attention phenomena, and the purpose of measuring blood pressure may be the investigation of the effect of psychological stressors on the cardiovascular system. Clearly, the issue of linearity (or at least of monotonicity) of the relationship is just as important here as in the case of the relationship between the observed measure and the physiological variable.

2.3. Continuous versus discrete measures

The distinction between continuous and discrete measures refers to the time at which information about the status of the physiological system under study is in principle available. Some psychophysiological measures can provide information at any time with no particular restriction. For instance, the diameter of the pupil can be monitored continuously, and provide a more or less continuous measure of the level of activation for particular subcomponents of the autonomic system. The EMG and EEG are continuous measures of the electric potentials produced by muscle and brain tissue, respectively. However, other physiological measures, such as measures of the heart rate

and respiration rate, reflect modification of parameters of cyclic events that occur at some intervals within the body. For these measures, information about psychological phenomena may be available only at discrete times. For instance, the state of activation of some subcomponents of the autonomic system can be studied using changes in heart rate, but information is available only when the heart beats (or when a particular EKG wave, e.g., the R-wave, is produced). Still other measures can only be obtained by using particular maneuvers that elicit special responses in the body. For instance, parameters of the blink reflex can only be measured by eliciting the blink reflex itself. Therefore, if the interest is in using the blink reflex to monitor changes in the status of a particular physiological system (e.g., one related to emotion), information may only be available at specific times (see Bradley, Cuthbert, & Lang, 1991). A similar situation is obtained when the P300 component of the ERP elicited by secondary task probes is used to monitor the level of attention of subjects to primary task stimuli (see Wickens, Kramer, Vanasse, & Donchin, 1983).

I will label those measures that can provide information about the state of a physiological system at any time "continuous," and those measures that provide information only at specific times "discrete." An advantage of continuous measures is that information about the time course of psychological phenomena is readily available on single trial records. Discrete measures can also provide information about the time course of psychological events, but their effective sampling rate is limited by the interval between the successive measurement windows. Finer sampling rates require pooling information obtained across trials, and are more complicated to obtain. An additional problem with some discrete measures is that the time at which information is available may not be completely under experimental control. For instance, certain measures related to circadian rhythms can only be obtained unobtrusively when the subject is awake. This may result in a "variable" sampling rate that may complicate the analysis. For example of solutions to this problem see Monk and Fookson (1986) and Monk (1987). Measures of heart interbeat interval changes as a function of the time at which the stimulus is shown during a cycle can also present special problems of identification because the time at which measures are available (i.e., the next heart beat) varies depending on the phenomenon under study. Appropriate representation of the effects requires special techniques (see Jennings, van der Molen, Somsen, & Ridderinkhof, 1991).

3. SIGNAL EXTRACTION AND ENHANCEMENT

3.1. Domains of analysis

Psychophysiological data can be considered as elements of a multidimensional matrix. We can consider the following dimensions specific to psychophysiological measures:

(a) type of measure, (b) time of sampling (or time with respect to some anchoring event), and (c) location in space (comprising one, two, or three subdimensions). Other dimensions may also be considered, such as experimental condition, subject, group, and so forth, but these dimensions are not specific to psychophysiological measures. Because some of the dimensions are typically grouped together (such as the three spatial axes) it is useful to talk about domains of analysis (such as temporal domain and spatial domain).

For some, and perhaps most, experiments some of these dimensions may have only one cell and are, therefore, fixed. For instance, we may record only data from one location or for one psychophysiological measure. It is important, however, to consider that different values on each of these dimensions all refer to the same individual case, and, as a consequence, possibly may be correlated. Thus, psychophysiological data can be expressed as elements of a multidimensional measurement matrix:

$$M_{m,t,x,y,z,c,s} \quad (35.3)$$

Note that each element of the measurement matrix $v\chi\xi M vH\chi\xi$ has several indices corresponding to the type of measure used (m), the time of observation (t), the spatial coordinates of the observation (x, y , and z), the conditions of observation (c), and the subject from whom the measure is recorded (s). A graphic representation of the multidimensionality of psychophysiological data is presented in Figure 35.6.

The fundamental multidimensionality of psychophysiological data creates special problems in the statistical analysis. In fact, the probability of spurious observations (i.e., alpha error) increases with the number of observations, although typically not linearly. Whereas it is essential that appropriate controls are made to reduce the probability of reaching conclusions on the basis of spurious observations (i.e., rejecting the null hypothesis when it is true), it is also equally important to maintain an acceptable probability of reaching some conclusion in the presence of noisy data (i.e., to maintain adequate power).

An additional problem is that the large number of qualifiers (i.e., indices) used for each observation may sometimes make it difficult to generalize the results. For instance, if an ERP peak is observed at a latency of 400 ms in condition A and at a latency of 600 ms in condition B, should it be concluded that the same ERP peak is delayed in condition B compared to condition A or that an altogether different type of ERP activity occurs in the two conditions?

To address these issues it is usually convenient to perform some intermediate analytical (or signal processing) steps between the level of observation of the raw data and the inferential statistical analysis *per se*, in which the data are used to provide support for or against theoretical arguments. These preliminary steps were previously labeled "data reduction" or "quantification." A consequence of

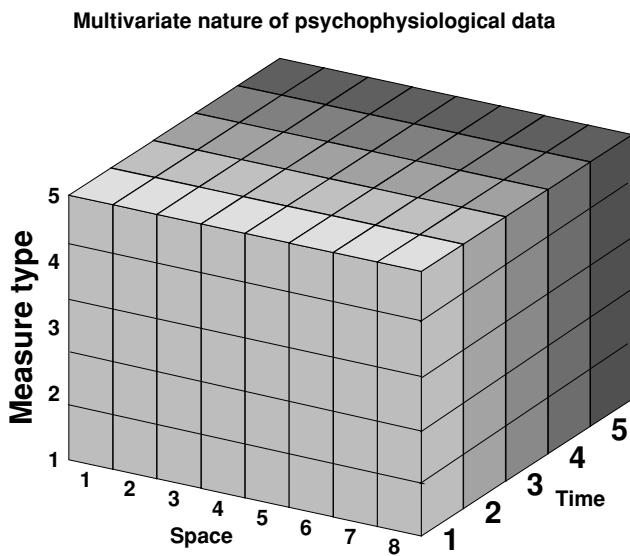

Figure 35.6. Graphic representation of the multidimensional nature of psychophysiological measures. Only three dimensions, specific to psychophysiological measures, are represented here (space, time, and type of measure). However, space itself may comprise several dimensions, and other dimensions (such as subject and experimental condition) are not represented. Note that the combination of different dimensions generates a large number of different observations for each subject. Because these are all observations from the same subjects, they may reflect different facets of the same phenomenon. Changes along one dimension may therefore be correlated to changes on another dimension.

these preliminary analysis steps is that the data should be no longer considered as “raw” observations, but as quantifications of parameters of some intermediate hypothetical construct that has heuristic value and is usually thought of as corresponding to some anatomical or physiological “entity” (e.g., activity in a particular brain structure in response to a particular stimulation condition or the blink response). In all cases, the data reduction implies some “interpretation” of the data. In other words, an analytical model is applied that makes more or less explicit assumptions about the underlying structure of the observed phenomenon, and involves some mathematical or logical transformation of the original “raw” data in order to estimate the value of some parameter of the underlying structure. The quality of the conclusions drawn from an experiment depends critically on the validity of these assumptions.

3.2. Temporal domain

3.2.1. Time domain and frequency domain

The time factor can be analyzed according to one of two basic models. According to the first model, the physiological events in the period under study evolve in a temporally ordered series that exhibits nonstationary properties (i.e., the basic structure of the activity changes over time). An example of data that fit this model well is the sequence of responses that occur in the brain after the presentation

of an individual stimulus. Another example is the changes in heart rate before and after the presentation of a critical stimulus. In these cases, it is profitable to use time as the main dimension of analysis (i.e., “time domain” analysis). Usually, particular aspects of the time series (such as maximum, minimum, integrated amplitude over an interval or a particular wave shape) are considered target features, and parameters of these features (such as amplitude, latency, or similarity with a particular template) are quantified and entered in the statistical analysis. In addition, time series can be averaged together (with or without alignment with respect to particular features) in order to increase the signal-to-noise ratio. This approach provides for a substantial data reduction, and data can be expressed in terms of properties of the target features. Averaging of ERP single trial waveforms and subsequent measurements of specific aspects of the waveforms (such as peaks) are exemplifications of this analytic approach.

The second model assumes that the basic structure of the activity does not vary over time and, therefore, exhibits stationary properties in which events repeat in a cyclical fashion. An example of data that appear to fit this model is the consistent response of the brain to a regular train of similar stimuli when habituation is not expected to play a role, and the oscillation in heart rate associated with respiration (sinus arrhythmia). When this model is appropriate, physiological activity can be analyzed by means of a set of tools that are able to extract the basic periodic structure of the activity – collectively referred to as “frequency domain” methods. In this case a new data series is built in which frequency replaces time as the ordering dimension, and data are expressed in terms of how much of the total variability over time is accounted for by fluctuations occurring at particular frequencies. Distinctive features of this new series can then be considered for quantification purposes (e.g., the “dominant” or most represented frequency in the data can be determined) in the same manner as time domain analyses. Frequency analyses may also provide information about the relative delay (or phase) at which particular rhythmic oscillations occur with respect to a reference time (such as the time of stimulation).

Recently, research has focused on mixed models, which assume that the presentation of a stimulus may lead to the *perturbation* of a basic oscillatory phenomenon. As a very simple example of this phenomenon, we may consider the change in the amplitude of the alpha rhythm (8–12 Hz) of the EEG that occurs when subjects open or close their eyes. Similarly, recent work has emphasized changes in gamma (approximately 40 Hz) and theta (4–8 Hz) rhythms that may accompany particular psychological processes (see Basar et al., 1999). Because it is assumed that a temporal event influences a specific rhythmic event, a mixed time-frequency model is required for the analysis.

3.2.2. Fourier analysis and autoregressive methods

Two types of analytic methods are most commonly used in the frequency domain: the Fourier transform and

autoregressive methods. Both approaches express the original time series in terms of how much certain frequencies are present in the data. However, the Fourier transform is based on a “deterministic” approach. That is, it represents all of the information (variance) contained in the original data in terms of the independent contributions of equally spaced frequencies. Autoregressive methods (of which there are actually different varieties) are instead based on a “modeling” approach. That is, they impose some constraints on the way in which individual frequencies contribute to the original time series and do not necessarily represent all of the variance in the data. This modeling approach reduces the number of “free” parameters in the data (i.e., it reduces the dimensionality of the data). This may allow the investigator to separate signal from noise.

The Fourier transform is a numerical method commonly used in engineering and other disciplines. A prerequisite for its application is that the sampling rate is constant across a given epoch (for an example of frequency analysis techniques with irregular sampling see Monk, 1987). The basic logic of this method is that any given time series (e.g., a recording epoch) can be expressed equivalently (i.e., without loss of information or interpolation/extrapolation) in the time and frequency domains. In the frequency domain a time series can be expressed as the sum of several time series, each characterized by the equal-amplitude oscillations of sinusoidal functions with frequencies equal to a multiple of the inverse of the length of the time series (e.g., if the recording epoch is one second long, then the frequencies used to describe it will be 1 Hz, 2 Hz, 3 Hz, etc.), plus an offset term related to the mean value across data points (usually called “0 frequency” or “DC value”). The number of frequencies is equal to the number of elements in the time series divided by two. So, if we are sampling a one second epoch at 128 Hz, the Fourier decomposition will be based on one DC value and 64 basic frequencies (1 Hz, 2 Hz, 3 Hz, ..., 64 Hz). Each basic frequency is associated with an *amplitude* value, related to how large the oscillation is at that particular frequency, and a *phase* value, related to the relative timing of the peak of the first oscillation with respect to the beginning of the time series. Derivation of the Fourier transform is numerically complex, and requires a number of exponential operations proportional to the square of the number of elements in the time series. Therefore, application of the Fourier transform to long time series may be cumbersome. Fortunately, when the number of elements in a time series is a power of 2 (e.g., 4, 8, 16, 32, 64, 128) the numeric problem simplifies and can be carried out using a procedure called the Fast Fourier Transform (FFT).

The outcome of the Fourier transform is a complex number associated with each frequency, in which the real and imaginary parts both contain information associated with the amplitude and phase of the basic oscillations. The real and imaginary components can be thought of as corresponding to the coordinates of a vector in a com-

plex plane. However, it is most convenient to express the results in terms of the polar coordinates of this vector (i.e., length and angle or orientation). This transformation separates the *amplitude* (equivalent to the length of the vector) and *phase* (equivalent to the orientation of the vector) associated with each frequency. Although informative, it should be remembered that this transformation is not linear. Therefore, data averaging (or other linear operations) are appropriately performed prior to this transformation.

These operations yield a set of phase and amplitude values for each frequency. In most cases, the attention of the investigators focuses on the amplitude data, although there are exceptions, such as in the study of visual evoked potentials (Tomoda, Celesia, & Taleikis, 1991). A common way of displaying the results is by plotting amplitude as a function of frequency (also known as the “periodogram”). In some cases, instead of the amplitude of each oscillation frequency, the data are expressed in terms of the square of this amplitude. This is called the “power” of a particular frequency. Amplitude and power are the frequency domain equivalents of the standard deviation and variance in the time domain. Indeed, the sum of the power values for all frequencies is related to the total variance in the data. For this reason, the Fourier transform can also be used as a method for partitioning the variance observed in a time series into subcomponents with different frequencies. As a consequence, it is possible to apply some of the standard tools used for analyzing variance (e.g., chi square test and analysis of variance) to power frequency analysis. Finally, it is a common practice to pool together the power for an interval of frequencies within a certain range (i.e., a frequency band). For example, in an EEG study we may be interested in quantifying the total power for frequencies ranging between 8 and 12 Hz (usually called the alpha band) and in a heart rate study on sinus arrhythmia we may wish to quantify the power for frequencies between 0.2 and 0.5 Hz (i.e., the respiration frequency range).

As mentioned above, the Fourier transform is based on the observation that any time series can be decomposed in a number of sinusoidal waves that extend with equal amplitude across the entire time series. Although mathematically valid in all cases, this way of describing the data may, in some cases, produce results that require further interpretation. This occurs for several reasons.

First, there may be cases in which the oscillations in the time series can be best described by functions other than a sinusoid. For instance, the pressure waves that propagate through the arteries after a heart beat are, at first approximation, triangular in shape (see the upper portion of Figure 35.7). When the shape of the oscillations departs from sinusoidal, the Fourier transform will decompose each wave into subcomponents (called “harmonics”), with each subcomponent having a frequency that is a multiple of the basic frequency (called “fundamental”) at which the wave repeats. As an example of this decomposition, the periodogram of the saw-tooth arterial pressure waves is reported at the bottom of Figure 35.7. Note that the

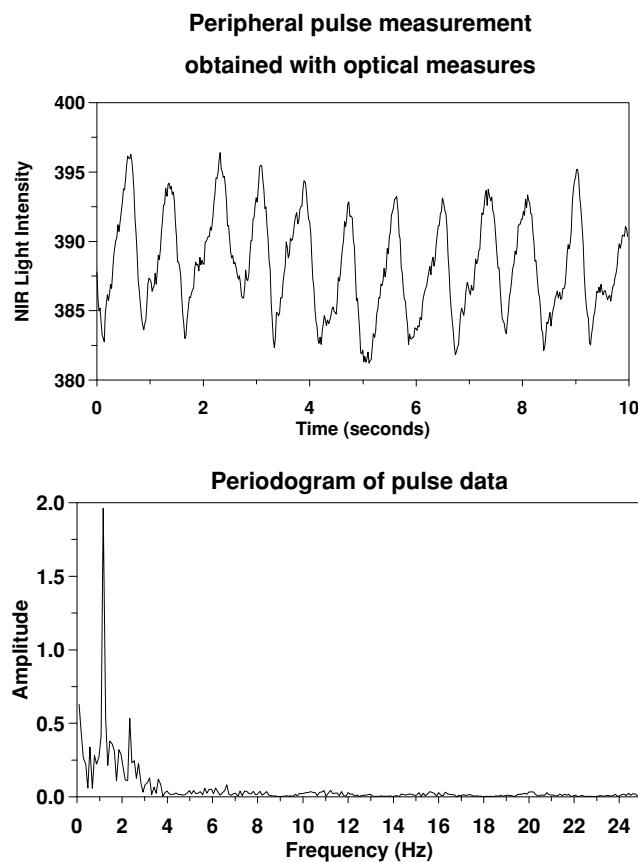

Figure 35.7. Top: Recording of the peripheral pulse from one subject during a psychological experiment obtained with near-infrared (NIR) optical methods (see Gratton, 1997). Note that intensity of the NIR light drops rapidly approximately every 0.8 seconds. The drops correspond to the times at which the arterial blood is pushed into the blood vessels by the beating of the heart. Each drop is followed by a slower increase in the light intensity, which reflects the flow of the arterial blood out of the blood vessels. The quick drop in light intensity, followed by the slow increase, generates a triangular shaped ("saw-tooth") wave that repeats approximately every 0.8 seconds. **Bottom:** Amplitude spectrum ("periodogram") corresponding to the data reported in the top portion of the figure is obtained using an FFT method (the DC component is omitted). Note that the spectrum is dominated by a 1.2 Hz frequency, which corresponds to the heart beat frequency. However, activity is also evident at 2.4 Hz and at 3.6 Hz, which are the first and second harmonics of the fundamental 1.2 Hz frequency. The presence of activity at these frequencies reflects the fact the cyclical pattern is not sinusoidal.

periodogram indicates activity not only at the basic frequency (around 1.2 Hz) but also at some of its harmonics (such 2.4 Hz). The pattern of harmonics is related to the particular wave shape of the basic, cyclical pattern. Given that in most psychophysiological measures the basic wave shape is not a sinusoid, psychophysicologists are often interested in the patterns of the harmonics as much as in the fundamental frequency.

A second way in which data may depart from the description underlying the Fourier transform is when the type of activity observed in one part of the epoch differs substantially from activity in another part of the epoch. An

extreme case is that of "phasic" features, which appear only once in a time series. Phenomena of this type, which are observed frequently in psychophysiological data, may be difficult to study using Fourier-transformed data because the variance associated with them will be distributed in a very complex manner between the DC component and various frequencies. However, this variance will still be represented in some form in the Fourier transform. In other words, the partitioning of the variance obtained using Fourier transforms is best suited for phenomena that repeat cyclically along the time series (i.e., "stationary" waves).

3.2.3. Mixed time-frequency models

3.2.3.1. Joint time-frequency domain analysis. In recent years, combinations of time-domain and frequency-domain approaches have been introduced (see Stiber & Sato, 1997). The major justification for these hybrid techniques is the assumption that the way in which the brain processes information involves the rapid modulation of basic frequencies of activity. A frequency that has been considered as particularly important in brain activity is approximately 40 Hz (also called the "gamma" band; see Gray, Engel, Konig, & Singer, 1989). According to this view, information processing may involve the amplitude modulation of a 40-Hz activity. When a new stimulus is presented, the oscillations at this frequency increase in size. A converse phenomenon is in some cases observed for the alpha band ("alpha blocking" or "enhancement"; see Pfurtscheller & Neuper, 1992). Other examples include (a) the analysis of the modulation of sinus arrhythmia over time as a method for studying the time course of vagal activity, and (b) the analysis of EMG activity, which often involves the occurrence of a brief series of high-frequency oscillations (typically above 30 Hz).

In all these cases, although the psychological events are transient (and therefore evolve over time), their physiological manifestations involve the modulation of a cyclic phenomenon. To represent appropriately this modulatory phenomenon it is necessary to study the change over time of the amplitude of specific frequencies. This involves a segmentation of the time series in shorter epochs, the determination of the amplitude of the frequency of interest in each epoch (the analysis of which is performed in the frequency domain), and the analysis of the time course of modulation of the amplitude of the frequency of interest (the analysis of which is performed in the time domain). This procedure is labeled Joint Time-Frequency Analysis (or JTFA; see Tallon-Baudry, Bertrand, Delpuech, & Pernier, 1996). In the case of EMG, the response is often analyzed entirely in the time domain, and involves: (a) recording EMG data using a relatively high-frequency band-pass (10–100 Hz), (b) rectification of the waveforms (i.e., transformation of the negative values into positive values), and (c) low-pass filtering (typically below 20 Hz). This process is adequate for determination of latency measures, but requires recordings with low noise levels.

3.2.3.2. Wavelet decomposition. Another method combining features from both time- and frequency-domain analyses is the wavelet decomposition method (Samar et al., 1999). Similarly to the Fourier and autoregressive methods, this procedure is also based on decomposing a complex waveform into subcomponents (called wavelets), which when added together form the original waveform. However, different from the frequency-domain methods, it is not assumed that these basic wavelets are cyclic or stationary. Rather, they are allowed to vary in duration and latency as well as amplitude. This “modeling” effort can be used to reduce the dimensionality of the data and fit an underlying structure to a particular waveform. This approach can be particularly useful for single-trial analysis of EEG data.

3.2.4. Amplitude domain measures

All of the temporal-domain data processing steps outlined so far result in descriptions of the observed activity as a function of time, frequency, or a combination of both. However, in some cases, it is preferable to analyze the overall “amount” of observed activity, without expressing it as a function of time or frequency (Cacioppo & Dorfman, 1987). This may be appropriate when the time or frequency variable is considered irrelevant, or when variations of the measurement over time depend on factors that are not related to the physiological (or psychological) variable of interest. For instance, when the stimulation condition cannot be conveniently subdivided into specific time epochs or periodic events, it may be advantageous to consider the overall physiological response observed during an experiment, rather than considering the individual responses. An example of this is the number of electrodermal responses during the presentation of a particular videotape that is not characterized by clearly identifiable time markers. Another case is when measures cannot be taken repeatedly, or whose time of acquisition is longer than the time during which the experimental manipulations are performed. An example of this is deoxyglucose-PET data, in which measures of the amount of radioactive material accumulated in various brain areas are taken at the end of the experiment (Cherry & Phelps, 1996). The temporal dimension in this case is reduced to one data point, and absolute amplitude measures are taken. Finally, there are cases in which there is interest in summarizing a unique number for all the variability of observations obtained across an extended epoch (e.g., Elui, 1969; Dorfman & Cacioppo, 1990).

3.3. Spatial domain

3.3.1. Spatial dimensions

In recent years there has been a substantial growth of interest in the spatial characteristics of psychophysiological measures because they may correspond to the anatomy of the human body, particularly to the brain. A particular impulse for this enterprise has been given by the intro-

duction of functional neuroimaging methods, for example, single-photon emission computerized tomography (SPECT), near-infrared spectroscopy (NIRS), PET, fMRI, and EROS. Brain anatomy is not conveniently expressed using frequency-domain methods because of the fundamental uniqueness of the various structures, thus other methods of analysis are most commonly used. An exception, though, is given by the use of the Fourier transform approach in the decoding of spatial information in MRI. (see Cohen, 1996).

Psychophysiological measures differ in the number of spatial dimensions used, and in their relationship with underlying anatomy. Some measures refer to brain activity (e.g., EEG, ERPs, MEG, fMRI, PET, NIRS, and EROS), whereas others refer to the activity of other body structures (e.g., EKG and heart rate, EMG, pupillary diameter, measures of the blink response, measures of EDA, blood pressure, and respiration). Although measures of both brain activity and bodily functions can be taken at different locations, usually the second group is less directly dependent on brain anatomy than the first.²

All measures of brain activity produce substantially different results depending on the location at which they are taken. Some of these measures provide data that can be localized to specific brain volumes (e.g., PET, fMRI, NIRS, and EROS). For these measures any recorded value will have three indices, which refer to the x, y, and z spatial coordinates of the observed value. Other measures (e.g., ERPs and MEG) provide data that refer to surface observations and have, therefore, only x and y coordinates. For these measures algorithms have been proposed that allow for the reconstruction of depth information, and thus pinpoint brain structures that are responsible for the activity observed at the surface. However, these reconstruction algorithms require a modeling effort that, for both ERPs and MEG, has multiple solutions, which are equally valid from a statistical point of view. Therefore, limited confidence must be placed on the results.

Maps and tri-dimensional (3D) reconstructions obtained with various techniques can be evaluated on the basis of two major properties: (a) localization power (i.e., the ability to attribute a particular activity to a particular location), and (b) resolution (i.e., the ability to distinguish activity coming from two closely located points). These two properties are different and should not be confused. Some techniques may possess a very good spatial localization power, but limited spatial resolution. This occurs because, as is often the case, the larger the activity, the greater the space over which it can be detected

² There are, however, notable exceptions to this rule, in particular in the area of the study of reflexes. For instance, Hackley and Johnson (1996) have used properties of the blink response (a peripheral measure) to determine whether a particular phenomenon (pre-pulse inhibition) is under the control of cortical or sub-cortical structures (which is clearly an issue of localization of function within the brain). This indicates that, if appropriate experimental designs are used, peripheral measures can provide some information about the localization of function within the brain.

(even from outside of the location at which it is generated). Therefore, two closely spaced sources may end up being fused in one single “blob.”

3.3.2. Analysis of surface data: Surface maps and 3D inference

As previously mentioned, some psychophysiological measures (ERPs and MEG) can be used to generate maps of the distribution of a particular physical parameter at the surface of the scalp. Usually, these maps are generated using a process of interpolation: a reduced number of surface observations, usually less than 50, but in some cases as many as 256, are used to derive representations of the activity over the whole head, or a segment of it. The interpolation procedure requires the assumption that the spatial sampling used represents the surface distribution of the underlying phenomenon in a satisfactory way.

When considering the time domain, an issue arises concerning the minimum spatial sampling required for producing representative electrical (and magnetic) maps of brain activity. In general, information theory indicates that the spatial resolution, but not necessarily the localization, is limited to twice the distance between two adjacent measurement locations. This is called the “spatial Nyquist frequency.” At first glance, it may appear that a greater spatial sampling will result in maps with superior quality. Some investigators have shown that the information content increases with the number of recording locations (Srinivasan et al., 1996). Their results make intuitive sense. However, practical and theoretical problems may limit the advantage of increasing spatial sampling of ERP and MEG data. One limiting factor is the cost of the devices required to record and analyze data from a large number of channels. Another limiting factor is that measurement errors are likely to increase with the number of recording channels, which may effectively decrease the signal-to-noise ratio.

To illustrate this problem, let us suppose that an experimenter is interested in running an ERP study to determine where a potential reaches its maximum over the scalp. Let us also suppose that, in this experiment, there exists a .01 probability that a large, inaccurate value (i.e., an artifact) may influence the measures at any given electrode location, and if such an artifact occurs, the maps may identify a maximum at an erroneous location. If only a small number of electrodes are used (e.g., <10), the probability of a “false” maximum is relatively small ($p < .10$). Some confidence can be attributed to the results, although the spatial resolution will be very low. However, as the number of recording locations increases, the probability that at least at one location there will be an artifactual value also increases. Therefore, the probability of incorrectly localizing the maximum will also increase, and, if enough electrode locations are used (e.g., over 100) the probability of an incorrect localization would become very high ($p > .63$). In this case, little confidence could be attributed to the results. This emphasizes the need of

using the “appropriate” number of recording locations. It also emphasizes the difference between spatial resolution and localization – procedures that enhance spatial resolution do not necessarily enhance localization, and vice versa.

As mentioned earlier, most maps are constructed using an interpolation process. There are various algorithms for interpolations. A relatively simple procedure involves using a linear interpolation to derive the values in between the observed locations. A problem with this method is that the maximum of activity in the maps is bound to be at one of the locations at which the recordings were obtained. However, more sophisticated techniques are now commonly used. Some of them are based on fitting polynomial surfaces, or other types of surfaces obtained with some form of smoothing function, through the various observed data points (e.g., spline interpolation; Perrin et al., 1987). These interpolations may increase the localization of activity in surface maps, but at the cost of a reduced spatial resolution. In addition, assumptions need to be made about the spatial frequencies contained in the data.

Some transformations of the surface maps may be useful for counteracting some limitations of the original observations. For instance, limitations of surface maps of the electrical potential over the scalp include: (a) the absolute value at each data point is dependent on the choice of reference, and (b) activity tends to be spread out across extended areas. This may make it difficult to appreciate differences between conditions. A way of addressing both of these issues is transforming the measures mapped from voltage difference into electric currents (“current source density,” or CSD, maps). According to Ohm’s law, currents flowing between two points are directly related to the differences in potential and inversely related to the resistance between the points. If the resistance is assumed to be constant, then current maps can be easily computed from voltage maps. In the case of the scalp, the current can be considered to flow almost exclusively along the skin, which is a path of lower resistance than the skull underneath. The flow of current in two dimensions can then be described as a current density, which is computed using the 2D spatial derivative of the voltage map. In practice, this provides a measure of a local gradient, which is independent of the definition of the reference level because a local reference system is used, and highlights local details of the maps. However, phenomena that extend across large areas become less visible. Furthermore, small error variance may be amplified by this method.

Whereas CSD maps (and other transformed maps) of surface potentials may be useful for highlighting differences between conditions, they should not be interpreted as 3D reconstructions of the activity inside the head. Such a reconstruction requires a model of (a) how the signal is generated inside the head, and (b) how it is transferred from interior sources to the surface. Both problems require different solutions depending on the type of

measure adopted. For electrical activity (EEG and ERPs), the propagation of the potential to the scalp requires information about the conductive properties of various media interposed between the sources and the surface electrodes (such as gray and white matter, cerebrospinal fluid, bones, and skin). Furthermore, because of the relatively low frequency of the data, impedance is typically not considered an issue here. The transmission of magnetic fields is less influenced by departures from homogeneity in the media than that of electric fields. Until recently, all source analysis algorithms were based on abstract models of the head (e.g., the “three-sphere model”), which modeled the head as a simple geometric shape. In the last few years, realistic head models, which are derived by using MRI or computerize axial tomography (CAT) scans, have been adopted, and the propagation of activity to the surface has been computed using finite computation methods. However, knowledge about the *in vivo* conductive properties of head tissues is still imperfect and may create substantial errors in the computation.

Notwithstanding these problems, substantial developments have been made in the modeling of the sources of electrical and magnetic activity in the last 20 years. Three types of approaches can now be used:

1. Regional source models. This approach models the propagation of potentials or fields within the head, rather than their generation. It produces results that tend to be quite robust (i.e., it converges to similar results if small variations in the observed activities are compared), but has low spatial resolution (up to several cm; Pascual-Marqui, Michel, & Lehmann, 1994).

2. Diffuse source models. With this approach, it is usually assumed that activity is generated by a large number of sources, for instance, the entire cortical surface. To reduce the number of free parameters, some assumptions can be made, for example, that sources are normal to the cortical surface, have overall as little activity as possible (i.e., minimum norm), and are spatially smooth. Diffuse source models may possess intermediate spatial resolution, but their accuracy is difficult to evaluate because they are typically largely overdetermined or the number of free parameters to estimate is several orders of magnitude greater than the number of observations (Dale & Halgren, 2001).

3. Point-dipole models. These models can be taken at a particular time point, or combine information accrued over time, which generates “spatiotemporal” dipoles (Scherg & von Cramon, 1986). This approach has greater spatial resolution and localization power, but also a greater level of uncertainty about the number of modeled sources. By and large, source modeling of electrical activity and, to some degree, magnetic activity still requires external validation.

The problem of how to derive 3D reconstruction of data from data with lower dimensionality is not restricted to

EEG, ERPs, and MEG, but is true for all imaging techniques. Each of these imaging methods solves the problem in a different way. CAT and PET scans use a large number of surface detectors to infer activity inside the brain. Both of them are based on high-energy radiation (photons) with minimum scattering. They use a form of 3D reconstruction that is based on inferring the distribution of activity inside the head from surface activity, which ignores variations in the local anatomy, but is entirely based on geometric and statistical principles.

Optical imaging methods (e.g., EROS) use light wavelengths at which scattering is the dominant phenomenon; further diffusion parameters (scattering and absorption coefficients) vary conspicuously between tissue types. Thus, a 3D reconstruction of optical imaging data needs to take into account these properties of the medium, similarly to EEG and ERPs. However, because the movement of photons inside the head is strongly limited by the scattering and absorption properties of the head, the spatial resolution of optical imaging is inherently much higher than that of methods based on electric potentials and magnetic fields.

Magnetic resonance imaging methods use a completely different approach to 3D reconstruction. Different from the instruments for electrophysiological, optical, and PET recordings, MR machines typically have one, or very few, detectors. In this case, to provide spatial information, the magnetic fields used to induce and measure the magnetization of individual nuclei are varied over time and space in a very special manner so to provide “tags” indicating where the signal originated. Whereas this technology provides, in principle, a very high spatial resolution, it generates a few problems: (a) there are limitations in how quickly the signal can be acquired, and (b) it is essential that the local variations in the magnetic fields are accurately predictable. To partially address this second issue, it is customary to “shim” the magnets before recording data. Nevertheless, characteristic artifacts are present when distortions in the magnetic fields occur because of, for example, the presence of metal prosthesis and dental work.

3.3.3. Analysis of 3D spatial data

Imaging methods provide 3D descriptions of how the signal is generated inside the body. If the data refer to changes in the strength of the signal as a consequence of the functioning of a particular organ, they are called “functional imaging methods.” Examples of functional imaging methods include fMRI and PET. Functional imaging methods vary in terms of spatial resolution and localization power, as well as other dimensions (e.g., how direct the measures are and how much temporal resolution they possess). The localization power of some of these techniques constitutes their major advantage, but it also requires attention to a number of methodological issues. One of these issues is that the anatomy of some organs – the brain in particular – varies across individuals. Therefore, a signal

that may appear at a particular location in one person may appear at another location in a different person. In order to generalize conclusions across people it is indispensable to “align” the data obtained in different individuals. This process requires re-scaling the various features of the anatomy of each single person to a “standard” anatomy, so that phenomena observed in different people can be directly compared.

A commonly used procedure to align different brain anatomies to a standard anatomy was introduced by Talairach and Tournoux (1988). According to this procedure, structural scans of brains of different individuals, which can be obtained using MRI or CAT scans, are first aligned using a set of basic anatomical features. The brain is then subdivided into regions, and each region is re-scaled independently to the dimensions of a standard provided by the Talairach and Tournoux atlas. This allows researchers to compare data across different subjects, in order to examine the reliability of findings, and compute “average” brain maps across subjects. Using the standard atlas, it is then possible to associate specific functional data to particular anatomical structures of the brain (e.g., the Brodmann cytoarchitectonic areas of the cortex). This procedure is likely to introduce small distortions because the large subdivisions used in the Talairach and Tournoux system may not capture all of the individual differences in anatomy. Furthermore, the subdivisions are based on subcortical, rather than cortical landmarks. Because the cortex is the most variable part of the human brain, the Talairach and Tournoux system can sometimes lead to significant alignment problems. Furthermore, the Talairach and Tournoux method is based on a single “model” brain. A variation of this approach is the Montreal Neurological Institute (MNI) model, which is based on a statistical average of a large number of brains. However, the Talairach and Tournoux transformation is a standard method that can provide useful approximations in a number of cases, and allows scientists to compare results obtained in different experiments and labs.

More recently, other alignment methodologies have been introduced, which take into account cortical features. Some of these methods preserve the 3D structure of the brain, whereas others generate flattened images of the cortical surface (Van Essen et al., 1998). These methods are generally based on complex warping algorithms in which each location on the surface of the cortex of a particular brain is associated, because of its relative position with respect to local landmarks, with a point in a standard 3D or flat representation of the cortex.

An additional problem with 3D spatial data is the huge number of dependent variables used. A 3D scan of the brain based on voxels (i.e., the small volumes used for sampling a large volume) with a 1.5–3 mm side may generate more than 100,000 data points, each of which should be considered as a dependent variable. This has two major consequences. First, multivariate techniques are difficult to apply to these data, unless a strong reduc-

tion in the number of points is considered. Second, even univariate analyses need to take into account the problem of multiple comparisons (i.e., the inflated probability of alpha error when a large number of comparisons are carried out). There are various solutions to this problem. One is to carry out analyses only for selected points, or regions, labeled regions-of-interest (ROIs). This, however, restricts the analysis to small portions of the brain. A second, simple solution to this problem is to apply the Bonferroni inequality, which consists in setting the criterion of alpha error for each comparison to crit/nc , where crit is the criterion normally used (e.g., .05) and nc is the number of comparisons (in this case, data points). This guarantees that the overall probability of alpha error is less than the original criterion. However, if the number of data points, or voxels, is large (e.g., 100,000) only data points whose statistical values are associated with extremely low probability values will be significant. Although this analysis would protect against alpha error, it would reduce the power of the study as to make it virtually useless.

A solution to this problem has been proposed by Friston (1996). This solution is based on the application to neuroimaging of random field theory (also called “blob” analysis), which was developed to deal with similar problems in other disciplines. Blob analysis is based on the idea that the observations obtained at different locations are not independent from each other – close voxels are likely to be similar to each other. This confers some level of “spatial smoothness” to the imaging data, and implies that the number of independent comparisons is in fact much smaller than the number of voxels recorded. In other words, although there may be 100,000 voxels recorded, there may be 1,000 or fewer independent comparisons. To determine what statistical level is needed to reach significance, it is important to establish the spatial smoothness of the data. A critical point is to establish the *spatial smoothness of the error term* and not that of the effect to be studied. This can be achieved in various ways. The most effective is based on the computation of the spatial derivative of the error term. This approach to the analysis protects against alpha errors and still maintains a reasonable power.

An interesting consequence of the use of spatial smoothness in the estimation of the statistical significance of the data is that the greatest power is obtained for data with high spatial smoothness. However, spatial smoothness can be considered as the reciprocal of spatial resolution – the higher the spatial resolution of the data, the smaller the spatial smoothness. Thus, in order to increase the power of a particular brain imaging technique it may be advantageous to reduce its spatial resolution. This may be easily achieved by “spatially filtering” the data (see section 3.4), so that data contain only relatively low spatial frequencies. In fact, most brain imaging studies use spatial filters that reduce spatial resolution to the order of 1 cm or less.

3.4. Filtering and artifact problems

One of the major issues in processing any type of data, in particular psychophysiological data, is that of distinguishing the signals of interest from noise. Noise can be broadly defined as any other phenomena observed in the data apart from the signal(s) of interest for the investigator. In general, the ability to distinguish signals from noise can be quantified using a construct called the “signal-to-noise” ratio, which is the amplitude ratio between the signal and the noise. The larger the signal-to-noise ratio, the easier it is to identify the signal. As a consequence, more reliance can be attributed to the observations. One of the major tasks of signal processing is to increase the signal-to-noise ratio. This can be achieved by amplifying the signal, reducing the noise, or both. In general, procedures or devices that reduce the amount of noise present in the data are called filters.

By and large, filters are based on the principle that the signal can be distinguished from the noise on the basis of some characteristic features. For instance, the signal may have a particular frequency that is different from that of the noise. Therefore, by amplifying the frequencies carrying the signal and dampening the frequencies carrying the noise, it is possible to increase greatly the signal-to-noise ratio. This is common practice in psychophysiological recording, and can be achieved while the data are recorded by the use of online, usually analog, filters or at any stage of data analysis with offline, usually digital, filters.

Generally filters are described in terms of the frequency at which they attenuate the signal. High-pass filters cut off activity with a frequency lower than a designated frequency, whereas low-pass filters cut off activity with a frequency higher than a designated frequency. Other types of filters, called notch filters, only cut off a very specific frequency (e.g., 60 Hz), and leave activity with lower or higher frequencies unaltered. Usually, the cut-off point of a filter indicates that at that point activity is reduced by 3 dB (approximately 70%). However, other parameters are important in describing the performance of a filter. Specifically, the performance of a filter is described by a “performance operating characteristic” (POC) function, which describes the proportional attenuation of the signal at different frequencies. Ideally, a filter should maintain all of the activity up (for low-pass filters) or down (for high-pass filters) to the cut-off frequency and eliminate all of the frequency above or below the cut-off frequency.

Most psychophysiological recordings involve online analog filters. The advantage of these filters is that they can reduce high frequencies before digitization occurs. This may reduce the possibility of aliasing high frequencies. As already mentioned, aliasing occurs when digitization is performed at a rate that is less than twice that of a frequency present in the data. In this case, activity at a high frequency will be reflected into activity at

a lower frequency. Because aliasing cannot be eliminated once it occurs, it is very important to prevent it by filtering high frequencies before digitization. Another advantage of online filters is that they can be used to cut-off large noise oscillations, which usually occur at very low frequencies. These large oscillations may generate signals that are outside the operating range of the analog-to-digital converter, which will “saturate” (i.e., it will provide an output that corresponds to the maximum or minimum value allowed by the converter, but not to the actual value).

Online frequency filters, however, are usually recursive: filtering is based on the activity that has already occurred and not on the activity that has yet to occur. Therefore, they introduce a phase distortion in the data – phenomena may appear to peak at different times from when they actually do, or their shape may be distorted.³ Online low-pass filters, which cut off high frequencies, tend to displace peaks to a later time than when they really occur. Online high-pass filters, which cut off low frequencies, tend to displace peaks to an earlier time than when they really occur. Offline filters can be designed to be nonrecursive and, therefore, do not necessarily produce phase distortion. The extents to which these displacements occur depend on the frequencies that are cut off by the filters. It is, therefore, preferable that data be recorded online using a wide band-pass, and that filtering used for signal enhancement be mostly carried out offline using nonrecursive filters.

Various types of offline digital filters are available. Because they do not need to be analog, it is relatively simple to produce filters with very good performance (i.e., with very sharp cut-off points). Whereas filters with such characteristics may be built using a frequency-domain transformation of the data, the operations required are complex and may slow down the data processing exceedingly. It is possible to construct filters that work in the time domain that approximate the performance of these filters. Cook and Miller (1992), as well as Farwell, Martinerie, Bashore, Rapp, and Goddard (1993), present a review of some of these filters.

Wiener (1964) introduced the concept of “optimal” filter. This is a filter whose POC function is optimized to increase the signal maximally compared to the noise. For instance, a filter may be built to maximize the between-condition variance with respect to the within-condition variance. To build such a filter it is necessary to define the signal in some manner, so that the frequency carrying the signal can be identified *a priori*. In addition, an optimal filter is practical only if it is designed in the frequency domain. However, as already mentioned, filtering in the frequency domain may actually reduce the speed of signal processing considerably. These problems have limited the use of optimal filters.

³ This phenomenon can be minimized by using a special type of filter (e.g., elliptical and/or Bessel filters).

In certain cases the investigator is interested in studying activity that is characterized by very specific frequencies. For instance, if the investigator is interested in the response to stimuli presented at regular intervals, the investigator may assume that the response also should be observed at regular intervals. In this case, the frequency of the signal is well known – either the frequency of stimulation or one of its harmonics – and activity at all other frequencies may be discarded as noise. An “inverted-notch” filter (also called a “band-pass” filter) may be used to selectively analyze the response, and may enhance greatly the signal-to-noise ratio. Procedures of this type are used to analyze “steady-state” evoked responses (Tomoda et al., 1991).

So far, this discussion has focused on filters used in the temporal domain to eliminate activity at undesirable frequencies. However, filters can also be built in the spatial domain in order to amplify activity with certain, particular spatial properties with respect to other types of activities. An example of this is the Vector Filter procedure proposed by Gratton, Coles, and Donchin (1989). The Vector Filter procedure can be considered as analogous to a planned contrast executed in the space domain. Gratton, Kramer, Coles, and Donchin (1989) and Fabiani, Gratton, Karis, and Donchin (1987) showed that this procedure could help in ERP component identification. This notion has been recently re-introduced with the label of “virtual channel,” which refers to a particular EEG channel constructed by appropriately weighting a number of different channels. The weights can be selected on the basis of specific procedures, for example, Principal Component Analysis (PCA; Spencer, Dein, & Donchin, 1999), independent component analysis (ICA; Makeig et al., 1997), or other methods.

A special type of noise, present in most psychophysiological data, is referred to as an “artifact.” This term is normally used to indicate large, isolated noise activities that originate outside the system of interest. Examples of artifacts include (a) the potentials associated with blinks and other types of eye movements during the recording of brain electrical activity, (b) susceptibility and movement artifacts during MRI and PET recordings, (c) missed heartbeats in measures of heart rate, and (d) pulse artifacts in the EROS and NIRS data. Artifacts may be very large – several times larger than the signal – and could, therefore, completely obliterate the signal. Furthermore, they may occur in a systematic fashion (i.e., the frequency of artifacts may be consistently greater in one experimental condition than another). However, artifacts are often easy to recognize because they have specific “signatures” that are clearly distinguishable from regular data. For instance, blinks generate electrical potentials with a characteristic spatial distribution over the scalp, and missed heartbeats in heart rate measures can produce exceedingly long intervals that are outside of the normal variability.

A number of manual and automatic procedures have been developed to detect, eliminate, or compensate for the effects of artifacts. These procedures vary from a particular physiological measure to another and, therefore, will not be reviewed here. It is important, however, to remember that appropriate procedures for dealing with artifacts are an essential step in the processing of any physiological signal.

4. DATA REDUCTION AND QUANTIFICATION

4.1. Quantification

Practically all analyses of physiological measures require a step in which a small number of numerical values are extracted from the large amount of data recorded, and are then used for inferential statistics. This step may be called quantification. Quantification usually involves two steps: (a) identification of a particular feature considered to represent a given physiological event, and (b) measurement of some parameter of this feature.

4.1.1. Feature identification

The procedures used to identify the feature of interest are quite variable. In some cases the feature can be easily identified by visual inspection of the data. This occurs when the signal-to-noise ratio is so large (e.g., $>3:1$) that the feature of interest can easily be distinguished from sources of noise or from other signals (e.g., blinks in electrooculographic (EOG) recordings, and R-waves in the EKG). In other cases the features of interest are buried under variable, and sometimes large, amounts of noise or other signals. An example of this is given by various components of the ERP, especially when measured from single trials, or from averages of a small number of trials. In this case, identification of the component of interest may be very complex, and require sophisticated pattern recognition algorithms, filtering procedures, or a combination of both. Thus, identification of the P300 component of the ERP on single trial recordings may require using a relatively heavy low-pass filter (band-pass 0–6 Hz or less) and pattern recognition algorithms such as cross-correlation methods (Fabiani et al., 1987; Gratton, Kramer et al., 1989). A step that is often required for identifying ERP components is the definition of a particular “time window” in which the component is expected to appear. Thus, it is possible to define P300 as a positive peak in the ERP waveform appearing in an interval between 300 and 700 ms, whereas a peak appearing earlier or later may be classified as a different component. Other attributes may also be considered important, for example, the particular location at which the activity is observed.

4.1.2. Measurement

The second step of the procedure is the measurement of a particular parameter of the feature of interest. Again,

parameters vary along different dimensions. By and large, three dimensions are considered in most cases: (a) a temporal dimension, (b) a spatial dimension, and (c) the intensity or frequency of occurrence.

4.1.2.1. Temporal dimensions. In the case of temporal dimensions, activity can be considered as having a particular latency, frequency, or phase. Measures include onset, peak, center-of-gravity, and fitting of particular functions to the data. The two measures that are most commonly used are onset and peak latency.

Onset measures may be very informative because they may define the latency of a particular physiological event as well as the maximum latency of the psychological phenomenon that is intended to signal. Onset can be measured as the first data point in the time series exceeding a preset value. This value can be obtained from previous work or from statistical computations of the variability in the measurements (Miller, Patterson, & Ulrich, 1998). However, the exact onset time of physiological measures can be difficult to determine when the measures contain even low levels of noise. In case of noisy measures (e.g., ERP activity measured on single trials or on a small number of trials), onset of a particular activity can be estimated by fitting regression lines to different segments of the data (Barrett, Shibasaki, & Neshige, 1986), and by determining the point at which the regression line corresponding to the pre- and post-onset periods meet. An alternative procedure is to consider the “half-amplitude” latency, which is the latency required for the signal to reach half of its maximum peak; other proportions of the maximum value can also be used (Smulders, Kenemans, & Kok, 1996). Whereas the latter approach is quite reliable (Smulders et al., 1996), the determination of which proportion of the maximum value to use is arbitrary, and the measure may not correspond to any particular psychological (or physiological) phenomenon. In addition, if the maximum value is systematically different across conditions, determination of the latency of half-amplitude measures may be misleading. An example is presented in Figure 35.8.

Peak measures are obtained by selecting the data point (in the time or frequency domain) of the time series at which the measure reaches its maximum value. If several peaks are present, the peak point can be defined as the maximum value within a certain interval, or as the “n-th” peak in the waveform (i.e., the first peak, the second peak, and so on). Peak measures tend to be more reliable than onset measures. However, they may be very sensitive to high-frequency noise. It is, therefore, often advisable to apply a low-pass filter before estimating the peak. The main advantage of peak latency measures is that they are easy to take even on noisy data. A disadvantage, in comparison to onset measures, is that they do not necessarily identify a point in time that is of theoretical importance. Thus, although from the onset of a particular activity we may infer that a given psychological process must

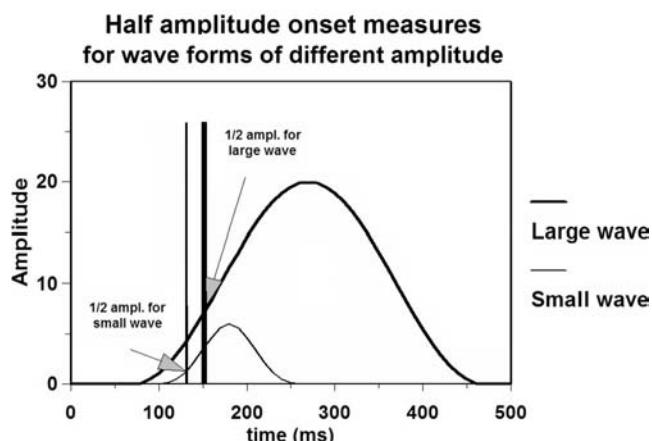

Figure 35.8. Half-amplitude onset measures for waves of large (thick curve) and small (thin wave) amplitude. The half-amplitude latency of the large wave (thick vertical line) was 170 ms, whereas that of the small wave (thin vertical line) was 147 ms. If half-amplitude measures are used to estimate onset latency, it may lead to the incorrect conclusion that the onset of the large wave occurred after the onset of the small wave.

have been carried out for the activity to occur, the peak of the physiological response may occur some time later and have no specific meaning. An extreme example is given by the time course of the hemodynamic response (measured with fMRI) and following the presentation of a train of stimuli. The time at which the fMRI response reaches its peak may provide little information about the time course of psychological events. The onset of the fMRI activity in a particular brain area, however, can be considered as the upper limit for the latency of activation of that area. It should be noted, of course, that activity in the area might in fact begin some time before it is detected. A similar situation exists for the latency of the peak of the skin conductance response. Note, however, that although for both types of signals the peak latency may provide little information about the timing of psychological events, the onset and the amplitude of either response may provide useful information about the nature of psychological events.

In general, temporal dimensions are considered as interval measures and are most commonly analyzed using parametric statistical approaches. However, temporal measures have usually a limited range. Additionally, in some cases, the distribution of the measurement error departs substantially from normality and both skewness and platykurtosis may be present (Fabiani et al., 1987). Both of these problems may lead to reduced power for statistical analysis.

4.1.2.2. Spatial dimension. The spatial dimension is most commonly analyzed in terms of the correspondence of the location of a physiological response to a particular anatomical structure, for example, it can be hypothesized that the blood-oxygenation-level-dependent (BOLD) fMRI response was observed in proximity of the calcarine fissure. In brain imaging techniques, analysis is often carried

out in parallel for different voxels. Then, the voxels showing a response are identified and compared with anatomical maps. The methodologies used to determine which voxels (or set of voxels) show signs of functional activation (i.e., changes in blood flow or BOLD signal) vary conspicuously. In most cases, some type of statistic is derived for each voxels (or group of voxels). For methods based on hemodynamic or metabolic phenomena, this statistic often involves comparisons across conditions. In this case, the voxels identified are those that show differences between conditions exceeding some criterion, often expressed in terms of probability of alpha error.

In most cases the response is observed over several contiguous voxels. Indeed, given the high probability of false positive in brain imaging studies, it is often the case that only responses extending over a number of voxels are considered meaningful. In this case, the exact location of the activity may be more difficult to identify. One procedure is to consider the geometrical center of the region (or group of voxels) that shows significant effects. An alternative solution is to interpret the data as indicating a response that extends over the whole area where a significant response was observed. There are two possible problems with the latter interpretation.

First, the size of the area where a significant response is observed depends on the criterion used for considering an effect as significant and on the power of the measurements. Therefore, the activated area may depend on the number of trials or number of subjects used in the study. Paradoxically, if enough trials were collected (or the signal-to-noise ratio was sufficiently high), larger areas of the brain could show signs of activation and the response would become less localized.

Second, for some measures, such as BOLD-fMRI measures, a very large activity in one voxel may actually cause other voxels (both contiguous and noncontiguous) to show activity. For this reason a strong activity localized to a very small volume in space produces effects that are difficult to distinguish from those of a weaker response localized to a larger area.

The statistical analysis of spatial information is sometimes carried on considering location as a categorical independent variable (or a factor). For instance, analysis of ERP scalp distribution is often carried out using electrode location as a factor in a factorial ANOVA design. Effects of experimental variables on scalp distribution would then be visible as interaction between these factors. Although quite popular, this approach has been criticized for two reasons.

First, the ANOVA model is an additive model, so that the contribution of electrode location as a factor to the overall variance is considered as independent from other factors. However, because ERPs always reflect the difference in voltage between locations, if a phenomenon influences the voltage of an ERP activity, it is likely to influence different electrode locations in a different manner. Therefore, an interaction between electrode location and any experimen-

tal factor may be due to a change in the overall size of a particular ERP activity, change in its spatial distribution (or scalp distribution), or interaction between these factors. McCarthy and Wood (1985) have proposed that, before submitting ERP data to an ANOVA, the values obtained at different electrodes be re-scaled by a factor related to the absolute size of the activity (e.g., the range of values or the standard deviation across all electrode locations). This "standardization" process is intended to eliminate variance across conditions or subjects due to changes in component amplitude, so that any effects observed as a function of electrode location can be interpreted as a change in the spatial distribution of the ERP activity. This approach is useful in those cases in which the ERP observed at the scalp (at all scalp locations) is determined by a single component. However, as shown in Figure 35.9, in the case of overlapping components, the standardization procedure does not eliminate the confounding between differences in scalp distribution and differences in component amplitude.

Second, the ERP values measured at different electrode locations are in fact observations of the same phenomenon from different vantage points. For this reason, both the signal and the noise can be correlated. The correlation of the noise observed at different electrode locations (or at different data points) generates a problem in the ANOVA model that is commonly known as "lack-of-sphericity" problem (Jennings & Wood, 1976). A solution to this problem is to use a multivariate approach to the analysis of scalp distribution data. Several multivariate approaches have been proposed. They include: MANOVA (Vasey & Thayer, 1987); multiple regression (Gratton, Coles et al., 1989); principal component analysis or single-value decomposition (Lamothe & Stroink, 1991); and independent component analysis (Makeig et al., 1997).

Other investigators have considered using nonparametric statistics to evaluate location information. One such example is the use of bootstrapping procedures for studying the location of the peak of surface distribution of ERPs or optical activity (Fabiani, Gratton, Friedman, & Corballis, 1998). The purpose of the bootstrap method proposed by Fabiani and colleagues is to estimate the reliability of maxima of maps of ERP or EROS activity obtained on average data. The bootstrap method involves analysis of a large number of samples of individual trials (bootstrap replications). Each bootstrap replication is obtained by extracting at random (and with replacement, so that a given trial can occur more than once) a number of trials from the original data set equal to the number of trials used to compute the regular average. For each new bootstrap replication, an average map is computed and the location of maximum is determined. The distribution of the maxima across a large number of different bootstrap replications is then obtained. The location of a maximum is reliable if it is obtained in a large proportion (e.g., 95%) of the bootstrap replications. This bootstrap method does not require assumptions about the distribution of

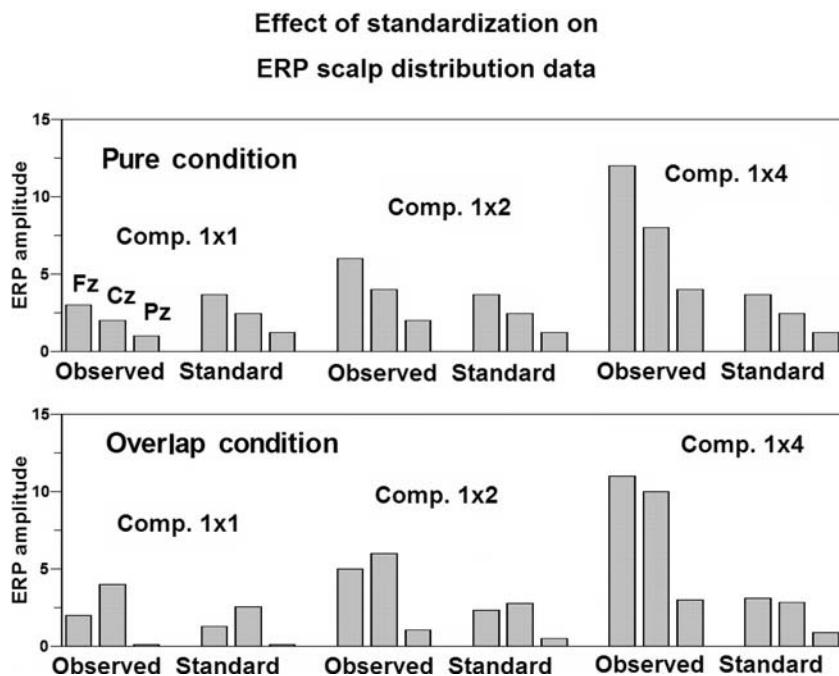

Figure 35.9. Effect of standardizing ERP scalp distribution data in conditions with different component amplitude and component overlap. **Top row:** data from a condition in which there is no component overlap (i.e., all the activity obtained at all electrode location can be attributed to one component). On the left are plots of the observed and standardized scalp distribution data from a condition in which the component is small. Standardization is obtained by dividing the data by the standard deviation across electrode locations. In the middle are similar plots for a condition in which the component has medium size. On the right are plots for a condition in which the component has large size. Note that plots of the standardized scalp distributions are identical for all component sizes. **Bottom row:** plot from conditions with component overlap. A component with central-maximum scalp distribution and fixed amplitude was added to the observed data presented on the top row. Note that the scalp distribution appears to change from a frontal to a central maximum as a function of component amplitude. Also note that the difference in scalp distribution is not eliminated by standardization.

maxima in the population, and is therefore quite robust. The method can be modified to consider the probability that the maximum is within a certain area. A limitation of the method is that it is “ad hoc,” though other bootstrap procedures can be used for different applications (Wasserman & Bockenholt, 1989). Other investigators have proposed other “distribution-free” methods for the analysis of spatial distribution data (Karniski, Blair, & Snider, 1994).

4.1.3. Intensity

Intensity is usually quantified using one of four approaches: (a) peak amplitude, (b) integrated activity over time (also called “area measure”), (c) covariance with a template (Fabiani et al., 1987), and (d) frequency of response. These measures are illustrated in Figure 35.10.

Peak and area measures are heavily dependent on the definition of a “baseline” level (i.e., these measures are taken by computing the difference between the peak, or the sum of the individual values, and the baseline; see section 4.3.1 for a discussion of baseline levels in psychophysiological measures), whereas the covariance measure requires some hypotheses about the shape of the response to be

studied. The response shape can also be obtained with statistical methods such as PCA or ICA. Area measures are less sensitive to high frequency noise than peak measures. However, empirical studies have shown that if a low-pass filter is applied before the peak measurement, the latter can be at least as reliable as area measures (Fabiani et al., 1987). Covariance measures can be used to separate the contribution of overlapping physiological responses, in which case a multiple regression approach can be used, and is quite reliable. Examples of covariance measures are given by estimates of the amplitude of different components of the ERP obtained with PCA (Donchin & Heffley, 1978) or with step-wise discriminant analysis (SWDA; Donchin, 1969; Donchin & Herning, 1975; Squires & Donchin, 1976). In these cases the covariance measures are taken with respect to a “weighting” function that has been optimized on the basis of statistical properties of the data (see the next section). Multiple regression approaches have been used to analyze hemodynamic data in complex, factorial designs (e.g., fMRI and PET). An advantage of this approach, compared to the more traditional “subtraction” methods used to analyze these data, is that it is possible to identify the effects associated with interaction terms on the brain image maps. However, the assumptions

underlying these methods – linearity and additivity – are as critical for these measures as they are for subtraction methods (see Sections 2.2 and 4.3.2).

All these measures are assumed to prove results along interval scales, which can be analyzed using parametric statistics. The error distribution tends to be skewed because of the fact that the range is usually limited at the lower end, but platykurtosis is not a problem as it was for latency measures. Amplitude measures may therefore be more reliable than latency measures (Fabiani et al., 1987).

Measures of the frequency of response are used for signals that are quite stereotyped and easily recognizable, but occur on a certain proportion of the trials or at irregular intervals. Note that, in many cases (e.g., blink or electrodermal responses), response frequency will not follow a normal distribution, and the distributions will be heavily positively skewed with some subjects exhibiting a large number of responses and others very few or none. Experimental variables will generally produce larger effects for the subjects exhibiting a greater base-rate of responses than for those exhibiting a smaller base-rate. For instance,

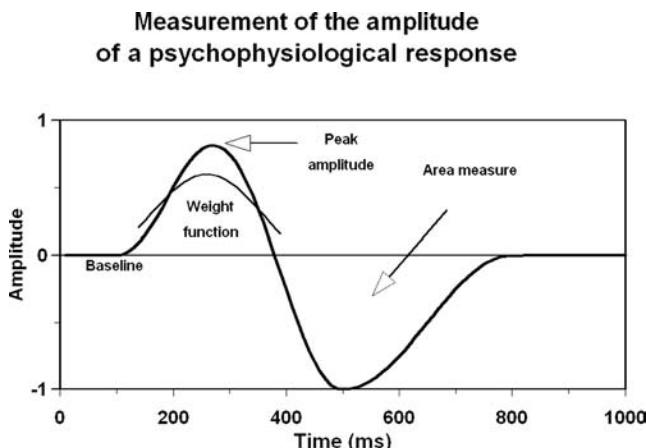

Figure 35.10. Different measures of the intensity of a psychophysiological response. Three measures are illustrated: peak amplitude, area measure, and weighted amplitude. Note that peak amplitude and area measures require a definition of the baseline value. Weighted amplitude measures can be made independent of the definition of the baseline.

all subjects may double their response frequency as a function of experimental manipulations. However, for those with a low base-rate this may generate a very small effect, whereas for those with a high base-rate the effect may be very large. This results in a large “subject by manipulation” interaction with a consequent reduced statistical power. In such cases, a logarithmic transformation of the response frequency may help increase the statistical power of the analysis. Alternatively, inferential analysis also can be conducted using a log-linear approach (Kennedy, 1984). For a discussion of other approaches, including standardization and re-scaling, see Ben-Shakhar (1985) and Stemmler (1987).

4.2. Statistical approaches to data reduction

As mentioned above, psychophysiological data are essentially multivariate. One of the major steps in the analysis is the reduction of the number of dependent variables, the number of which is often bewildering, to a smaller number appropriate for inferential analysis. Statisticians have developed a number of procedures to deal with the problem of data reduction on the basis of the statistical properties of the data. One of the simplest and most popular approaches is PCA (Donchin & Heffley, 1977). PCA is a statistical procedure for grouping dependent variables in a smaller subset of underlying (or “latent”) variables that possess the following properties: (a) they explain the variance and covariance of the original set of dependent variables as much as possible, and (b) are orthogonal to each other or, in other words, are uncorrelated. PCA components can be rotated (e.g., by using the procedure of VARIMAX) to facilitate interpretability. PCA components are interpreted in terms of their correlations (or covariances) with the original variables, which are also called “component loadings.” Donchin and collaborators wrote a

series of papers outlining the application of PCA to the analysis of ERP data. In this approach, ERP data are viewed as a data matrix in which data points are viewed as variates (i.e., dependent variables in a multivariate approach) and different subjects, conditions, and electrode locations are viewed as individual observations. A standard PCA is then run on the covariance matrix obtained from this data matrix. In most cases, a VARIMAX rotation is run on the results of the PCA. The component loadings are used to describe different components of the ERPs. These loadings are then used as sets of weights to compute component scores for each subject, condition, and location. The component scores are used as estimates of the amplitude of each component for each of the original waveforms, and submitted to inferential analysis (such as ANOVA). This approach has been used in a number of studies (McCallum & Curry, 1984; Karis, Fabiani, & Donchin, 1984; Squires, Squires, & Hillyard, 1975; Ruchkin, Sutton, & Stega, 1980), mostly because it provides separate estimates of the amplitude of individual components even when they overlap in time.

This PCA/VARIMAX/ANOVA approach has been subsequently criticized (Wood & McCarthy, 1984; Möcks, 1986; Möcks & Verleger, 1985) on the grounds that variance is misattributed to different components. Indeed, in principle, the subdivision of the variance into different components as obtained with PCA is entirely arbitrary, and there exist an infinite number of other ways of subdividing the variance on the basis of the same number of components. Therefore, it is unjustified to consider the components obtained with PCA as if they were physiological entities. Further problems with the use of PCA in the analysis of ERPs include the difficulty of incorporating latency shifts within the PCA model (Möcks, 1986) and possible correlations between components. However, PCA remains an interesting attempt at a principled way for data reduction, in which the original variance is retained as much as possible while the number of independent variables is minimized. This, as already mentioned, is one of the major goals of signal processing.

Recently, similar approaches have been proposed to address the issue of data reduction. For instance, Maier, Dagnelie, Spekrejse, and van Dijk (1987) have used a “spatial” PCA, in which the dependent variables used are spatial locations rather than data points, as a preliminary step for source analysis of ERPs. Spatial PCA has also been used to determine the number of active components at a certain moment in time, as a preliminary step for dipole analysis (see BESA; Scherg & von Cramon, 1986). A sequence of spatial and temporal PCAs have been recently employed by Spencer, Dien, and Donchin (1997), whereas Möcks (1988) has proposed a multivariate approach that also combines spatial and temporal information. Singular-value decomposition has also been proposed as an alternative to PCA (see EMSE; Greenblatt, 1996). A problem with most of these alternative approaches, just as for PCA, is that the results are not “unique” because an infinite number of

alternative descriptions of the data are possible. Furthermore, it is often difficult to interpret the results of the various data reduction procedures used and to compare results obtained in different experiments.

Independent component analysis (Makeig et al., 1997) has also become a popular method for data reduction. As with PCA, ICA is method to decompose the variance of a set of data in a set of underlying components. It is often associated with the problem of "blind source separation," which refers to the issue of separating simultaneous signals from a time series, for example, two speech signals occurring at the same time. This problem may be considered similar to separating different concomitant psychophysiological signals. However, in contrast to PCA, components are not selected by hierarchically maximizing the amount of variance they account for. Rather, the components are selected so as to maximize their statistical independence. The extraction procedure is more complex than in PCA. Several methods are available, which typically involve a stepwise procedure. ICA has been applied to many psychophysiological studies, with two major purposes: (a) separating signals from noise (e.g., ERP from eye-movement artifacts); (b) separating different types of brain activities from each other.

4.3. Other quantification issues

4.3.1. Absolute versus relative effects: The problem of baseline and reference

In a number of cases, psychophysiological measures are intended to reflect a change in a physiological variable from a level that exists prior to the introduction of an experimental manipulation (e.g., the presentation of a stimulus or the administration of a drug) to a level that exists after the manipulation. The level of the physiological variable before the manipulation begins is called the "rest," or "baseline," level. For some variables, this level is characterized by the absence of any measurable activity (e.g., there may be little EMG activity in a muscle at rest). However, most commonly, the targeted physiological systems are already active prior to the experiment, and remain active during the experiment, which is clearly the case for the heart and the brain. In these cases, the baseline level may change as a function of subject, location, and time of measurement. For this reason, most physiological measures are expressed as changes with respect to a baseline level. Determination of an appropriate baseline level is not always simple because it is not necessarily possible to induce a pure "rest" condition. In most cases, even when the experimental condition does not require a measurable overt response, the subject may be actively predicting and evaluating situations from both a cognitive and an emotional standpoint. In addition, the subject may be paying attention to internal or external stimuli that are not experimentally controlled. All of these psychological activities may influence the measurements obtained during the baseline period. If they do so in a manner that is systematically different from that observed at the time of

the experimental measurement, or in different ways in different experimental conditions, there is the possibility that systematic effects may influence the measurements. For instance, in most experiments using ERPs, measurements are taken as differences compared with a prestimulus baseline level. However, if subjects can anticipate certain properties of the stimulus during the prestimulus period, it is possible that an anticipation component of the ERP, for example, the contingent negative variation (CNV) may be elicited during this interval (Walter et al., 1964). The differential measures taken at a later time will then be affected by the presence of a CNV during the baseline period. The same may occur if the dependent variable is heart rate. In this case, expectation for an external stimulus may induce heart rate deceleration (Lacey, Kagan, Lacey, & Moss, 1963). Note, however, that if the interest is in comparing conditions in which anticipation can be expected to be the same, this is not necessarily a critical problem because a similar value is subtracted from both conditions. Because of this and other similar reasons, it is generally easier to compare activity observed in different experimental conditions than to draw conclusions from the activity observed in a single condition alone. In other words, it is much easier to consider relative than absolute effects.

Whereas the problem of the baseline or rest level is common to most physiological measures, some measures (e.g., ERPs) entail the problem of the reference. The term "reference" is used to indicate a comparison value that is valid for all points in space and is in contrast with the term "baseline," which is used to indicate a comparison value that is valid for all points in time. In some cases, physiological measures are obtained by considering the difference in electric potential between two locations. Electric potentials do not possess absolute values, but are defined as differences between two energy levels. Therefore, measures of electric potentials should be considered with respect to the locations that are involved. It is, however, possible to compare the difference in potential that exists between point A and point B and between point C and point B. If the first difference is more positive than the second, it can be concluded that point A has a more positive voltage level than point C. In this case point B will be used as a common reference point. If measures were taken only at a single point in time, then the point that is used as a common reference makes little difference. However, voltage measures often are taken at different times, and points of maximum difference (or peak values) are identified. The point at which A is most different from B may not be the same point at which A is most different from C. Therefore, the time of the occurrence of the peak on A may differ depending on whether B or C is used as a reference. For this reason, appropriate selection of a reference location is a critical aspect of recording electrical activity.

Historically, there have been three approaches to the problem of reference selection. The first approach is to consider measurements obtained between selected

pairs of electrode locations; the measurement is labeled “bipolar.” Bipolar measurements are common practice in the study of EMG, EKG, and EOG. In some cases, bipolar derivations are used to study local phenomena, as in the cases of EMG and EOG. In these cases, the two electrodes are placed very close to each other, so that activity generated far away is likely to influence the electrodes equally, (i.e. to cancel out each other), whereas activity generated locally is more likely to generate differences. This approach is adequate when the interest is in studying the time course of activity of relatively simple electric field configuration, such as for EMG and EOG, and, to some extent, EKG. For EEG studies, the bipolar approach fails to account for the complexities of the fields generated by the brain, and is only used in some clinical applications or special cases, for example, the recording of auditory brainstem averaged evoked potentials (BAEPs).

A second approach is to consider measurements from a number of locations as differences with respect to the same location (or to a common value). This approach is called a “common reference system.” There are a number of choices for the location of the reference value, including the ears, mastoids, nosetip, forehead, or locations outside the head (i.e., extracephalic reference). The latter may pick up electrical activity from the heart (EKG) and, therefore, require special compensation procedures (Fortgens & de Bruin, 1983). Finally, some researchers have advocated the use of an average reference, which is obtained by subtracting or adding a value to all of the observed locations, so that the algebraic sum of all of the potential values observed at different locations is equal to zero. Although arguments in favor of one or another of these systems have been proposed (Skrandies & Lehmann, 1982), there appears to be no clear advantage in using one reference system over another – the choice is arbitrary. However, because the selection of the reference may alter the shape of waveforms, including both the amplitude and the latency of the peaks, it is very important that the selection of the reference is made explicit and the same reference system is used when comparing across different data sets. The common reference system is the one most used in ERP research. Its greatest advantages are ease of computation and possibility of comparing values obtained at different locations. Its major drawback is the arbitrariness of the choice of the reference.

A third approach is that of using a transformation of the data, so that the data are expressed in terms of absolute dimensions (e.g., current flow) instead of relative dimensions (e.g., difference in potential). As seen above (Section 3.3.2), this can be achieved by computing the local gradient in potential instead of the difference with a common reference, but this requires the assumption of constant resistance between electrode locations.

4.3.2. Subtraction, comparisons, and linearity of the measures

In most cases, psychophysologists are interested in comparing physiological responses in two (or more) condi-

tions. The comparison process usually involves a study of the statistical reliability of differences between measures. This, in turn, involves computing several differences across subjects, time points, and locations. Data obtained in different conditions can be interpreted either along ordinal scales, which require using less powerful nonparametric statistics, or along interval scales, which may be analyzed using more powerful parametric statistics. The basic assumption of interval scales is that differences between intervals at any level of the scale are directly comparable. For example, the difference between the values 2 and 4 in some scale has the same significance as the difference between the values 22 and 24. This allows the investigator to subtract common terms and to compare data directly. We have previously considered a similar property called “linearity” (see Section 2.2).

Most psychophysiological measures, however, depart from linearity to some extent. One of the reasons is that the measures often have a limited range because physiological systems have feedback mechanisms that counteract extreme values in order to maintain homeostasis. For example, heart rate is very unlikely to drop below 40 beats per minute even under strong vagal activation. There are also other limitations because of the number of units (e.g., neurons) that can respond to particular stimuli. However, for most psychophysiological measures, there exists an interval of values for which linearity is valid. For practical purposes, it is advantageous that, if at all possible, measurements be taken in conditions in which the psychophysiological measures are within the range in which they exhibit linearity.

Range and scale differences may also vary as a function of subject or location on the body. For example, certain subjects may exhibit higher variability in a psychophysiological variable than others. Similarly, measures of a psychophysiological variable may have a greater range at a location than another. This will make it more difficult to compare data across subjects or locations. To counteract this problem, standardized measures in which the data are transformed, so to have equal means and standard deviations, are often used in these types of comparisons.

For a number of psychophysiological variables, it has been found that variability is correlated with the average level of the variable itself for a particular subject or condition. This relationship sometimes takes the form of “ceiling” or “floor” effects, which in psychophysiology often have been considered as examples of the “law of initial value” (Wilder, 1967). This would produce departure from linearity. Psychologists have often used special transformations (such as “logit” or “probit” transformations) to correct these forms of departures from linearity. In other cases, effects are proportional to the original value. In these cases, a logarithmic transformation of the data (or the division by the average value) may equalize variances (and differences) across conditions, and produce a scale that has linear properties. For a discussion of several procedures for comparing conditions with different base rates see Wainer (1991).

5. CONCLUDING REMARKS

This chapter has reviewed several issues related to the analysis of psychophysiological data. In most cases, procedures used in data analysis can be viewed as an effort to extract meaningful information from the data that are often under conditions in which the data are noisy. In these cases, the majority of the data-analyst efforts are devoted to increasing the signal-to-noise ratio. Although there are procedures that increase this ratio under all conditions, it is often the case that a priori hypotheses about what types of signals to expect will help in the design of appropriate analysis procedures. These a priori hypotheses do not necessarily have to be very specific (i.e., activity at a particular latency and at a particular location is determined by factor A or factor B). Even simple hypotheses, for example, that some activity should be observed somewhere during a particular latency interval or at a particular location, will help design appropriate analytical methods. However, in general, the power of the analytical procedure increases with the specificity of the hypotheses that are entertained.

It is often the case that psychophysiological phenomena are quite complex and unpredicted effects are obtained in a number of studies. In some cases, discovery of these new effects is what affords the greatest scientific advancements. This generates a dilemma for the data analyst – how can maximum power be obtained, while still maintaining a wide focus in the analysis? In most cases the answer is in alternating studies conducted with an “exploratory” attitude, which enables the investigators to detect unexpected findings, with other more “hypothesis-driven” studies, which provide more rigorous tests of specific hypotheses. This problem emphasizes that data analysis needs to be integrated with experimental design in a bidirectional fashion.

Data-Storage Formats in Neuroimaging: Background and Tutorial

JOHN D. HERRINGTON, BRADLEY P. SUTTON, AND GREGORY A. MILLER

The growth and development of spatially multidimensional electromagnetic, hemodynamic, and optical data analysis methods in psychophysiology over the past two decades have been substantial but also fragmented. This fragmentation is partly attributable to the diversity of backgrounds of researchers using positron emission tomography (PET), magnetic resonance imaging (MRI), and dense-array MEG and EEG (in few if any other research contexts do psychologists, chemists, engineers, psychiatrists, radiologists, neurologists, and physicists so regularly work alongside one another), as well as competition between commercial interests to develop or protect proprietary standards, methods, and software. Although the parallel distributed nature of psychophysiological analysis methods development can foster creativity, it sometimes comes at the cost of clarity and comparability of methods and data across research laboratories. With an estimated 1500 new functional MRI (fMRI) studies per year producing an estimated 30–50 terabytes of data per year (Kupfer, First, & Regier, 2002), issues of data storage, data access, and transparency of methods have become critical. Most urgently, the recent development of fMRI methods as a sort of multinational cottage industry complicates the development of shared expertise and increases the risk that home-grown methods from one laboratory may be underutilized or incorrectly applied by others.

Furthermore, as the applications of functional imaging techniques cross disciplines, the consequences of misunderstanding these techniques increase. Whereas clinical applications of fMRI and MEG are presently rare, they will certainly be common within a few years, especially in applications such as presurgical planning. The use of functional imaging in clinical settings requires an awareness of data formats and spatial coordinate systems both within and across modalities (as in, e.g., the coregistration of structural MR images with EEG data). A failure to understand something like the orientation or spatial localization of imaging data could have tragic consequences for individual patients. Clearly, it is the responsibility of professionals who use this technology to take every precaution to avoid these types of errors.

Fortunately, despite the fragmentation of brain-imaging methods in research and clinical settings, in most cases their foundational principles are quite consistent. This includes the format in which MR data are stored, which may differ across research groups and software packages, but follows some basic principles. The present paper is intended as a tutorial on some of these principles and emphasizes critical concepts of data formatting and storage, differences across computer platforms, and techniques for representing and documenting multidimensional data in the unidimensional space of computer RAM and storage media. Although the formatting of MRI data in the spatial frequency domain (e.g., k-space) is considered briefly, the paper focuses on data in the image intensity domain – the domain typically preferred in fMRI data analysis. Two of the most common data formats used in fMRI research, Analyze and DICOM, are used as examples of how these principles are operationalized. In general, the presentation is geared toward structural and functional MRI as typically used by researchers in psychophysiology and cognitive neuroscience (the terms are synonymous for present purposes). However, most of it is equally applicable to other typically multidimensional data in psychophysiology such as PET, EEG, and MEG.

THE STORAGE OF MRI IMAGE INTENSITY VALUES

Common storage formats share a few basic principles related to how the intensity data are represented. The signal intensity in each voxel of a MR image depends on the number of protons in that voxel, the particular imaging sequence used (and the timings intrinsic to that sequence), the relaxation times of the protons, and proton transport properties such as flow and diffusion. MRI scanners generally record the spatial frequency (k-space) of the voltages these protons induce in the receiver coils. As described below, either for initial data storage or later in the analysis path, an inverse Fourier transform is used to convert values in k-space to per-voxel magnitude values.

The value of each point in k-space is recorded as two numbers, referred to as “real” and “imaginary”

components, respectively. Therefore, when MR scanners save k-space data to disk, two integers must be saved for every sampled frequency. As a result k-space data files tend to be very large. The format of k-space data files depends on a variety of factors, including the type of imaging sequence and MRI console software used. To date, there appear to be few if any standards for k-space file formats; this information typically has to be obtained directly from scanner manufacturers. This lack of consistency is highly unfortunate because it complicates the development of new algorithms and software to manipulate and convert k-space data.

With the exception of flow-encoding sequences, the k-space data are converted from spatial frequency to spatial location via a complex manipulation of the real and imaginary components of the spatial frequency signals. After this conversion, the data are generally ordered in a manner that reflects spatial organization, in which values represent the intensity of the MR signal at each location (i.e., each voxel, for “volume element”). MRI raw data files store voxel values as binary integers. However, the number of binary digits (bits) comprising the data values (often referred to as “bit depth” and determining precision) varies depending on the type of image and software used. Analysis software must know the storage precision of a given MRI data file for the data in that file to be interpretable. This information is typically stored in the header for a given image (see the section below on headers).

Storage precision. The precision and bit depth of the integers comprising a MRI data file dictate the range of numbers that can be represented by that integer.¹ For example, if a file uses 16-bit integers, and all 16 bits are used to represent a value, the range of numbers that that integer can represent is 0000000000000000 to 1111111111111111 in base 2, which is 0 to 65535 in base 10. (This range contains 2^{16} values. Zero counts as one of the 65536 values, so the last value is $2^{16}-1$.) Integers that use all of their bits

¹ Binary (base-2) numbers are readily convertible to base-10 numbers by multiplying each bit by two, raising the resulting number to a certain power in base 10, and then adding up the results for the bits. The power to which each binary digit is raised is dictated by the ordinal position of that number within the number and by the endian format of the number (discussed in the main text). The 8-bit binary number 11111111 interpreted in little-endian format will serve as an example. The first step in the conversion, multiplying each of these numbers by two, results in the number 22222222. In the second step, each 2 is raised to a power corresponding to its position among the eight digits, beginning from the right-most position, here denoted position zero. Moving across the numbers from right to left, the second number is therefore in position 1, the third number is in position 2, and so on. Raising each digit to a power corresponding to its position, the set of eight 2s becomes $2^7 \ 2^6 \ 2^5 \ 2^4 \ 2^3 \ 2^2 \ 2^1 \ 2^0$. Summing these eight values produces the value 255 in base 10. I.e., $11111111_2 = 255_{10}$. Given that at the other extreme the binary number 00000000 has the value 0 and that an eight-bit binary number can have any combination of 0s and 1s, the eight binary digits can represent $2^8 = 256$ different values, from 0 to 255.

to represent a number are called “unsigned” because they do not contain any information to indicate whether the number is positive or negative. In practice, the number is assumed to be positive. “Signed” integers, on the other hand, reserve one of the bits to indicate whether the integer is positive or negative (e.g., a bit value of zero represents a positive integer, and one represents a negative integer), which leaves one less bit available to indicate the absolute value of that integer. A signed 16-bit integer therefore has a range of -2^{15} or $+2^{15}$, or -32768 to +32767. (Zero counts as one of the values, so there are still $2^{16} = 65536$ possible values.) This example illustrates that the choice to use a signed or unsigned integer does not affect the resolution that can be achieved – both signed and unsigned 16-bit integers can represent up to $2^{16} = 65536$ different values.

The choice of signed versus unsigned integers for MRI data rests largely on whether negative values have a sensible interpretation.² The desired signal for most MR studies relies on a relationship between the magnitude of the voxel intensity and other properties, such as the number of protons in the voxel, contrast from acquisition timing, and hemodynamics. For that reason, in MRI only magnitude information is retained routinely in raw the MRI image files. Because of the illogic of obtaining a negative MRI image intensity, raw MRI files use unsigned integers. However, for subsequent data files in the analysis path that are structured like MR volumes but whose values represent the results of scaling or demeaning operations or statistical comparisons such as z-scores or correlations, the values could be negative as well as positive. In this case signed integers are the straightforward choice. Such values may be stored as floating-point numbers rather than integers and commonly consume 32 or 64 bits per value as discussed below.

The selection of storage precision. The MR machine will observe some range of voltages measured from the receiver coil, amplify these voltages and digitize them with an analog-to-digital converter (ADC). The ADC has a range of voltages (its input) that it maps linearly onto a range of integer values (its output). The storage precision in the raw data is a function of the number of different values the ADC can output, which is determined by the number of bits in each integer. As discussed above and in footnote 1, an n-bit ADC can represent 2^n distinct values. This degree of granularity must provide sufficient resolution to capture the smallest variation in signal that one hopes to find and interpret. In principle, the choice of signed versus unsigned integers has no bearing on resolution. It is bit depth of an integer that critically impacts the range of values (and, therefore, the intensity resolution) that can be represented.

² In addition to the representation of integers as unsigned or signed as described above, a third method is available. This method uses an implicit offset implemented as one’s-complement or two’s-complement. This method is not typically used in MRI data formats and will not be considered further.

In the fMRI literature, researchers often find statistically significant differences between signals that change little – usually less than 5% of the actual signal, often less than 1%. In order for an integer to be able to represent a difference of 1%, it must be able to represent at least 100 values. If the bit depth is 8, which allows representation of 2^8 or 256 different values, even the smallest binary integer representation would typically suffice to contain adequately detailed numeric information for calculating robust statistics on differences in MR signal. However, this would be workable only in an ideal case, in which there is no quantization noise from the ADC process, and every voxel of the image uses the full extent of the available range of values without overranging. In practice one needs more resolution. Furthermore, in addition to resolution, one needs to consider the dynamic range of potential values over both spatial and temporal dimensions. For example, there may be slow drift during a recording session, on top of which one wants to be able to observe a 1% change. One might need far more than 100 values to accommodate both the change in baseline and the more rapid changes of interest. At least 12 bits (i.e., the DICOM standard for file storage and transfer) and often 16 bits are commonly used to represent fMRI signal intensity data in the hope that small variations in signal can be captured despite sampling error and other issues, such as a wide range of absolute magnitudes seen across tissue types and subjects. It should be noted that the actual resolution depends not only on the bits allocated to store a value but on how that value was obtained in the conversion from frequency to spatial intensity values. For example, a given processing step might use only 12 bits of information, while storing values in 16-bit integers. Resolution cannot be added: the 16-bit value would still have 12 bits of information.

Floating-point representation. Statistical operations with fMRI data are generally computed via floating-point arithmetic conceived in base-10 numbers. This is often done on a voxel-by-voxel basis with computational results stored in the same structure as the raw data. That result is referred to as a statistical parametric map (SPM) or a “stat map.” Although fractional numbers can be represented in fixed-point integers by adjusting the implicit decimal place, floating-point arithmetic allows for the storage of a varying number of decimal places and a wide range of magnitudes. As with bit depth, the preference for floating-point numbers is largely a matter of how those numbers will be directly interpreted. In fMRI statistics it is often meaningful to interpret fractional numbers. For example, in a “normal” distribution, only 5% of values fall outside $+/-1.96$ standard deviations from the mean and exceed the conventional p-value threshold of 0.05 (two-tailed) in statistical hypothesis testing.

Floating-point number storage in computers is typically implemented and interpreted in terms of standard scientific notation. The bits storing each value typically

are allocated among three elements: the sign, the mantissa (a number between 0.0 inclusive and 1.0 exclusive with some finite resolution based on number of bits allocated to it), and the exponent (the power to which 10 is raised, also with some finite number of bits allocated, thus limiting the range of exponents). Any 32-bit representation can take on 2^{32} values (i.e., approximately 4 billion). A 32-bit floating-point number typically allocates one bit to indicate the sign of the number, with some of the other 31 bits representing the mantissa, and the remainder representing the exponent. The balance between these allocations depends on hardware and software choices that affect the resolution and range of numbers that can be represented. A 64-bit floating-point number provides additional resolution, range of mantissa and exponent, or both. Knowing whether the numbers are 32- or 64-bit and how many bits are allocated to the mantissa versus the exponent can be imperative when writing one’s own analysis software and, in some cases, when using others’ software.

Big-endian and little-endian representation. For binary numbers that are longer than 8 bits, modern computers usually allocate space in multiples of 8 bits referred to as bytes. Most numbers in RAM or on disk are stored in adjacent storage units that each consume more than one byte. For example, 16-bit or 32-bit fixed-point (integer) values and 32-bit or 64-bit floating-point (real) values consuming 2, 4, or 8 bytes are now common, and 64-bit integers will become common as 64-bit central processing units (CPUs) become widespread.

Importantly, the way that multibyte values are stored is not identical across brands of CPUs. In a manner analogous to the difference between written languages that are read left to right versus right to left, CPUs differ in whether the high-order byte is stored in the first- or last-addressed byte within a multibyte storage unit. As a result, problems may arise in transferring binary data between computing platforms. It may be that the bit order within a byte, the bit order within a multibyte storage unit, or the byte order within a multibyte storage unit should be inverted to accommodate the way the target machine processes binary values. Failure to adjust the storage format appropriately could produce arbitrarily corrupted data. The details of this issue depend not only on the storage format for each CPU but on whether ASCII, integer, or real values are used and whether, for real values, the source and target CPUs use the same conventions for allocation of bits to the sign, fraction, and exponent. Besides these hardware differences, software may assume different sizes of storage unit assigned to a given type of data, for example 32 bits versus 64 bits for real numbers. Software may read a data file as if it is composed of 32-bit values when it is actually written with 16-bit values.

In evaluating how these issues are dealt with in different CPUs investigators may encounter inconsistent

terminology. "Endian-ness" is sometimes used to refer to the standard storage order for a given model of CPU, but typically refers to whether the lowest or highest addressed byte contains the least significant portion of a number. (See http://www.rdrop.com/~cary/html/endian_faq.html for a detailed discussion of endian-ness.) Endian-ness is important to consider in MRI analysis, given that many research groups regularly move data between machines running Windows or versions of Unix (e.g., Mac OS, Linux, or Solaris) because the transfer may involve a mix of "big-" and "little-endian" machines. Most CPUs in the traditional Unix world (e.g., Sun SPARC) are big-endian and interpret the highest addressable byte as containing the least significant byte (LSB), whereas x86 CPUs common in the Microsoft Windows world (e.g., Pentium, Xeon, Athlon, Opteron) are little-endian and interpret the lowest addressable byte as containing the LSB. The Linux variant of Unix is available for all of these and other platforms. At the hardware level, the IBM/Motorola/Apple POWER CPU architecture used in most Apple Macintosh PCs can handle either order, depending on software settings. Apple recently began to migrate the Macintosh operating system to x86 CPUs, and Sun now sells x86-based machines as well as SPARC-based machines. Thus, the endian issue can arise within a brand of computer. It can also arise at the very beginning of the data path. For example, in recent years the manufacturer has changed the console of the Siemens Allegra 3T system from a big-endian to a little-endian CPU.

Another source of inconsistency is that endian-ness may refer to how bytes within a storage unit are processed versus how bits within a byte are processed. LSB may stand for "least significant bit" rather than "least significant byte" (and MSB for "most significant . . ."). The common practice of referring to this storage issue in terms of "left-to-right" versus "right-to-left" addressing can be confusing because there is no left or right in RAM, there are only ascending or descending addresses. Generally, data stored in ASCII format are immune to this cross-platform storage-order issue, but transfer of data written in binary should be done with an understanding of the formats on both ends.

Fortunately, converting between little- and big-endian representations of binary data is straightforward. However, users may not know when this conversion is needed, especially if data have been moved across several machines. There may be no way to tell from a data file containing binary integers whether it was written in big- or little-endian format, except when, examining the numbers, one way of reading the integers makes more sense superficially (e.g., the numbers fall within the range that one would predict given that one is examining an MR intensity image, statistical map, etc.).

Rather than relying on such a fallible judgment call, users have three choices: (1) stay on a single platform and confine analyses to software explicitly designed for that platform, which ensures invariant (if unknown) endian-ness at the cost of limiting one's analysis options; (2) con-

struct a data set with known values designed to test the storage-order properties of the cross-platform data path and run appropriate comparisons; or (3) rely on unambiguous documentation. Often in MRI work, such documentation is stored in a file header, which may be part of the same file containing the image data or may be an associated but separate file. Thus, information is usually stored in the file header specifying whether the data are in big- or little-endian format. One notable exception to this is the header file of images that are in Analyze 7.5 format, which is one of the most widely used formats in the MRI literature. According to the Analyze 7.5 standard (see <http://www.mayo.edu/bir/PDF/ANALYZE75.pdf>), in the header there is no specific information regarding whether that header and its corresponding integer data were written in big- or little-endian format. The developers of MRI analysis software packages SPM (<http://www.fil.ion.ucl.ac.uk/spm>) and FSL (<http://www.fmrib.ox.ac.uk/fsl/>) have adopted various solutions to this problem. FSL software capitalizes on the fact that the first field within an Analyze format header contains an integer representing the size of that header file, which is typically 348 bytes. FSL programs read the first entry in the header in the endian format native to the machine running the program and check to make sure that the first integer represents the number 348. If it does not, the software converts the number to the complement endian format and checks whether the result is 348. If this is the case, the FSL software assumes that conversion is necessary for the image data as well and converts to the proper endian format when reading the data.

The issue of endian format is a prime example of a potential problem for MRI analyses that can go undetected during the analysis process unless particular care is taken. It is also an important consideration for researchers writing their own software to work with MRI data, especially if they intend to use the software across platforms or on data that have crossed platforms. To take one example, using a programming language common in the MRI, EEG, and MEG literatures, the syntax for some Matlab functions that read and write binary data (e.g., fread and fwrite) differs when working with big-endian versus little-endian byte-order formats and must be modified accordingly. Even the pervasive Matlab function that opens a file (fopen) allows the user to specify whether the contents are to be interpreted in big- or little-endian formats.

THE STORAGE OF MR DATA FILES: IMAGE FILE FORMATS

Commercial MRI manufacturers provide more or less integrated systems for acquiring, viewing, and storing MR data at the console, but these systems are often incompatible across manufacturers and models and are often not designed to anticipate the ever-growing variety of research applications for MRI because their primary market is routine clinical scanning. This market relies primarily on

(from a research perspective) a very limited analysis, which is rapid and standardized. The native file storage format of manufacturers differs is not an issue in the clinical market because clinical users rely on processed output. Nevertheless, MRI data formats have converged sufficiently to share a number of common design elements. These elements apply equally to MR images (functional or structural) and statistical maps based on those images. Although the two forms of data may differ in integer size and precision (as noted above, more bytes are often required for statistical maps), they typically use similar file formats. The following is a description of the major common elements of MRI image files in terms of two storage-format standards, Analyze and DICOM.

Image data and headers. The header of an MR image is a file or a portion of a file that contains descriptive information about the image. MRI header information may be stored with the intensity data in the same file (as in the DICOM standard) or in a separate file (as in the Analyze 7.5 standard). The header information may be stored as simple ASCII text, as binary integers, or as a combination of the two.

A critical aspect of writing software to work with MRI data is having detailed documentation of the precise format and content of the image header. Depending on the standard in question and how it is licensed, this information may be more or less accessible by individual researchers and software developers. On one hand, the format of an image file and its header may be publicly unavailable, necessitating the purchase of and reliance on software developed by the company creating the standard. On the other hand, detailed information for some image formats is considered open-source and can be acquired easily via the internet or from the group responsible for the standard.

MRI file headers typically contain at least two types of information that describe the data they represent: scan parameters and details regarding the layout of the intensity data in the file. Some headers also contain information regarding the individual from whom the MR data were collected. This information as well as the scan information often represents an important historical record, but the information related to data layout may also be critical for working with the actual image data. Misunderstanding the relationship of the layout of integers in an image file, which is inherently 1D in computer storage, to the 3D structure of the object imaged can result in a variety of misinterpretations of MRI data and thorough compromise of research findings.

Image orientation. In order to understand how headers can describe the multidimensional layout of imaging data, it is critical to be familiar with a few basic principles of how MRI data are organized. The storage of MRI data starts with a fundamental problem: how to represent 3D spatial information (and 4D, when 3D volumes are acquired

repeatedly over time) stored in a file that is essentially a 1D vector of data? This problem applies equally to 3D k-space data and 3D or 4D intensity data in real-world space. With k-space data, each point is typically saved to disk in the temporal order it was sampled during data acquisition. The order in which k-space values are saved therefore reflects the particular scanning trajectory used (e.g., rectilinear, spiral, or radial spoke).

The general solution to this problem with respect to image intensity data is to start with intensity values from one corner of 3D (or 4D) space, moving through each dimension in succession, and save them to the file on disk. The nesting order of the traversal of these dimensions and the direction in which each dimension is traversed are critical. Taking a single axial 3D structural MR volume as an example, one may chose to store intensity values by beginning with the inferior, posterior, leftmost corner of the volume and proceeding one voxel at a time toward the anterior end of the head. Then, moving one row of data to the right, one proceeds again anteriorly until that slice is completed, and then moving one slice superior repeats this procedure until the entire volume is stored. If multiple volumes are obtained over time, the temporal dimension is likely written as the slowest moving dimension (although it may not be slowest moving in subsequent analysis). Two important decisions were made in this example: the nesting order of the dimensions and what end of each dimension to start from. (In the standard of Talairach and Tournoux (1988) X refers to the dimension from left to right in the brain, Y from back to front, and Z from bottom to top. However, the convention in some of the EEG and MEG literature interchanges X and Y.) Given these two considerations, there are 48 ways in which a 3D array of data can be stored in a 1D vector (i.e., $3!$ possible dimension nesting orders * 2^3 possible direction combinations). In the case of 3D functional MRI data acquired over time (i.e., 4D), there are 384 possibilities ($4! * 2^4$), although it is unlikely that initial data storage formats would interperse the time dimension with the space dimensions or reverse the ordering in the time dimension. These principles are fundamentally quite simple, but their consistency and salience are essential if the detailed spatial information of MRI is to be treated correctly.

One of the most significant potential problems in processing MRI data is the failure to adequately document the translation between 1D computer storage and the multidimensional image. A number of terms and coding systems have emerged to represent this correspondence – terms that fall in and out of favor over time. Confusion about this is a frequent topic on MRI email discussion lists. One of the most common ways of characterizing the layout of MR data is to refer to the “orientation” of the data. The MRI research literature has adopted from medicine the terms “neurological” or “radiological” orientation, which are rooted in metaphors referring to where a caregiver might choose to stand while observing a patient. The metaphor is based on the assumption that a radiologist

would view a patient lying face-up on a table while standing at that patient's feet. Thus, the left side of the patient's body (and brain) would appear to the radiologist's right side, and the patient's right side would appear to the radiologist's left side. Metaphorically, in the case of neurological orientation, the neurologist stands at the patient's head, and thus the patient's left side appears to the neurologist's left side.

As initially conceived, these terms refer specifically to how one identifies which side of the body (or brain) one is looking at. The left/right dimension is the most difficult to determine by visual inspection because of the body's gross lateral symmetry. In recent MRI research the meaning of these two terms has been extended to refer to how spatially organized data are written in an inherently unidimensional data file. Thus, a file may be described as storing data in radiological or neurological orientation. These terms should be used cautiously because the degree to which there is agreement on these meanings is unclear, and in any case they do not completely specify the mapping of 3 or 4D space into the 1D space of a data file.

Another orientation coding system, which has become more common in MRI research, uses a sequence of three letters to indicate both the nesting order of and direction along which the three spatial dimensions are stored in a 1D vector. The letters L, R, A, P, S, and I refer to each pole of the three dimensions corresponding in brain space to Left and Right in the X dimension, Anterior and Posterior in the Y dimension, and Superior and Inferior in the Z dimension. The selection of and order in which the letters are combined dictates the order in which the dimensions are written. For example, in an image file described as RAS, the order in which each dimension is stored as a 1D vector is unambiguously X, then Y, then Z. In addition, these letters indicate that, when moving from the beginning of the 1D vector of data toward its end, one is moving *toward* or *away* from that pole (as *toward* that pole is more common, we will adopt this convention here). For example, if one of the letters in the code is R, the data are ordered from the left to the right side of the brain. Thus, this coding system efficiently conveys the mapping of 3D data into a 1D vector. Although the time dimension is not represented in this system, it is assumed that 3D images are stored in forward temporal order with time being the slowest moving dimension. When researchers refer to neurological and radiological orientation as aspects of the storage layout of image files, according to the above letter coding system, neurological orientation is coded as RAS and radiological orientation is coded as LAS. Though, as mentioned above, the use of the terms neurological and radiological in reference to anything other than how images are displayed should be avoided.

The Analyze 7.5 standard. "Analyze" refers to a program for examining medical imaging data as well as the default data format program's (see <http://www.mayo.edu/bir> and <http://www.mayo.edu/bir/PDF/ANALYZE75.pdf> for An-

alyze software and format information). Although newer versions of the Analyze file format have been developed, Analyze version 7.5 remains the most used standard and has been the native format for a large number of MRI programs including SPM and FSL.

The Analyze 7.5 standard associates two separate files for each image – one contains the intensity data, the other a header. Names for these files typically have .img and .hdr extensions, respectively. The header for Analyze 7.5 contains basic information about the scan, including some information pertaining to the orientation of multidimensional images in the 1D file. Table 36.1 is an example of the contents of an Analyze 7.5 header output by the FSL program avwhd (for FSL software see <http://www.fmrib.ox.ac.uk/fsl/>). The number of blank fields in the table suggests that not all software alters or uses every field in the header.

The header specifies six numeric values that can be used to identify a specific 1D orientation for the image (see the orient field in Table 36.1):

0 = transverse unflipped	3 = transverse flipped
1 = coronal unflipped	4 = coronal flipped
2 = sagittal unflipped	5 = sagittal flipped

The orientation term (transverse, coronal, or sagittal) specifies the nesting order of the 3D in the 1D vector. Using the Talairach and Tournoux (1988) meaning of X, Y, and Z, the "transverse" format nests X within Y within Z, the "sagittal" format nests Y within Z within X, and the "coronal" format nests X within Z within Y. "Unflipped" data move from right to left, posterior to anterior, and inferior to superior. "Flipped" data move in the opposite directions.

This system unambiguously specifies the organization of 3D data in an image file, but it does not allow for the coding of most of the 48 different ways in which 3D data can be stored in a 1D vector. Because of this limitation, software that relies on this field within the header for spatial information is prone to error. As a safety feature, many MRI programs ignore this field altogether.³ Furthermore, the Analyze 7.5 standard does not address the time dimension, though as noted above this dimension generally does not vary across file formats. Newer image standards based on the Analyze format have improved on some of the limitations of Analyze 7.5, although these newer versions have yet to achieve widespread use.

The Analyze 7.5 header contains a variety of additional information – information about the size and organization of the voxels is most relevant here. However, not all of these fields contain information that is typically relevant for fMRI researchers. For this reason, some fMRI software (including SPM and FSL) deviates from the Analyze 7.5 standard by using nonessential fields to hold other, more relevant information. For example, SPM uses the

³ FSL software does tag the left/right orientation of images by using a negative integer in the pixdim field of the header.

Note: The contents of the Analyze 7.5 header file corresponding to the image avg152T1.hdr, one of the brain templates accompanying the FSL software package. See the Analyze 7.5 technical documentation (<http://www.mayo.edu/bir/PDF/ANALYZE75.pdf>) for more information about each field.

space allocated to the “originator” field of the Analyze 7.5 standard to contain three fields, which are referred to collectively as the origin (one field for the x, y, and z coordinate; see the origin1, origin2, and origin3 fields in Table 36.1). These fields facilitate the coregistration of Analyze files by providing a common location for aligning images. For data that have been registered into the stereotactic space of the Talairach and Tournoux standard (1998), these coordinates are often used to specify the location of the anterior commissure. However, they could be set to any coordinate triplet in the 3D space of the image. (It is assumed that, if a file is 4D, each 3D image within that file is essentially aligned. Therefore, the origin applies to all volumes in the 4D file.) However, reliance on the origin fields can complicate attempts to overlay images collected using different software and protocols that treat this field differently. If steps are not taken to assure that the origin fields of different headers are matched to the same anatomical landmark in 3D space, then programs relying on these coordinates may output grossly inaccurate results. This problem is of course not unique to the Analyze 7.5 format. It would apply to any format containing origin fields.

Recently a group under the Neuroimaging Informatics Technology Initiative (NIfTI) developed a new image format, which is also titled NIfTI (<http://nifti.nimh.nih.gov/dfwg>). The NIfTI format uses the Analyze 7.5 header as a framework, but embeds additional information within it regarding image orientation and data acquisition parameters. The NIfTI format also allows for options in storage precision and data organization that are not standard under Analyze 7.5 (see <http://nifti.nimh.nih.gov/pub/dist/src/> for commented source code to read and write headers in this format). This format has been integrated into recent versions of some analysis packages, including FSL and AFNI (<http://afni.nimh.nih.gov>), and SPM is said to be committed to support it as well. Because NIfTI is new and still under development, it is not clear how widespread it will become, but it has been carefully designed via a consensus process to address important issues in neuroimaging data formats.

The DICOM standard. The Digital Imaging and Communications in Medicine (DICOM) standard was first published in 1985 by the American College of Radiology and National Electrical Manufacturers Association (Bidgood & Horii, 1992). This standard (available from <ftp://medical.nema.org/dicom/>) is well over 1000 pages long and much of its content is tailored to individuals with substantial expertise in software engineering. DICOM is primarily an image data transfer protocol not limited to MR images, for which the image formatting information is just one part, but the format specified in the conformance standard has become common across MRI scanners. In various manufacturers’ implementations, the standard is sometimes customized in proprietary ways, such that in practice it is not a single, uniform standard.

DICOM header and image information is stored together in a single file. Because the DICOM image format standard is designed primarily for use by professionals in clinical medicine, its header allocates space for a substantial amount of information related to the individual being imaged (e.g., name, height, and weight). This can complicate attempts to maintain confidentiality. In fact, after data collection many researchers use software that “anonymizes” these headers by blanking fields containing identifying information. DICOM headers also contain more detailed information about the scan parameters used to generate the image than is true of other formats such as Analyze 7.5.

The DICOM header contains what are referred to as public and private fields. Public fields are considered strictly standardized and contain specific values with predefined meanings. Private fields, on the other hand, can contain values defined uniquely by different programs and manufacturers. This is one factor leading to the development of multiple versions of DICOM and can cause some compatibility problems across software. In a sense, DICOM is not truly a standard but a template with a variety of instantiations.

The way DICOM treats image orientation has evolved somewhat in recent years. The 2004 version uses what it refers to as a “patient-based coordinate system,” which would be coded as LPS in the three-letter coding system discussed above⁴. Additionally, the DICOM header provides coordinate information that specifies the location in real space (e.g., mm) within the field of view of the first voxel of data transmitted from the scanner. It also provides the direction (in real space) of each subsequent voxel relative to the patient’s axis.

CONCLUSION

The availability of affordable digital computers led to a boom in the number of EEG labs worldwide and opened

⁴ All information from this paragraph is taken from the 2004 revision of the DICOM standard, NEMA Standards Publication PS3.3, section C.6.2, pp. 237–238. NEMA has published multiple revisions to their original standard since 1985 (most recently, American College of Radiology and National Electronics Manufacturing Association, 2006).

up the technique to a broader array of professionals. With this increase came the necessity to articulate a standard set of basic methodology issues, principles, and practices for EEG studies to facilitate the shared understanding of EEG research (e.g., Donchin et al., 1977; Pivik et al., 1993; Picton et al., 2000). The much younger field of hemodynamic neuroimaging has much to learn from the decades of developing EEG methods. The recent explosion of hemodynamic imaging studies owes much to the advance of personal computers that are able to process very large datasets rapidly. As with EEG, the growth of these techniques must be accompanied by the ready availability of resources for understanding them. With this objective in mind, this chapter has covered some fundamental aspects of MRI data storage and formatting. These principles, in turn, can be applied to EEG, MEG, and optical imaging research that employ increasing numbers of recording channels.

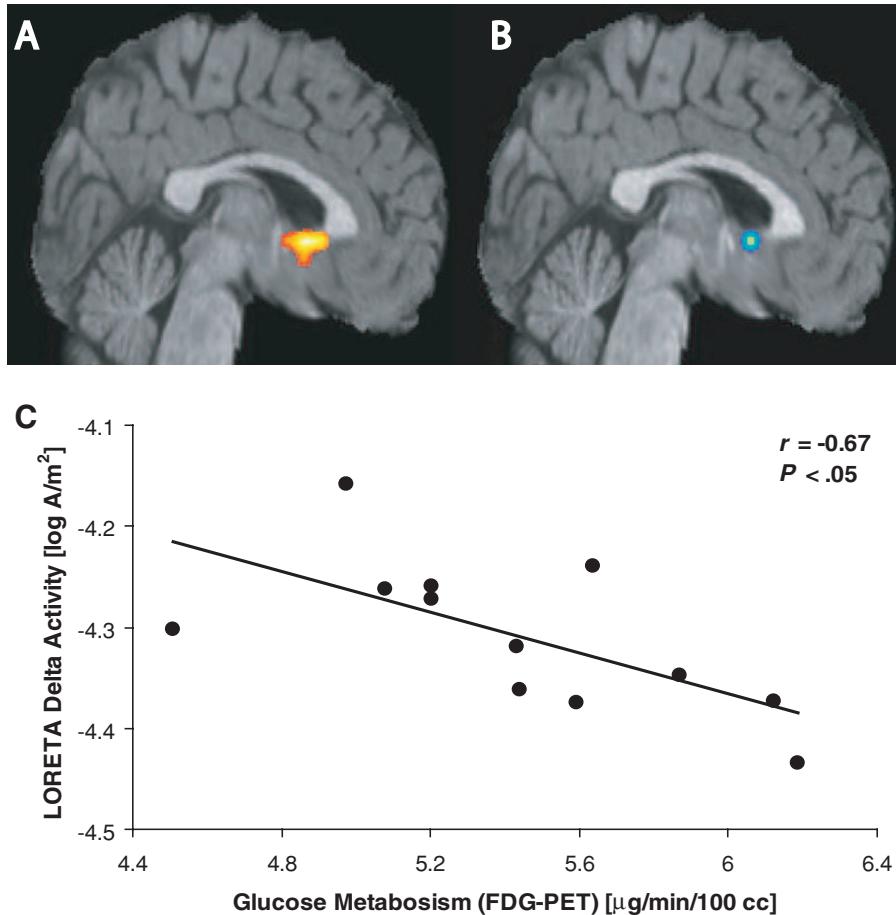

Plate 1. Reciprocal relation between delta activity and glucose metabolism. In a recent study integrating concurrently recorded electric (28-channel scalp EEG) and metabolic ($[^{18}\text{F}]$ -2-fluoro-2-deoxy-D-glucose positron emission tomography, FDG-PET) measures of brain activity, melancholic depression was characterized by (A) significantly increased delta current density (see yellow-red colors), as assessed with LORETA (see Section 8.2.3.); and (B) significantly decreased glucose metabolism (see blue colors). Statistical maps are thresholded at $P < .05$ (corrected) and displayed on a representative structural MRI. In psychiatrically healthy subjects, a significant negative correlation between delta current density and glucose metabolism in the subgenual prefrontal cortex emerged (C). Adapted from Pizzagalli et al. (2004) with permission.

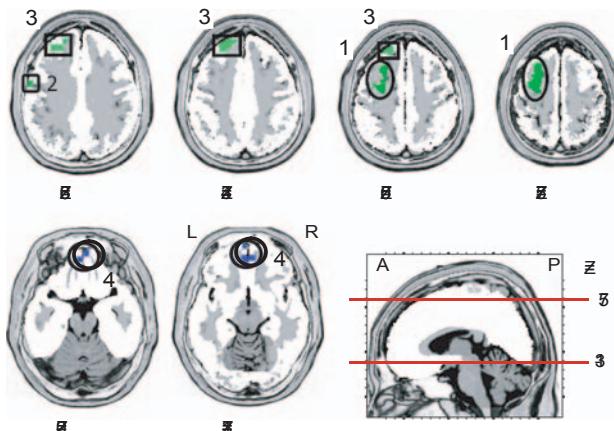

Plate 2. Example of LORETA findings highlighting relations between resting intracerebral EEG sources and approach-related behavior. Whole-brain analyses showing voxel-by-voxel correlations between resting alpha2 (10.5–12 Hz) current density and response bias toward reward-related cues for 18 healthy subjects. Six axial brain slices (head seen from above, nose up, L = left, R = right; A = anterior, P = posterior) are shown. Alpha2 current density within both dorsolateral prefrontal regions (clusters #1–3; see green colors) and ventromedial prefrontal regions (cluster #4; see blue colors) was negatively correlated with reward bias, indicating that higher resting activity within these regions was associated with stronger reward bias. Adapted from Pizzagalli et al. (2005).

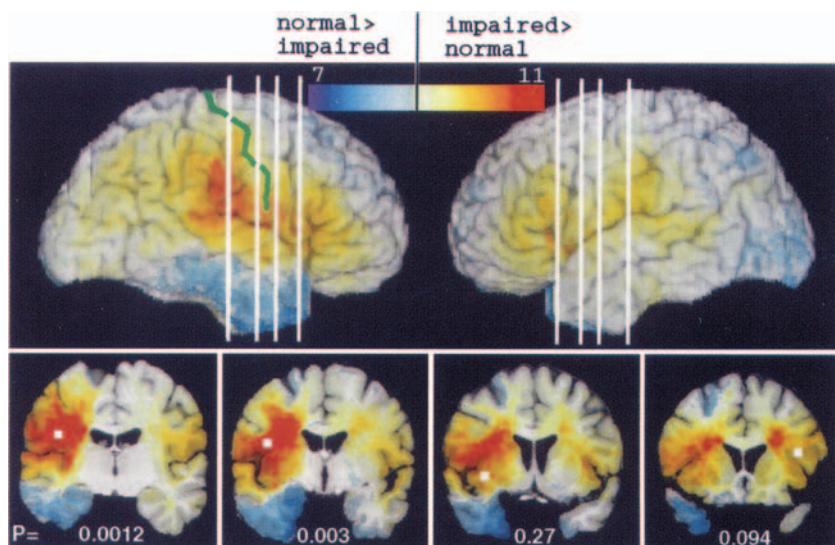

Plate 3. Lesion overlap map created with Map-3. In this study 108 subjects performed emotion recognition task. Color (scale at top) encodes the difference in the density of lesions between the subjects with the lowest and those with the highest scores. Thus, *red regions* correspond to locations at which lesions resulted in impairment more often than not, and *blue regions* correspond to locations at which lesions resulted in normal performance more often than not. *p* values indicating statistical significance are shown in white for voxels in four regions (white squares) on coronal cuts (bottom) that correspond to the *white vertical lines* in the 3-D reconstructions (top). (From Adolphs et al., 2000, used with permission.)

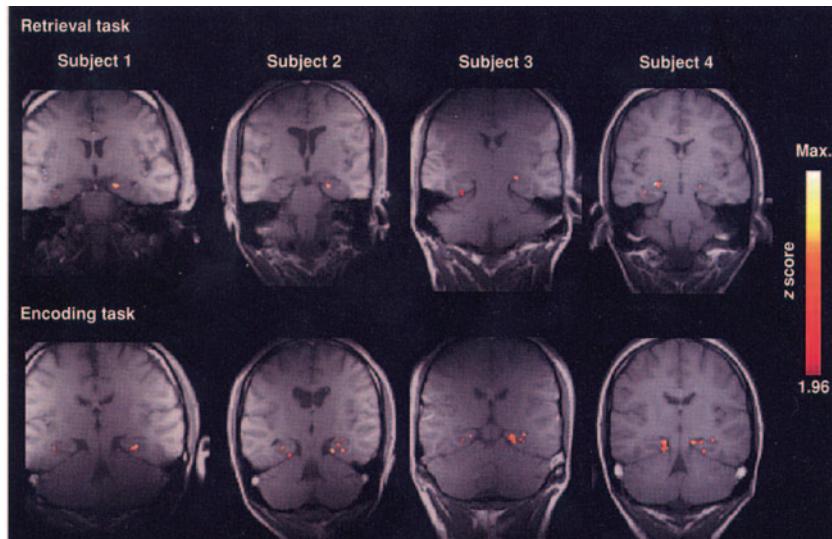

Plate 4. Mesial temporal lobe activations during memory encoding and retrieval. The top row shows activations in the subiculum of the hippocampus during the retrieval memory task that were greater for words corresponding to previously seen than unseen line drawings (Subjects 1, 2, and 3) or greater for line drawings corresponding to previously seen than unseen words (Subject 4). The bottom row shows activations in the parahippocampal cortex during the encoding memory task that were greater for novel than for repeated color scenes (Subjects 1, 2, and 3) or greater for novel than for repeated line drawings (Subject 4). (From Gabrieli et al., 1997, used with permission.)

Plate 5. Bilateral activation of amygdala in response to subliminal presentation of fearful faces compared to happy faces (From Whalen et al., 1998, used with permission).

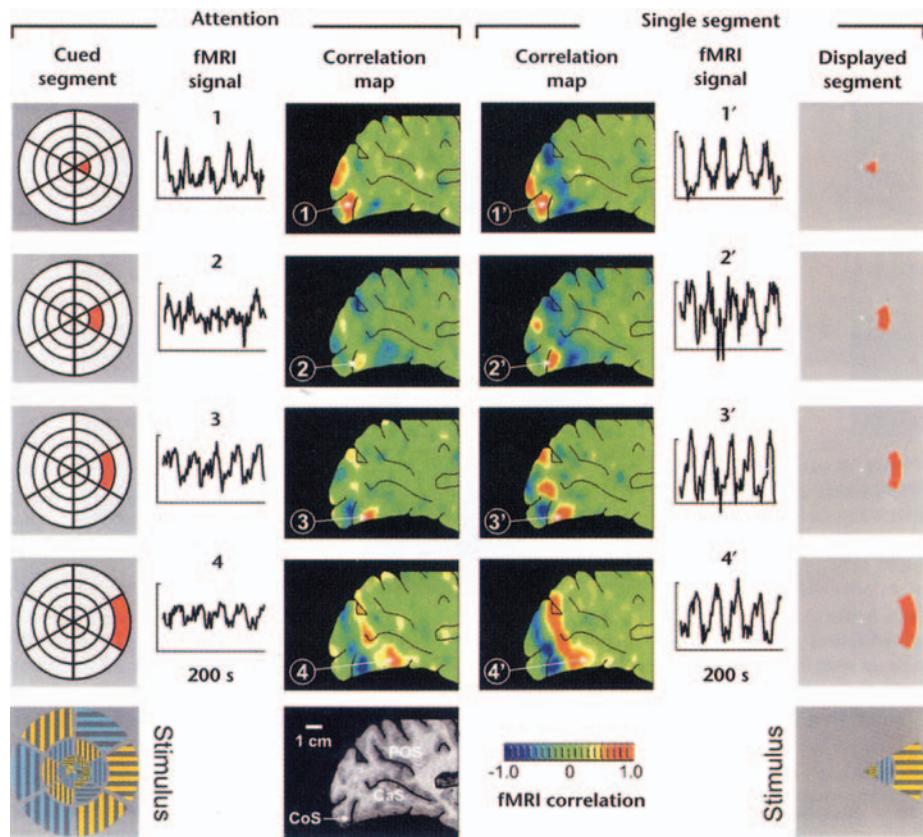

Plate 6. Retinotopic attentional modulation compared to activation evoked by cued targets alone. Cued segment (left column) shows schematic sequence of target segments cued for attentional scrutiny. Stimulus (bottom left) is actual target array. FMRI signal (left) shows signal modulation of individual voxels at sites indicated on adjacent correlation maps. Temporal phase shift of the signal at each site identifies the corresponding locus of attention. Correlation maps show sites where timing of modulation was positively correlated (red) or anti-correlated (blue) with the timing of attentional shifts. Displayed segment (right column) shows schematic sequence of single segments presented during otherwise identical control experiment. Composite of single segments shown in stimulus bottom right. FMRI Signal and correlation map on right show results of control experiment. Structural MRI (bottom) is a parasagittal section (13.6 mm left of midline) through occipital lobe in same plane as correlation maps. Sulcal landmarks; CaS, calcarine sulcus; CoS, collateral sulcus; POS, parieto-occipital sulcus. (From Brefczynski and DeYoe, 1999, used with permission)

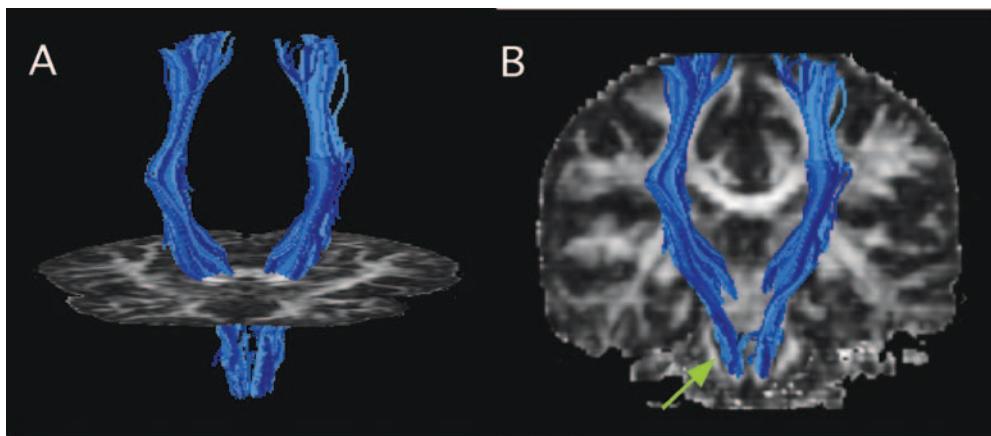

Plate 7. Image of the cortico-spinal tract of humans using DTI. These figures show in blue, cortico-spinal fibers going from cortical motor and sensory areas, in their way to brain-stem and spinal cord. **a.** Descending fibers shown in three dimensions, crossing through an axial structural MRI. **b.** Same fibers superimposed to a coronal MRI slice. Note how the right and left parts of the pathway get close together at the level of the medulla where they will cross over to the contralateral side. Courtesy of K. Arfanakis. Department of Biomedical Engineering, Illinois Institute of Technology (IIT).
