HANDBOOK OF PSYCHOPHYSIOLOGY, THIRD EDITION

The *Handbook of Psychophysiology, Third Edition* is an essential reference for students, researchers, and professionals in the behavioral, cognitive, and biological sciences. Psychophysiological methods, paradigms, and theories offer entry into a biological cosmos that does not stop at skin's edge, and this essential reference is designed as a road map for explorers of this cosmos. The scope and coverage in the *Handbook* have expanded to include both a context for and coverage of the biological bases of cognitive, affective, social, and developmental processes and behavior. In addition to updated coverage of the traditional areas of psychophysiology, coverage of the brain and central nervous system has been expanded to include functional neuroimaging, event-related brain potentials, electrophysiological source dipole localization, lesion methods, and transcranial magnetic stimulation. It also includes a section on cellular and humoral systems with attention to the communication across and interactions among cellular, immunological, endocrinological, and neural processes.

John T. Cacioppo is the Tiffany and Margaret Blake Distinguished Service Professor and the Director of the Center for Cognitive and Social Neuroscience at the University of Chicago. He is the former president of the Society for Psychophysiological Research, president of the Association for Psychological Science, and a recipient of the Society's Award for Distinguished Scientific Contribution and the American Psychological Association's Distinguished Scientific Contribution Award.

Louis G. Tassinary is Professor of Architecture and the Associate Dean for Research in the Department of Architecture at Texas A & M University. He was also the Director of the Environmental Psychophysiology Laboratory at the College of Architecture at Texas A & M University from 1991 to 2001. He has written many articles for journals including *Psychological Science*, *Journal of Environmental Psychology*, *Cognition and Emotion*, and *Journal of Personality and Social Psychology*.

Gary G. Berntson received his Ph.D. in psychology and life sciences from the University of Minnesota, and then completed NSF and USPHS postdoctoral fellowships at Rockefeller University before moving to Ohio State University, where he is currently Professor of Psychology, Psychiatry, and Pediatrics, and a member of the Neuroscience graduate program. He is the Secretary and a member of the Board of Society for Psychophysiological Research.

Psychophysiological Science: Interdisciplinary Approaches to Classic Questions About the Mind

JOHN T. CACIOPPO, LOUIS G. TASSINARY, AND GARY G. BERNTSON

Psychophysiology is an old idea but a new science. It is a likely assumption that ever since man began to experience himself as an object of his own awareness he has had some intuitive notion that bodily changes were, in some measure, related to his moods, his sentiments, his frustrations, his elations. How to relate these dual aspects of human functioning has been a concern of philosopher-scientists throughout the course of intellectual history. (Greenfield & Sternbach, 1972, p. v)

The first *Handbook of Psychophysiology* was published more than three decades ago (Greenfield & Sternbach, 1972). Coverage in that *Handbook* emphasized the peripheral nervous system, an emphasis that many still identify with the term psychophysiology in accord with the history of psychophysiology. As is the case for physiological and other scientific fields, however, psychophysiology has changed dramatically since the appearance of its first *Handbook*. With the advent of new and powerful probes of the central nervous system (e.g., brain imaging techniques), there is an increased emphasis in the field on investigating the brain and central nervous system as they relate to behavior. Investigations of elementary physiological events in normal thinking, feeling, and interacting individuals are commonplace, and new techniques are providing additional windows through which the neural events underlying psychological processes can be viewed unobtrusively. Instrumentation now makes it possible for investigators to explore the selective activation of discrete parts of the brain during particular psychological operations in normal individuals and patients. Transcranial magnetic stimulation has made it possible to stimulate or temporarily disable a region of the brain to study its role in cognitive operations, and studies of patients with lesions are becoming more precise both in their definition of the lesion and in their specification of behavior.

Developments in tissue and blood assays, ambulatory recording devices, non-contact recording instruments, and powerful and mobile computing devices make it possible to measure physiological, endocrinological, and immunological responses in naturalistic as well as laboratory settings. New, powerful assays, including DNA genotyping, are now possible using minimally invasive or noninvasive procedures. With recent developments in molecular biology, behavioral genetics is becoming an important new player in the field. However, the views from these windows are clear only because of the deliberate efforts of knowledgeable investigators. Knowledge and principles of physiological mechanisms, biometric and psychometric properties of the measures, statistical representation and analysis of multivariate data, and the structure of scientific inference are important if veridical information is to be extracted from psychophysiological data. These are among the topics covered in depth in this *Handbook*.

The field of psychophysiology has changed dramatically in other ways as well. Psychophysiology used to be divided into distinct territories, typically defined by organ systems (e.g., the heart, eye blinks), with relatively little integration across these systems. The concept of arousal – the peripheral equivalent of the early notions of the reticular activating system in the brain – dominated the field for the better part of the twentieth century and made the selection of measure a matter of preference rather than a theoretical choice because the responses presumably reflected modulations of arousal regardless of the system one was measuring. Although low correlations among such measures were well recognized, the differences across measures were viewed as less interesting and informative at the time than the confluence of these measures.

Advances in our understanding of the neurophysiological basis of these measures have underscored the importance of the unique patterns of peripheral responses that typically emerge across situations and individuals, and the peripheral and central mechanisms that orchestrate these patterns are active areas of inquiry. As part of these inquiries, animal research, molecular studies, and computational modeling are being embraced in the

Preparation of this chapter was supported by National Institute of Aging Program Project Grant No. P01 AG18911. Address correspondence to John T. Cacioppo, Center for Cognitive and Social Neuroscience, 5848 S. University Avenue, Chicago, IL 60637, or by email to Cacioppo@uchicago.edu.

field despite the original definition of psychophysiology in terms of the study of humans rather than nonhuman animals. Moreover, the larger social, cultural, and interpersonal contexts are now recognized as powerful determinants of brain and behavior. Monism has replaced any lingering notions of dualism, as psychological states are more likely to be conceived as represented in and acting through cortical, limbic, and brain stem regions, with influences on autonomic, neuroendocrine, and immune activity, which in turn serve to modulate crucial cellular and molecular processes. Afferent information, in turn, travels from the peripheral to the central nervous system to influence the brain and behavior in social contexts. For instance, interleukin-1 β (IL-1 β) in the periphery increases in response to the introduction of antigens, and this increase is reflected in the information carried along the vagal afferent nerve to the brain. As a result of these signals from the periphery, IL-1 β levels in the brain are increased, producing feelings of illness and fatigue. The notion of embodied cognition has been alive and well in psychophysiology for decades (see review by Cacioppo & Petty, 1981), and the identification of canonical and mirror neurons has renewed interest in this area (Garbarini & Adenzato, 2004).

Rose (2005) noted that there are at least two voluminous scientific literatures on psychological states and physiological events that have not been effectively related to one another: the literature on the CNS mechanisms underlying a variety of psychological processes, and the literature on psychological factors and peripheral biological activities including physical health. These literatures have tended to focus on different psychological processes, but there is an increasing recognition that these two areas of study have much in common. For instance, studies of the brain during exposure to potentially stressful stimuli can be an important tool in studying stress biology and evaluating its impact in various systems (Rose, 2005). Both of these literatures are covered in this *Handbook* and, although much needs to be done to integrate these distinct lines of research, it should be apparent from the chapters in this *Handbook* that this work has begun.

With the dawning of the twenty-first century, recording standards, procedures for signal representation, and powerful techniques for multivariate statistical analyses have been established. Investigators are now as likely to be studying the interrelationships among brain, autonomic, somatic, endocrinologic, immunologic, and/or genetic processes as they are to be studying any of these systems in isolation. Moreover, given that there are many things going on in the brain at any moment in time, only a few of which are relevant to any particular peripheral organ or effect, it is now recognized that the identification of psychological and brain mechanisms that are related to peripheral changes can be advanced significantly by working from the peripheral effects back to central, psychological, and social conditions, just as it can be advanced by the more traditional, complementary approach of manip-

ulating psychological states and observing the subsequent changes in CNS and PNS processes.

Finally, psychophysiology has always had a special appeal in scientific investigations of the mind because it offers tools for mining information about nonconscious and nonreportable states, processes, and events. Psychophysiological studies of attention and cognitive development in neonates, early sensory and attentional processes in schizophrenics, the cognitive operations underlying psychological states, and the study of sleep and dreams in older adults have helped lift the veil from these otherwise difficult-to-gauge behavioral processes.

In sum, psychophysiological research has provided insights into almost every facet of human nature, from the attention and behavior of the neonate to memory and emotions in the elderly. This book is about these insights and advances – what they are, the methods by which they came about, and the conceptualizations that are guiding progress toward future advances in the discipline. Historically, the study of psychophysiological phenomena has been susceptible to “easy generalizations, philosophical pitfalls, and influences from extrascientific quarters” (Harrington, 1987, p. 5). Our objectives in this chapter are to define psychophysiology, briefly review major historical events in the evolution of psychophysiological inference, outline a taxonomy of logical relationships between psychological constructs and physiological events, and specify a scheme for strong inference within each of the specified classes of psychophysiological relationships.

THE CONCEPTUALIZATION OF PSYCHOPHYSIOLOGY

The body is the medium of experience and the instrument of action. Through its actions we shape and organize our experiences and distinguish our perceptions of the outside world from sensations that arise within the body itself. (Miller, 1978, p. 14)

Anatomy, physiology, and psychophysiology are all branches of science organized around bodily systems with the collective aim of elucidating the structure and function of the parts of, and interrelated systems in, the human body in transactions with the environment. Anatomy is the science of body structure and the relationships among structures.

Physiology concerns the study of bodily function or how the parts of the body work. For both of these disciplines, what constitutes a body part varies with the level of bodily organization, going from the molecular to cellular to tissue to organ to body system to the organism. Thus, the anatomy and physiology of the body are intricately interrelated. Neuroscience, in particular, stands at this intersection.

Psychophysiology is intimately related to anatomy and physiology but is also concerned with psychological phenomena – the experience and behavior of organisms in the physical and social environment. The primary distinctions between psychophysiology and behavioral neuroscience

are the focus of the former on higher cognitive processes and the interest in relating these higher cognitive processes to the integration of central and peripheral processes. Among the complexity added when moving from physiology to psychophysiology are the capacity by symbolic systems of representation (e.g., language, mathematics) to communicate and to reflect on history and experience; and social and cultural influences on physiological response and behavior. These factors contribute to plasticity, adaptability, and variability in behavior. Psychology and psychophysiology share the goal of explaining human experience and behavior, and physiological constructs and processes are an explicit and integral component of theoretical thinking in psychophysiology. The subject matter of psychophysiology, after all, is an embodied phenomenon.

The technical obstacles confronting early studies, the importance of understanding the physiological systems underlying observations, and the diverse goals and interests of the early investigators in the field fostered a partitioning of the discipline into physiological/measurement areas. The organization of psychophysiology in terms of underlying physiological systems, or what can be called *systemic psychophysiology*, remains important today for theoretical and pedagogical reasons. Physiological systems provide the foundation for human processes and behavior and are often the target of systematic observation. An understanding of the physiological system(s) under study and the bioelectrical principles underlying the perceptual and output responses being measured contribute to the plausible hypotheses, appropriate operationalizations, laboratory safety, discrimination of signal from artifact, acquisition and analysis of the physiological events, legitimate inferences based on the data, and theoretical advancement.

Like anatomy, physiology, and psychology, however, psychophysiology is a broad science organized in terms of a thematic as well as a systemic focus. The organization of psychophysiology in terms of topical areas of research can be called *thematic psychophysiology*. For instance, cognitive psychophysiology concerns the relationship between elements of human information processing and physiological events. Social psychophysiology concerns the study of the cognitive, emotional, and behavioral effects of human association as related to and revealed by physiological measures, interventions, and consequences including the reciprocal relationship between physiological and social systems. Developmental psychophysiology deals with ontological changes in psychophysiological relationships as well as the study of psychological development and aging using physiological measures. Clinical psychophysiology concerns the study of disorders in the organismic-environmental transactions and ranges from the assessment of disorders to interventions and treatments. Environmental psychophysiology elucidates the vagaries of organism-place interdependencies as well as the health consequences of design through unobtrusive physiological measurements. And applied psychophysi-

ology generally deals with the implementation of psychophysiological principles in practice, such as operant training ("biofeedback"), desensitization, relaxation, and the detection of deception.

In each of these areas, the focus of study draws on, but goes beyond, the description of the structure or function of cells or organs, to investigate the organism in transactions with the physical or sociocultural environment. Some of these areas, such as developmental psychophysiology, have counterparts in anatomy and physiology but refer to complementary empirical domains that focus on human experience and behavior. Others, such as social psychophysiology, have a less direct counterpart in anatomy or physiology because the focus begins beyond that of an organism in isolation; yet the influence of social and cultural factors on physiological structures and functions, and their influence as moderators of the effects of physical stimuli on physiological structures and functions, leaves little doubt as to the relevance of these factors for anatomy and physiology as well as for psychophysiology. Meaney and colleagues (Meaney, Bhatnagar, Larocque, McCormick, Shanks, Smythe, Viau, & Plotsky, 1996), for instance, provide evidence that rat pups who are ignored by their mothers develop a more reactive hypothalamic pituitary adrenocortical (HPA) axis than rat pups who are licked and groomed by their mothers.

Because psychophysiology is intimately related to anatomy and physiology, knowledge of the physiological systems and responses under study contribute to both theoretical and methodological aspects of psychophysiological research. However, knowledge of the physiological systems is logically neither necessary nor sufficient to ascribe psychological meaning to physiological responses. The ascription of psychological meaning to physiological responses ultimately resides in factors such as the quality of the experimental design, the psychometric properties of the measures, and the appropriateness of the data analysis and interpretation. For instance, although numerous aspects of the physiological basis of event-related brain potentials remain uncertain, functional relationships within specific paradigms have been established between elementary cognitive operations and components of these potentials by systematically varying one or more of the former and monitoring changes in the latter.

The point is not that either the physiological or the psychological perspective is preeminent, but rather that both are fundamental to psychophysiological inquiries; more specifically, that physiological and psychological levels of organization are complementary. Inattention to the logic underlying psychophysiological inferences simply because one is dealing with observable physiological events is likely to lead either to simple and restricted descriptions of empirical relationships or to erroneous interpretations of these relationships. Similarly, "an aphysiological attitude, such as is evident in some psychophysiological research, is likely to lead to misinterpretation of the empirical relationships that are found between psychophysiological

measures and psychological processes or states" (Coles et al., 1986, ix-x). Thus, whether organized in terms of a systemic or a thematic focus, psychophysiology can be conceptualized as a natural extension of anatomy and physiology in the scientific pursuit of understanding human processes and behavior. It is the joint consideration of physiological and functional perspectives, however, that is thought to improve operationalization, measurement, and inference and therefore to enrich research and theory on cognition, emotion, and behavior.

Early definitions of the field of psychophysiology were of two types. One emphasized the operational aspects of the field such as research in which the polygraph was used, research published by workers in the field, and research on physiological responses to behavioral manipulations (e.g., Ax, 1964b). Other early definitions were designed to differentiate psychophysiology from the older and more established field of physiological psychology or psychobiology. Initially, psychophysiology differed from physiological psychology in the use of human in contrast to animals as participants, the manipulation of psychological or behavioral constructs rather than anatomical structures or physiological processes, and the measurement of physiological rather than behavioral responses (Stern, 1964). Although this heritage can still be found, this distinction is often blurred by the fact that psychophysologists may modify physiology with drugs or conditioning procedures, and psychobiologists often manipulate psychological or behavioral variables and measure physiological outcomes. Contemporary definitions are more likely to emphasize the mapping of the relationships between and mechanisms underlying psychological and physiological events (e.g., Hudgahl, 1995; Stern, Ray, & Quigley, 2001).

A major problem in reaching a consensus has been the need to give the field direction and identity by distinguishing it from other scientific disciplines while not limiting its potential for growth. Operational definitions are unsatisfactory for they do not provide long-term direction for the field. Definitions of psychophysiology as studies in which psychological factors serve as independent variables and physiological responses serve as dependent variables distinguish it from fields such as psychobiology but have been criticized for being too restrictive (Furedy, 1983). For instance, such definitions exclude studies in which physiological events serve as the independent/blocking variable and human experience or behavior serve as the dependent variable (e.g., the sensorimotor behavior associated with manipulations of the physiology via drugs or operant conditioning, or with endogenous changes in cardiovascular or electroencephalographic activity) as well as studies comparing changes in physiological responses across known groups (e.g., the cardiovascular reactivity of offspring of hypertensive vs. normotensive parents).

Moreover, psychophysiology and psychobiology share goals, assumptions, experimental paradigms, and, in some instances, databases, but differ primarily in terms of the analytic focus. In psychophysiology the emphasis is on

integrating data from multiple levels of analysis to illuminate psychological functions and mechanisms rather than physiological structures per se. All of these substantive areas have a great deal to contribute to one another, and ideally this complementarity should not be masked in their definition by the need to distinguish these fields. Indeed, the formulation of structure-function relationships is advanced to the extent that "top down" and "bottom up" information can be integrated. The emergence of areas of research in cognitive neuroscience, psychoneuroendocrinology, and psychoneuroimmunology raise additional questions about the scope of psychophysiology.

Anatomy and physiology encompass the fields of neurology, endocrinology, and immunology due both to their common goals and assumptions, and to the embodiment, in a literal sense, of the nervous, endocrine, and immunologic systems within the organism. Relatedly, psychophysiology is based on the assumptions that human perception, thought, emotion, and action are embodied phenomena; and that measures of physical (e.g., neural, hormonal) processes can therefore shed light on the human mind. The level of analysis in psychophysiology is not on isolated components of the body, but rather on organismic-environmental transactions. That is, psychophysiology represents a top-down approach within the neurosciences that complements the bottom-up approach of psychobiology. Thus, psychophysiology can be defined as the scientific study of social, psychological, and behavioral phenomena as related to and revealed through physiological principles and events in functional organisms. Thus, psychophysiology is not categorically different from behavioral neuroscience, but rather there is currently a greater emphasis in psychophysiology on higher cognitive processes and on relating these higher cognitive processes to the integration of central and peripheral processes.

In the following section, we review some of the major historical developments that have influenced contemporary thinking and research in psychophysiology. As might be expected from the discussion thus far, many of these early developments have stemmed from studies of human anatomy and physiology.

HISTORICAL DEVELOPMENTS

Psychophysiology is still quite young as a scientific field. Studies dating back to the turn of the prior century can be found involving the manipulation of a psychological factor and the measurement of one or more physiological responses (e.g., Berger, 1929; Darrow, 1929; Eng, 1925; Jacobson, 1930; Mosso, 1896; Peterson & Jung, 1907; Sechenov, 1878; Tarchanoff, 1890; Wenger, 1941; Wilder, 1931; see also, Woodworth & Schlosberg, 1954), and such studies would now be considered as falling squarely under the rubric of psychophysiology. Chester Darrow (1964), in the inaugural Presidential Address of the Society for Psychophysiological Research, identified Darwin (1872/1873), Vigoroux (1879), James (1884), and Fere (1888)

as among the field's earliest pioneers, yet the mixed responses of the scientific community to this pioneering work affected the field for decades (see Daston, 1978).

The first scientific periodical devoted exclusively to psychophysiological research, the Polygraph Newsletter, was not begun until 1955 and was published until 1963 (Ax, 1964a). There was an organizational meeting in 1959 in Cincinnati, a business meeting in 1960 in Chicago, and the first scientific meeting in 1961 in New York City. The first independent meeting of Society for Psychophysiological Research, however, occurred in Denver in 1962, and the Society was incorporated in 1963 at the Detroit meeting. Based on this history, one might surmise that the Society formed in 1959 and began functioning as a scientific society in 1961. The first edition of the journal, *Psychophysiology*, then subtitled "The Journal of Objective Research in the Physiology of Behavior," was published in July, 1964. When precisely psychophysiology emerged as a discipline, therefore, is difficult to specify, but it is usually identified with the first business meeting of the Society for Psychophysiological Research in 1960 or with the publication of the first issue of the journal, *Psychophysiology*, in 1964 (e.g., Fowles, 1975; Greenfield & Sternbach, 1972; Sternbach, 1966).

Although psychophysiology as a formal discipline has been around just over half a century, interest in interrelationships between psychological and physiological events can be traced as far back as the early Egyptians and Greek philosopher-scientists. The Greek philosopher Heraclitus (c. 600 B.C.) referred to the mind as an overwhelming space whose boundaries could never be fully comprehended (Bloom, Lazerson, & Hofstadter, 1985). Plato (c. 400 B.C.) suggested that rational faculties were located in the head; passions were located in the spinal marrow and, indirectly, the heart; and instincts were located below the diaphragm where they influenced the liver. Plato also believed the psyche and body to be fundamentally different; hence, observations of physiological responses provided no grounds for inference about the operation of psyche (Stern, Ray, & Quigley, 2001). Thus, despite the fact that the peripheral and central nervous system, brain, and viscera were known to exist as anatomical entities by the early Greek scientists-philosophers, human nature was dealt with as a incorporeal entity not amenable to empirical study.

In the second century A.D., Galen (c. 130–200) formulated a theory of psychophysiological function that would dominate thought well into the eighteenth century (Brazier, 1961; Wu, 1984). Hydraulics and mechanics were the technology of the times, and aqueducts and sewer systems were the most notable technological achievements during this period. Bloom et al. (1985, p. 13) suggest: "It is hardly by accident, then, that Galen believed the important parts of the brain to lie not in the brain's substance, but in its fluid-filled cavities" (p. 13). Based on his animal dissections and his observations of the variety of fluids that permeated the body, Galen postulated that humors (fluids) were responsible for all sensation, move-

ment, thoughts, and emotion; and that pathologies – physiological or behavioral – were based on humoral disturbances. The role of bodily organs was to produce or process these humors, and the nerves, although recognized as instrumental in thought and action, were assumed to be part of a hydraulic system through which the humors traveled. Galen's views became so deeply entrenched in Western thought that they went practically unchallenged for almost 1500 years (cf. Kottek 1979).

In the sixteenth century, Jean Fernel (1497–1558) published the first textbook on physiology, *De Naturali Parte Medicinae* (1542). According to Brazier (1959), this book was well received, and Fernel revised and expanded the book across numerous editions. The ninth edition of the book was retitled *Medicina*, and the first section was entitled *Physiologia*. Although Fernel's categorization of empirical observations was strongly influenced by Galen's theory, the book "shows dawning recognition of some of the automatic movements which we now know to be reflexly initiated" (Brazier, 1959, p. 2). This represented a marked departure from traditional views that segregated the control of human action and the affairs of the corporeal world.

Studies of human anatomy during this period in history also began to uncover errors in Galen's descriptions (e.g., Vesalius, 1543/1947), opening the way for questions of his methods and of his theory of physiological functioning and symptomatology. Within a century, two additional events occurred that had a profound impact on the nature of inference in psychophysiology. In 1600, William Gilbert (1544–1603) recognized a difference between electricity and magnetism and, more importantly, argued in his book, *De Magnete, Magneticisque Corporibus, et de Magno magneti tellure*, that empirical observations and experiments should replace "the probable guesses and opinions of the ordinary professors of philosophy."

In addition, the reign of authority as the source of answers to questions about the basis of human experience and behavior was challenged by the work of scholars including Galileo, Bacon, and Newton. Galileo (1564–1642) challenged knowledge by authority in matters of science, by which Galileo meant physical sciences and mathematics. He argued that theologians and philosophers had no right to control scientific investigation or theories, and that observation, experiment, and reason along could establish physical truth (Drake, 1967). Galileo was also aware of limitations of sense data. Concerned with the possibility of illusion and misinterpretation, Galileo believed that mathematics alone offered the kind of certainty that could be completely trusted. Galileo did not extend this reasoning beyond the physical sciences, but scientific investigations of the basis of human experience and behavior benefited from his rejection of authority as a source of knowledge about physical reality, his emphasis on the value of skepticism, and his insistence that more could be learned from results that suggested ignorance (disconfirmation) than from results that fit preconceptions (confirmation).

Francis Bacon (1561–1626) took the scientific method a step further in *Novum Organum* (1620/1855), adding induction to observation and adding verification to inference. Bacon was not a scientist, yet he is regarded as a forerunner of the hypothetico-deductive method (Brazier, 1959; Caws, 1967). Subsequent work on the logic of scientific inference (Popper, 1959/1968) led to the now familiar sequence underlying scientific inference: (1) devise alternative hypotheses; (2) devise a crucial experiment, with alternative possible outcomes, each of which will disfavor if not exclude one or more of the hypotheses; (3) execute the experiment to obtain a clean result; and (4) recycle to refine the possibilities that remain. Such a scheme was accepted quickly in the physical sciences, but traditional philosophical and religious views segregating human existence from worldly events slowed its acceptance in the study of human physiology, experience, and behavior (Brazier, 1977; Harrington, 1987; Mecacci, 1979).

William Harvey's (1578–1657) doctoral dissertation, *De Motu Cordis* (1628/1941), represented not only the first major work to use these principles to guide inferences about physiological functioning, but it also disconfirmed Galen's principle that the motion of the blood in the arterial and venous systems ebbed and flowed independent of one another except for some leakage in the heart. Pumps were an important technological development during the seventeenth century, and Harvey perhaps drew on his observations of pumps in positing that blood circulated continuously through a circular system, pushed along by the pumping actions of the heart, and directed through and out of the heart by the one-way valves in each chamber of the heart. Galen, in contrast, had posited that blood could flow in either direction in the veins. To test these competing hypotheses, he tied a tourniquet above the elbow of his arm just tight enough to prevent blood from returning to the heart through the veins but not so tight as to prevent blood from entering the arm through the arteries. The veins swelled below, but not above the tourniquet, implying that the blood could be entering only through the arteries and exiting only through the veins (Miller, 1978). A variation on Harvey's procedure is used in contemporary psychophysiology to gauge blood flow to vascular beds (Williams, 1984).

During this period, which coincided with a burgeoning world of machines, the human eye was conceived as functioning like an optical instrument. Images were conceived as projected onto the sensory nerves of the retina. Movement was thought to reflect the mechanical actions of passive balloon-like structures (muscles) that were inflated or deflated by the nervous fluids or gaseous spirits that traveled through canals in the nerves. And higher mental functions were still considered by many to fall outside the rubric of the physical or biological sciences (Bloom et al., 1985; Brazier, 1959; Harrington, 1987). The writings of René Descartes (1596–1650) reflects the presumed division between the mind and body. The actions of animals were viewed as reflexive and mechanistic in

nature, as were most of the actions of humans. But humans alone, Descartes argued, also possess a consciousness of self and of events around them, a consciousness which, like the body, was a thing but, unlike the body, was not a thing governed by material principles or connections. This independent entity called mind, Descartes proposed, resides over volition from the soul's control tower in the pineal gland located at the center of the head:

The soul or mind squeezed the pineal gland this way and that, nudging the animal fluids in the human brain into the pores or valves, 'and according as they enter or even only as they tend to enter more or less into this or that nerve, they have the power of changing the form of the muscle into which the nerve is inserted, and by this means making the limbs move.' (Jaynes, 1973, p. 172, paraphrasing and quoting from Descartes, 1624, p. 347)

Shortly following Descartes' publication of *Traité de l'Homme* (c. 1633), Steno (1638–1686) noted several discrepancies between Descartes' dualistic and largely mechanistic characterization of human processes and the extant evidence about animal and human physiology. For instance, Steno noted that the pineal gland (the purported bridge between the worlds of the human mind and body) existed in animals as well as humans, that the pineal gland did not have the rich nerve supply implied by Descartes' theory, and that the brain was unnecessary to many animal movements (cf. Jaynes, 1973). Giovanni Borelli (1608–1679) disproved the notion that movement was motivated by the inflation of muscles by a gaseous substance in experiments in which he submerged a struggling animal in water, slit its muscles, and looked for the release of bubbles (Brazier, 1959). These observations were published posthumously in 1680, shortly after the suggestion by Francesco Redi that the shock of the electric ray fish was muscular in origin (Basmajian & De Luca, 1985, Ch. 1; Wu, 1984).

Despite the prevalent belief during this period that the scientific study of animal and human behavior could apply only to those structures they shared in common (Bloom et al., 1985; Harrington, 1987), the foundations laid by the great seventeenth-century scientist-philosophers encouraged students of anatomy and physiology in the subsequent century to discount explanatory appeals to the human soul or mind (Brazier, 1959). Consequently, experimental analyses of physiological events and psychological constructs (e.g., sensation, involuntary and voluntary action) expanded and inspired the application of technological advances to the study of psychophysiological questions. For instance, the microscope was employed (unsuccessfully) in the late seventeenth century to examine the prevalent belief that the nerves were small pipes through which nervous fluid flowed.

According to Brazier (1959, 1977), that electricity might be the transmitter of nervous action was initially seen as unlikely because, drawing upon the metaphor of electricity running down a wire, there was believed to be insufficient

insulation around the nerves to prevent a dissipation of the electrical signal. Galvani and Volta's (c. 1800) experiments demonstrated that nerves and muscles were indeed electrically excitable, and research by Du Bois-Reymond (1849) established that nerves and muscles were electrically polarized as well as excitable. Based on reaction times, Helmholtz (c. 1850) correctly inferred that nerves and muscles were not like wires because they propagated electrical impulses too slowly. The work that followed ultimately verified that neural signals and muscular actions were electrical in nature, that these electrical signals were the result of biochemical reactions within specialized cells, and that there was indeed some dissipation of these electrical signals through the body fluids that could be detected noninvasively at the surface of the skin. Specific advances during the nineteenth and twentieth centuries in psychophysiological theory and research are discussed in the remainder of this book. However, the stage had been set by these early investigators for the scientific study of psychophysiological relationships.

PSYCHOPHYSIOLOGICAL RELATIONSHIPS AND PSYCHOPHYSIOLOGICAL INFERENCE

We praise the 'lifetime of study,' but in dozens of cases, in every field, what was needed was not a lifetime but rather a few short months or weeks of analytical inductive inference . . . We speak piously of taking measurements and making small studies that will 'add another brick to the temple of science.' Most such bricks just lie around the brickyard. (Platt, 1964, p. 351)

The importance of the development of more advanced recording procedures to scientific progress in psychophysiology is clear, as previously unobservable phenomena are rendered observable. Less explicitly studied, but no less important, is the structure of scientific thought about psychophysiological phenomena. For instance, Galen's notions about psychophysiological processes persisted for 1500 years despite the availability for several centuries of procedures for disconfirming his theory in part because the structure of scientific inquiry had not been developed sufficiently.

An important form of psychophysiological inference to evolve from the work of Francis Bacon (1620/1855) and Galileo (Drake, 1967) is the hypothetico-deductive logic outlined above. If the data are consistent with only one of the theoretical hypotheses, then the alternative hypotheses with which the investigator began become less plausible. With conceptual replications to ensure the construct validity, replicability, and generalizability of such a result, a subset of the original hypotheses can be discarded, and the investigator recycles through this sequence. One weakness of this procedure is the myriad sources of variance in psychophysiological investigations and the stochastic nature of physiological events and, consequently, the sometimes poor replicability or generalizability of the results. A second is the intellectual invention and omniscience that is required to specify all relevant alternative hypotheses for

the phenomenon of interest. Because neither of these can be overcome with certitude, progress in the short term can be slow and uncertain. Adherence to this sequence provides grounds for strong inference in the long term, however (Platt, 1964).

Physiological responses are often of interest, however, only to the extent that they allow one to index a psychological process, state, or stage. A general analytic framework that has aided the design and interpretation of studies in the area is the subtractive method that has been adapted from studies of mental chronometry. Donders (1868), a Dutch physiologist, proposed that the duration of different stages of mental processing could be determined by subtracting means of simpler tasks that were matched structurally to subsequences of more complex tasks. At the simplest level, experimental design begins with an experimental and a control condition. The experimental condition represents the presence of some factor, and the control condition represents the absence of this factor. The experimental factor might be selected because it is theoretically believed to depend on n information processing stages, and the construction of the control condition is guided to incorporate $n - 1$ information processing stages. This kind of analysis assumes, and depends mathematically on the assumption, that the information processing stages are arranged in strictly serial order with each stage running to completion prior to the initiation of the next.

Nevertheless, the principle underlying the extension of the subtractive design to include physiological (e.g., functional magnetic resonance imaging) measures is twofold: (a) physiological differences between experimental conditions thought to represent n and $n - 1$ processing stages supports the theoretical differentiation of these stages, and (b) the nature of the physiological differentiation of experimental conditions (e.g., the physiological signature of a processing stage) may further support a particular psychological characterization of that information processing stage. According to the subtractive method, the systematic application of the procedure of stage deletion (across conditions of an experimental design) makes it possible to deduce the physiological signature of each of the constituent stages underlying some psychological or behavioral response. For instance, if the experimental task ($n + 1$ stages) is characterized by greater activation of Broca's area than the control task, this is consistent with both the theoretical conception of the experimental and control tasks differing in one (or more) processing stage(s) and the differential processing stage(s) relating to language production.

If using conventional reaction time measures, the psychological significance of timing differences comes primarily from the putative differences between experimental conditions. With biological measures, however, the psychological significance of specific physiological differences (e.g., activation of Broca's area) comes both from the theoretical differences between experimental conditions

and from the prior scientific literature on the psychological significance of the observed physiological difference. The convergence of these two sources of information makes social neuroscience methods potentially quite powerful even though they tend to be more complicated and nuanced.

It is important to note a critical difference in the properties of the kinds of measures used for response time experiments and for physiological measurements. If we assume that a process takes a certain period of time because it is composed of a series of steps that each takes a measurable time and wherein each must be completed before the next is begun, the decomposition of the total time into the time for each step seems relatively transparent. Note, however, that the conditions under which this kind of analysis fails are precisely those that hold in imaging experiments (Townsend & Ashby, 1983).

When a particular hypothesized stage of information processing is thought to be responsible for the differential impact of two different conditions on behavior, analyses of concomitant physiological activity can be informative, in one of two ways. If the patterns of physiological activity resulting from the isolation of presumably identical stages are dissimilar, the similarity of the stages is challenged even though there may be similarities between the subsequent behavioral outcomes (cf. Cacioppo & Tassinary, 1990). If, on the other hand, similar patterns of physiological activity result from the isolation of stages that are hypothesized to be identical, convergent evidence is obtained that the same fundamental stage is operative. Note that the greater the extant evidence linking the observed physiological event/profile to a specific psychological operation, the greater the value of the convergent evidence. These data do not provide evidence for a strong inference that the stages are the same (Platt, 1964), but instead such a result raises a hypothesis that can be tested empirically in a subsequent study (Cacioppo & Tassinary, 1990).

There are additional issues that should be considered when using a subtractive framework to investigate elementary stages of psychological processes whether using reaction time or physiological (brain) measures. The subtractive method contains the implicit assumption that a stage can be inserted or deleted without changing the nature of the other constituent stages. But this method has long been criticized for ignoring the possibility that manipulating a factor to insert or delete a processing stage might introduce a completely different processing structure (e.g., Townsend & Ashby, 1983). Using multiple operationalizations to insert or delete a stage may be helpful but this still does not insure strong inference. In addition, to construct the set of comparison tasks using the subtractive method one must already have a clearly articulated hypothesis about the sequence of events that transpires between stimulus and overt response. This assumption renders the subtractive method particularly useful in testing an existing theory about the stages constituting a psychological process and in determining whether a given

stage is among the set constituting two separate processes (Cacioppo, Berntson, Lorig, Norris, Rickett, & Nusbaum, 2003). Note, however, that confirmatory evidence can still be questioned by the assertion that the addition or deletion of a particular stage results in an essentially different set of stages or substages, just as is the case with self-report or reaction time measures. If a large corpus of animal and human research links a psychological event to a processing operation, however, the plausibility of the alternative interpretation is greatly diminished.

Whenever a physiological response (or profile) found previously to vary as a function of a psychological processing stage or state is observed, yet another hypothesis is raised – namely, that the same processing stage or state has been detected. A person might be thought to be anxious because they show physiological activation, inattentive because they show diminished activation, happy because they show an attenuated startle response, deceptive because they show activation of the anterior cingulate, and so on. However, one cannot logically conclude that a processing stage or state has definitely been detected simply because a physiological response found previously to vary as a function of a psychological processing stage or state has been observed. (The logical flaw in this form of inference is termed affirmation of the consequent.) We therefore next turn to a general framework for thinking about relationships between psychological concepts and physiological events, and we discuss the rules of evidence for and the limitations to inference in each (see also Cacioppo & Tassinary, 1990; Cacioppo, Tassinary, & Berntson, 2000).

THE PSYCHOLOGICAL AND PHYSIOLOGICAL DOMAINS

A useful way to construe the potential relationships between psychological events and physiological events is to consider these two groups of events as representing independent sets (domains), where a set is defined as a collection of elements who together are considered a whole (Cacioppo & Tassinary, 1990). Psychological events, by which we mean conceptual variables representing functional aspects of embodied processes, are conceived as constituting one set, which we shall call Set Ψ . Physiological (e.g., brain, autonomic, endocrinological) events, by which we mean empirical physical variables, are conceived as constituting another, which we shall call Set Φ . All elements in the set of psychological events are assumed to have some physiological referent – that is, the mind is viewed as having a physical substrate. This framework allows the specification of five general relations that might be said to relate the elements within the domain of psychological events, Ψ , and elements within the domain of physiological events, Φ . These are as follows:

- A one-to-one relation, such that an element in the psychological set is associated with one and only one element in the physiological set, and vice versa.

- A one-to-many relation, meaning that an element in the psychological domain is associated with a subset of elements in the physiological domain.
- A many-to-one relation, meaning that two or more psychological elements are associated with the same physiological element.
- A many-to-many relation, meaning two or more psychological elements are associated with the same (or an overlapping) subset of elements in the physiological domain.
- A null relation, meaning there is no association between an element in the psychological domain and that in the physiological domain.

Of these possible relations, only the first and third allow a formal specification of psychological elements as a function of physiological elements (Cacioppo & Tassinary, 1990). The grounds for theoretical interpretations, therefore, can be strengthened if either (1) a way can be found to specify the relationship between the elements within Ψ and Φ in terms of one-to-one, or at worst, in terms of many-to-one relationships, or (2) hypothetico-deductive logic is employed in the brain imaging studies (Cacioppo, Tassinary, & Berntson, 2000).

Consider that when differences in brain images or physiological events (Φ) are found in contrasts of tasks that are thought to differ only in one or more cognitive functions (Ψ), the data are often interpreted prematurely as showing that Brain Structure (or Event) Φ is associated with Cognitive Function (Ψ). These data are also treated as revealing much the same information that would have been obtained had Brain Structure (or Event) Φ been stimulated or ablated and a consequent change in Cognitive Function Ψ been observed. This form of interpretation reflects the explicit assumption that there is a fundamental localizability of specific cognitive operations, and the implicit assumption that there is an isomorphism between Φ and Ψ (Sarter, Berntson, & Cacioppo, 1996). Interpreting studies of the form $P(\Phi/\Psi)$ (i.e., fMRI studies) as equivalent to studies of the form $P(\Psi/\Phi)$ is misleading unless one is dealing with 1:1 relationships.¹ Fundamentally, this is a premise that needs to be tested rather than treated as an assumption.

It may be useful to illustrate some of these points using a simple physical metaphor in which the bases of a multiply

determined outcome are known. Briefly, let Φ represent the HVAC system, and Ψ the temperature in a house. In the context of psychophysiology, the HVAC system parallels a neural mechanism and the temperature represents the cognitive manifestation of the operation of this mechanism. Although the HVAC system and the temperature are conceptually distinct, the operation of the HVAC system represents both the manipulable cause (see Shadish, Cook, & Campbell, 2002) and a physical basis for the observed temperatures in the house. Thus, $\Psi = f(\Phi)$. A bottom-up approach (i.e., $P(\Psi/\Phi)$) makes clear certain details about the relationship between Ψ and Φ , whereas a top-down approach (i.e., $P(\Phi/\Psi)$) clarifies others. For instance, when the activity of the HVAC system is manipulated (i.e., Φ is stimulated or lesioned), a change in the temperature in the house (Ψ) results. This represents a bottom-up approach to investigating the physical substrates of cognitive phenomena. The fact that manipulating the activity of the HVAC system produces a change in the temperature in the house can be expressed as $P(\Psi/\Phi) > 0$. Note that the $P(\Psi/\Phi)$ need not equal 1 for Φ be a physical substrate of Ψ . This is because, in our illustration, there are other physical mechanisms that can affect the temperature in the house (Ψ), such as the outside temperature (Φ') and the amount of direct sunlight in the house (Φ). That is, there is a lack of complete isomorphism specifiable, at least initially, between the regulated variable (Ψ) and a physical basis (Φ).

In any given context, the temperature in the house may be influenced by any or all of these physical mechanisms. If the outside temperature or the amount of direct sunlight happens to vary when the HVAC system is activated, then the temperature may not covary perfectly with the activation of the HVAC system (i.e., $P(\Psi/\Phi) < 1$) even though the temperature is, at least in part, a function of the operation of the HVAC system (i.e., $P(\Psi/\Phi) > 0$). If the outside temperature and amount of direct sunlight are constant or are perfectly correlated with the activation of the HVAC system, then the temperature in the house and the activity of the HVAC system may covary perfectly (i.e., $P(\Psi/\Phi) = 1$). In the context of psychophysiology, this is analogous to a brain lesion study accounting for some of the variance ($P(\Psi/\Phi) > 0$) or all of the variance ($P(\Psi/\Phi) = 1$) in the cognitive measure in the study. The latter result does not imply the lesioned brain region is a necessary component just as the fact that the temperature in the house covaries perfectly with the activity of the HVAC system does not mean necessarily that there are not other physical mechanisms that may also influence the temperature. Thus, as long as $P(\Psi/\Phi) > 0$, Φ could be considered a predictor (or component) of Ψ ; the fact that $P(\Psi/\Phi) = 1$ does not imply that Φ is the only or a necessary cause of Ψ .

The asymmetry between $P(\Psi/\Phi)$ and $P(\Phi/\Psi)$ and the interpretive problems that may result when simply assuming $P(\Psi/\Phi) = P(\Phi/\Psi)$ are also evident in this metaphor. As outlined above, the former term represents variations in temperature in the house given variations in the activity of the HVAC system, whereas $P(\Phi/\Psi)$ represents the activity

¹ Research in which psychological or behavioral factors serve as the independent (or blocking) variables and physiological structures or events serve as the dependent variable can be conceptualized as investigating the $P(\Phi/\Psi)$. Research in which physiological structures or events serve as the independent (or blocking) variables and psychological or behavioral factors serve as the dependent variable, in contrast, can be conceptualized as investigating the $P(\Psi/\Phi)$. These conditional probabilities are equal only when the relationship between Ψ and Φ is 1:1 (Cacioppo & Tassinary, 1990). Accordingly, approaches such as stimulation and ablation studies provide complementary rather than redundant information to studies in which physiological (e.g., fMRI) measures serve as dependent measures. This is because stimulation and ablation studies bear on the relationship $P(\Psi/\Phi)$, whereas studies in which physiological variables serve as dependent measures provide information about $P(\Phi/\Psi)$.

of the heater given variations in the temperature in the house. Although one would expect to find $P(\Phi/\Psi) > 0$ in some contexts, the fact that the temperature in the house is regulated when the HVAC system is activated does not necessarily imply that changes in the temperature in the house will be associated with variations in the activity of the HVAC system. In the context of local changes in temperature distant from the thermostat of the HVAC system, for example, the observed temperature will fluctuate whereas the HVAC system remains inactive (e.g., outside temperature, Φ' ; exposure to direct sunlight, Φ). Thus, the finding that $P(\Phi/\Psi) = 0$ does not mean Φ has no role in Ψ , only that Φ has no role in Ψ in that context. In the context of brain imaging studies, areas that are not found to become active as a function of a cognitive operation may nevertheless be part of a physical substrate for that cognitive operation (just as a HVAC system may remain a part of the physical mechanism responsible for the temperature in a house).

The preceding example illustrates why one would not want to exclude a brain area as potentially relevant to a cognitive operation based on the area not being illuminated in a brain image as a function of the cognitive operation. The converse also holds – that is, a brain area that is illuminated as a function of a cognitive operation may or may not contribute meaningfully to the production of the cognitive operation. Consider an LED on a thermostat (which we will call Φ') that illuminates when the HVAC system (Φ) is operating. In this case, the $P(\Phi/\Psi) = P(\Phi'/\Psi) > 0$. That is, the LED represents a physical element that would show the same covariation with the temperature in the house as would the operation of the HVAC system as long as a top-down approach was used. When the complementary bottom-up approach were used, it would become obvious that disconnecting (lesioning) the HVAC system has effects on the temperature in the house whereas disconnecting (or directly activating) the LED has none.

FOUR CATEGORIES OF PSYCHOPHYSIOLOGICAL RELATIONSHIPS

Relations between elements in the psychological and physiological domains should not be *assumed* to hold across situations or individuals. Indeed, elements in the psychological domain are delimited in the subtractive method in part by holding constant other processes that might differentiate the comparison tasks. Such a procedure is no unique to psychophysiology or to the subtractive method, as most psychological and medical tests can involve constructing specific assessment contexts in order to achieve interpretable results. The interpretation of a blood glucose test, for instance, can rest on the assumption that the individual fasted prior to the onset of the test. Only under this circumstance can the amount of glucose measured in the blood across time be used to index the body's ability to regulate the level of blood sugar. The relationship between the physiological data and theoretical construct is said to have a limited range of validity, because the relationship

is clear only in certain well-prescribed assessment contexts. The notion of limited ranges of validity, therefore, raises the possibility that a wide range of complex relationships between psychological and physiological phenomena might be specifiable in simpler, more interpretable forms within specific assessment contexts.

To clarify these issues, it is useful to conceptualize psychophysiological relationships generally in terms of a 2 (One-to-one vs. Many-to-one) \times 2 (Situation Specific vs. Cross Situational) taxonomy. The specific families (i.e., categories) of psychophysiological relationships that can be derived from this taxonomy are depicted in Figure 1.1. The criterial attributes for, and theoretical utility in, establishing each of these categories are specified in the three dimensions illustrated in Figure 1.1; causal attributes of the relationships, and whether the relationships are naturally occurring or artificially induced constitute yet other, orthogonal dimensions and are explicitly excluded here for didactic purposes. For instance, the category in Figure 1.1 labeled "concomitant" refers only to the conditions and implications of covariation and is not intended to discriminate between instances in which the psychological factor is causal in the physiological response, vice versa, or a third variable causes both. In the sections that follow, each type of psychophysiological relationship and the nature of the inferences that each suggests are outlined.

Psychophysiological outcomes. In the idealized case, an *outcome* is defined as a many-to-one, situation-specific (context-dependent) relationship between Ψ and Φ . Establishing that a physiological response (i.e., an element in Φ) varies as a function of a psychological change (i.e., an element in Ψ) means one is dealing at the very least with an outcome relationship between these elements. Note that this is often the first attribute of a psychophysiological relationship that is established in laboratory practice. Whether the physiological response follows changes in the psychological event across situations (i.e., has the property of context independence), or whether the response profile follows only changes in the event (i.e., has the property of isomorphism) is not typically addressed initially. Hence, a given psychophysiological relationship may appear to be an outcome but subsequently be identified as being a marker as the question of isomorphism is examined; a relationship that appears to be an outcome may subsequently be reclassified as being a concomitant once the range of validity is examined; and a relationship that appears to be a marker (or concomitant) may emerge as an invariant upon studying the generalizability (or isomorphism) of the relationship. This progression is not problematic in terms of causing erroneous inferences, however, because, as we shall see, any logical inference based on the assumption one is dealing with an outcome relationship holds for marker, concomitant, or invariant psychophysiological relationships, as well.

Despite the outcome serving as the most elemental psychophysiological relationship, it can nevertheless provide

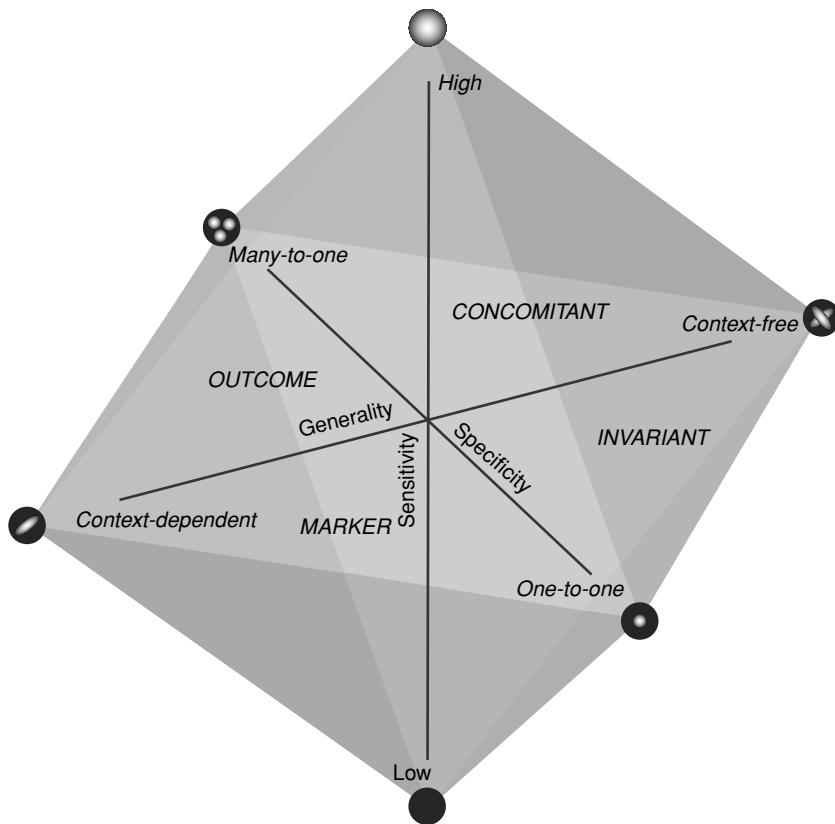

Figure 1.1. Taxonomy of psychophysiological relationships. The dimensions of sensitivity and specificity are related but not synonymous with those used in either signal detection theory or clinical decision analysis. Sensitivity, in this context, refers to likelihood that a physiological response will covary with any psychological element. Specificity, in contrast, refers to the likelihood that that a physiological response will be linked to a particular psychological element or set of elements and simultaneously not linked to another psychological element or set of elements. The horizontal plane bisecting the square bipyramid represents the level of sensitivity necessary to afford maximal differentiation among the psychophysiological relationships.

the basis for strong inferences. Specifically, when two psychological models differ in predictions regarding one or more physiological outcomes, then the logic of the experimental design allows theoretical inferences to be drawn based on psychophysiological outcomes alone. That is, a psychophysiological outcome enables systematic inferences to be drawn about psychological constructs and relationships based on hypothetico-deductive logic. Of course, no single operationalization of the constructs in a crucial experiment is likely to convince the adherents of both theories. If multiple operationalizations of the theoretical constructs result in the same physiological outcome, however, then strong theoretical inferences can be justified.

Importantly, the identification of a physiological response profile that differentiates the psychological element of interest is sufficient to infer the absence of one or more psychological elements, but it does not provide logical grounds to infer anything about the presence of a psychological element. Hence, the identification of psychophysiological outcomes can be valuable in disproving theoretical predictions, but they are problematic as indices of elements in the psychological domain. This caveat is often

noted in discussions of the scientific method and is perhaps equally often violated in scientific practice (Platt, 1964). Skin conductance, for instance, has been a major dependent measure in psychological research because emotional arousal is thought to lead to increased skin conductance. Similarly, EMG activity over the forehead region has been a frequent target measure in relaxation biofeedback because tension has been found to increase EMG activity over this region. As noted in the previous section, however, simply knowing that manipulating a particular element in the psychological domain leads to a particular response in the physiological domain does not logically enable one to infer anything about the former based on observations of the latter, because one does not know what other antecedents might have led to the observed physiological response. Procedures such as holding constant any variations in the elements in the psychological domain that are not of interest, measuring these elements in addition to those of immediate theoretical interest to determine to which of the observed changes in physiological response are likely to be attributable, and excluding those physiological responses believed to covary with these irrelevant elements all represent attempts to reduce many-to-one relationships to one-to-one

relationships (i.e., going from psychophysiological outcomes to psychophysiological markers; see Figure 1.1). Such procedures clearly strengthen the grounds for psychophysiological inference, but they do not assure that all relevant factors have been identified or controlled, nor do they provide a means of quantifying the extent of other influences on psychophysiological responding.

Consider, for example, what can be expected if the probability of a physiological element $\{P(\Phi)\}$ is greater than the probability of the psychological element of interest $\{P(\Psi)\}$. Because this implies that $P(\Psi, \Phi)/P(\Psi) > P(\Psi, \Phi)/P(\Phi)$, it can be seen that the $P(\Phi|\Psi) > P(\Psi|\Phi)$, and, consequently, that research based only on outcome relationships would result in an overestimation of the presence of the psychological element.

We should emphasize that these probabilities are simply a way of thinking more rigorously about psychophysiological relations; one still needs to be cognizant that these relationships (e.g., probabilities) may vary across situations (e.g., assessment contexts). Indeed, comparisons of these probabilities across assessment contexts can provide a means of determining the individual or situational

specificity of a psychophysiological relation. Before proceeding to this dimension of the taxonomy outlined in Figure 1.1, however, we elaborate further on psychophysiological relations within a specific assessment context when viewed within the framework of conditional probabilities. In particular, as the $P(\Psi, \Phi)$ approaches 1.0 and the $P(\text{Not-}\Psi, \Phi)$ approaches 0.0 within a specific assessment context, the element in the physiological domain can be described as being an ideal marker of the element in the psychological domain.

Psychophysiological markers. In its idealized form, a psychophysiological *marker* is defined as a one-to-one, situation-specific (i.e., context-dependent) relationship between abstract events Ψ and Φ (see Figure 1.1). The psychophysiological marker relation assumes only that the occurrence of one (usually a physiological response, parameter of a response, or profile of responses) predicts the occurrence of the other (usually a psychological event) within a given context. Thus, markers are characterized by limited ranges of validity. Such a relationship may reflect a natural connection between psychological and physiological elements in a particular measurement situation or it may reflect an artificially induced (e.g., classically conditioned) association between these elements. Importantly, minimal violations of isomorphism between Ψ and Φ within a given assessment context can nevertheless yield a useful (although imperfect) marker when viewed in terms of conditional probabilities.

Markers can vary in their specificity and sensitivity. The more distinctive the form of the physiological response and/or the pattern of associated physiological responses, the greater the likelihood of achieving a one-to-one relationship between the physiological events and psychological construct, and the wider may be the range of validity of the relationship thereby achieved. This is because the utility of an element in Φ to index an element in Ψ is generally strengthened by the defining the physiological element so as to minimize its occurrence in the absence of the element in the psychological domain.

In terms of sensitivity, a psychophysiological marker may simply signal the occurrence or nonoccurrence of a psychological process or event, possessing no information about the temporal or amplitude properties of the event in a specific assessment context. At the other extreme, a psychophysiological marker may be related in a prescribed assessment context to the psychological event by some well-defined temporal function, such that the measure can be used to delineate the onset and offset of the episode of interest, and/or it may vary in amplitude such that it reflects the intensity of the psychological event.

In sum, markers represent a fundamental relationship between elements in the psychological and physiological domains which enables an inference to be drawn about the nature of the former given measurement of the latter. The major requirements in establishing a response as a marker are to: (1) demonstrate that the presence of

the target response reliably predicts the specific construct of interest, (2) demonstrate that the presence of the target response is insensitive to (e.g., uncorrelated with) the presence or absence of other constructs, and (3) specify the boundary conditions for the validity for the relationship. The term "tracer" can be viewed as synonymous with marker, for each refers to a measure so strictly associated with a particular organismic-environmental condition that its presence is indicative of the presence of this condition. The term "indicant," on the other hand, is more generic, including invariants, markers, and concomitants because each allows the prediction of Ψ given Φ . We turn next to a description of concomitants.

Psychophysiological concomitants. A psychophysiological *concomitant* (or correlate), in its idealized form, is defined as a many-to-one, cross-situational (context-independent) association between abstract events Ψ and Φ (see Figure 1.1). That is, the search for psychophysiological concomitants assumes there is a cross-situational covariation between specific elements in the psychological and physiological domains. The assumption of a psychophysiological concomitant is less restrictive than the assumption of invariance in that one-to-one correspondence is not required, although the stronger the association between the elements in the psychological and physiological domains, the more informative tends to be the relationship.

Consider, for instance, the observation that pupillary responses varied as a function of individuals' attitudes toward visually presented stimuli – an observation which was followed by the conclusion that pupillary response was a "correlate" of people's attitudes (Metals & Hess, 1982). However, evidence of variation in a target physiological response as a function of a manipulated (or naturally varying) psychological event establishes an outcome relation, which is necessary but insufficient for the establishment of a psychophysiological concomitant or correlate.

First, the manipulation of the same psychological element (e.g., attitudes) in another context (e.g., using auditory rather than visual stimuli) may alter or eliminate the covariation between the psychological and physiological elements because the latter is evoked either by a stimulus that had been fortuitously or intentionally correlated with the psychological element in the initial measurement context, or by a noncriterial attribute of the psychological element that does not generalize across situations. For instance, the attitude-pupil size hypothesis has not been supported using nonpictorial (e.g., auditory, tactile) stimuli, where it is possible to control the numerous light-reflex-related variables that can confound studies using pictorial stimuli. It is possible, in several of the studies showing a statistical covariation between attitudes and pupillary response, that the mean luminance of individuals' selected fixations varied inversely with their attitudes toward the visual stimulus.

Second, the manipulation of the same psychological element in another situation may alter or eliminate the covariation between the psychological and physiological elements because the latter is evoked not only by variations in the psychological element but also by variations in one or more additional factors that are introduced in (or are a fundamental constituent of) the new measurement context. Tranel et al. (1985), for instance, demonstrated that the presentation of familiar faces (e.g., famous politicians, actors) evoked larger skin conductance responses (SCRs) than did the presentation of unfamiliar faces. This finding, and the procedure and set of stimuli employed, were subsequently used in a study of patients with prosopagnosia (an inability to recognize visually the faces of persons previously known) to demonstrate that the patients can discriminate autonomically between the familiar and unfamiliar faces despite the absence of any awareness of this knowledge. Thus, the first study established a psychophysiological relationship in a specific measurement context, and the second study capitalized on this relationship. To conclude that a psychophysiological concomitant had been established between familiarity and SCRs, however, would mean that the same relationship would hold across situations and stimuli (i.e., the relationship would be context-independent). Yet ample psychophysiological research has demonstrated the opposite psychophysiological outcome as specified by Tranel et al. (1985) – that is, that novel or unusual (i.e., unfamiliar) stimuli can also evoke larger SCRs than familiar stimuli. Hence, it is safe to conclude that the relation between stimulus familiarity and skin conductance should not be thought of as a psychophysiological concomitant.

Unfortunately, evidence of faulty reasoning based on the premature assumption that one is dealing with a true psychophysiological correlate (or invariant) is all too easy to find:

I find in going through the literature that the psychogalvanic reflex has been elicited by the following varieties of stimuli... sensations and perceptions of any sense modality (sight, sounds, taste, etc.), associations (words, thoughts, etc.), mental work or effort, attentive movements or attitudes, imagination and ideas, tickling, painful or noxious stimuli, variations in respiratory movements or rate, suggestion and hypnosis, emotional behavior (fighting, crying, etc.), relating dreams, college examinations, and so forth.... Forty investigators hold that it is specific to, or a measure of, emotion of the affective qualities; ten others state that it is not necessarily of an emotional or affective nature; twelve men hold that it is somehow to be identified with conation, volition, or attention, while five hold very definitely that it is nonvoluntary; twenty-one authorities state that it goes with one or another of the mental processes; eight state that it is the concomitant of all sensation and perception; five have called it an indicator of conflict and suppression; while four others have used it as an index of character, personality, or temperament. (Landis, 1930, p. 391)

The hindrances to scientific advances, it would seem, stem not so much from impenetrable psychophysiological

relationships as from a failure to recognize the nature of these relationships and their limitations to induction.

As in the case of psychophysiological marker, the empirical establishment of a psychophysiological concomitant logically allows an investigator to make a probability statement about the absence or presence (if not the timing and magnitude) of a particular element in the psychological domain when the target physiological element is observed. It is important to emphasize, however, that the estimate of the strength of the covariation used in such inferences should not come solely from evidence that manipulated or planned variations of an element in Ψ are associated with corresponding changes in an element in Ψ . Measurements of the physiological response each time the psychological element is manipulated or changes can lead to an overestimate of the strength of this relationship and, hence, to erroneous inferences about the psychologic element based on the physiological response. As can be seen in Equations (1) and (2), this overestimation occurs to the extent that there are changes in the physiological response not attributable to variations in the psychological element of interest. Hence, except when one is dealing with an invariant relationship, establishing that the manipulation of a psychological element leads cross-situational to a particular physiological response or profile of responses is not logically sufficient to infer that the physiological event will be a strong predictor of the psychological element of interest; baserate information about the occurrence of the physiological event across situations must also be considered. This is sometimes done in practice by quantifying the natural covariation between elements in the psychological and physiological domains, and by examining the replicability of the observed covariation across situations.

Psychophysiological invariants. The idealized *invariant* relationship refers to an isomorphic (one-to-one), context-independent (cross-situational) association (see Figure 1.1). To say that there is an invariant relationship, therefore, implies that: (1) a particular element in Φ is present if and only if a specific element in Ψ is present, (2) the specific element in Ψ is present if and only if the corresponding element in Φ is present, and (3) the relation between Ψ and Φ preserves all relevant arithmetical (algebraic) operations. Moreover, only in the case of invariants does $P(\Psi|\Phi) = P(\Phi|\Psi)$, and $P(\text{Not-}\Psi,\Phi) = P(\text{Not-}\Phi,\Psi) = 0$. This means that the logical error of affirmation of the consequent is not a problem in psychophysiological inferences based on an invariant relation. Hence, the establishment of an invariant relationship between a pair of elements from the psychological and the physiological domains provides a strong basis for psychophysiological inference. Unfortunately, invariant relationships are often assumed rather than formally established, and, as we have argued, such an approach leads to erroneous psychophysiological inferences and vacuous theoretical advances.

It has been suggested occasionally that the psychophysiological enterprise is concerned with invariant

relationships. As we have seen, the search to establish one-to-one psychophysiological relationships is important. Moreover, as S. S. Stevens (1951) noted:

The scientist is usually looking for invariance whether he knows it or not. Whenever he discovers a functional relation between two variables his next question follows naturally: under what conditions does it hold? In other words, under what transformation is the relation invariant? The quest for invariant relations is essentially the aspiration toward generality, and in psychology, as in physics, the principles that have wide application are those we prize. (p. 20)

It cannot be overemphasized, however, that evidence for invariance should be gathered rather than assumed, and that the utility of psychophysiological analyses does not rest entirely with invariant relationships (Donchin, 1982). Without this recognition, the establishment of any dissociation between the physiological measure and psychological element of interest invalidates not only the purported psychophysiological relationship, but also the utility of a psychophysiological analysis. However, as outlined in the preceding sections of this chapter, and in the chapters that follow, psychophysiology need not be conceptualized as offering only mappings of context-independent, one-to-one relationships to advance our understanding of human processes and behavior.

To summarize, the minimum assumption underlying the psychophysiological enterprise is that psychological and behavioral processes unfold as organismic-environmental transactions and, hence, have physiological manifestations, ramifications, or reflections. Although invariant psychophysiological relationships offer the greatest generality, physiological concomitants, markers, and outcomes also can provide important and sometimes otherwise unattainable information about elements in the psychological domain. These points hold for the neurosciences, as well. In laboratory practice, the initial step is often to establish that variations in a psychological element are associated with a physiological change, thereby establishing that the psychophysiological relationship is, at least, an outcome. Knowledge that changes in an element in the psychological domain is associated with changes in a physiological response/profile neither assures that the response will serve as a marker for the psychological state (because the converse of a statement does not follow logically from the statement), nor that the response is a concomitant or invariant of the psychological state (because the response may occur in only certain situations or individuals, or may occur for a large number of reasons besides changes in the particular psychological state). Nevertheless, both forms of reasoning outlined in this chapter can provide a strong foundation for psychophysiological inferences about behavioral processes.

CONCLUSION

Psychophysiology is based on the dual assumptions that human perception, thought, emotion, and action are

embodied and embedded phenomena; and that the measures of the processes of the corporeal brain and body contain information can shed light on the human mind. The level of analysis in psychophysiology is not on isolated components of the body, but rather on organismic-environmental transactions, with reference to both physical and sociocultural environments. Psychophysiology, therefore, like anatomy and physiology, is a branch of science organized around bodily systems whose collective aim is to elucidate the structure and function of the parts of and interrelated systems in the human body in transactions with the environment. Like psychology, however, psychophysiology is concerned with a broader level of inquiry than anatomy and physiology and can be organized in terms of both a thematic as well as a systemic focus. For instance, the social and inferential elements as well as the physical elements of psychophysiology are discussed in the chapters that follow.

The metaphor of the human mind as computer software on a discrete personal computer and the brain the hardware on which this software runs dominated psychology and the cognitive sciences in the latter half of the twentieth century. Interestingly, the notion of a computer disconnected from others is already passé, as mobile computers that are linked through ubiquitous broadband wireless connections have produced remarkable capacities in the form of the Internet. Although access and deposits to the Internet are achieved through the operation of a discrete computer, the study of the software alone of that computer would not reveal its functional capacities given its connectivity and the presence of the Internet. The human brain, of course, has long been mobile and connected to others through broadband telereceptors. A hallmark feature of psychophysiology is the longstanding attention not only to physiological correlates of cognitive or behavioral states but to the elucidation of the structure and function of the parts of and interrelated systems in the human body in transactions with the environment.

The importance of the development of more advanced recording procedures to scientific progress in psychophysiology is clear, as previously unobservable phenomena are rendered tangible. However, advanced recording procedures are not sufficient for progress in the field. The theoretical specification of a psychophysiological relationship necessarily involves reaching into the unknown and, hence, requires intellectual invention and systematic efforts to minimize bias and error. Psychological theorizing based on known physiological and anatomical facts, exploratory research and pilot testing, and classic psychometric approaches can each contribute in important ways here by their generation of testable hypotheses about a psychophysiological relationship. It should be equally clear, however, that the scientific effectiveness of psychophysiological analyses does not derive logically from physiologizing or from the measurement of organismic rather (or in addition to) verbal or chronometric responses. Its great value stems from the stimulation of interesting hypotheses and from the fact that when an

experiment agrees with a prediction about orchestrated actions of the organism, a great many alternative hypotheses may be excluded. The study of physiological mechanisms and techniques can sharpen our thinking and reduce the error of our conceptualizations and measurements. Although necessary and important, one should not lose sight of the fact that they are means rather than ends in psychophysiology. Little is gained, for instance, by simply generating an increasingly lengthy list of "correlates" between specific psychological variables and additional psychophysiological measures.

A scientific theory is a description of causal interrelations. Psychophysiological correlations are not causal. Thus in scientific theories, psychophysiological correlations are monstrosities. This does not mean that such correlations have no part in science. They are the instruments by which the psychologist may test his theories. (Gardiner, Metcalf, & Beebe-Center, 1937, p. 385)

To further theoretical thinking, therefore, a taxonomy of psychophysiological relations was outlined, and a scheme for strong inference based on these relationships was suggested. Among the questions the formulation outlined here can help to address are: (1) how does one select the appropriate variable(s) for study, (2) how detailed or refined should be the measurement of the selected variables, (3) how can situational and individual variability in psychophysiological relationships be integrated into theoretical thinking about psychophysiological relationships, and (4) how can physiological measures be used in a rigorous fashion to index psychological factors. The ultimate value of the proposed way of thinking about psychophysiological relationships rests, however, on its effectiveness in guiding psychophysiological inference through the channels of judgmental fallacies, for as Leonardo Da Vinci (c. 1510) noted:

Experience does not ever err, it is only your judgment that errs in promising itself results which are not caused by your experiments.

Elements of Functional Neuroimaging

TOR D. WAGER, LUIS HERNANDEZ, JOHN JONIDES, AND MARTIN LINDQUIST

There has been explosive interest in the use of brain imaging to study cognitive and affective processes in recent years. Examine Figure 2.1, for example, to see the dramatic rise in numbers of publications using positron emission tomography (PET) and functional Magnetic Resonance Imaging (fMRI) from 1985 to 2004. A recent surge in integrative empirical work that combines data from human performance, neuroimaging, neuropsychology, and psychophysiology provides a more comprehensive, but more complex, view of the human brain-mind than ever before. Because the palette of evidence from which researchers draw is larger, there is an increasing need to for cross-disciplinary integration and education. Our goal in this chapter is to provide an introduction to the growing field of neuroimaging research, including a brief survey of important issues and new directions.

The many aspects of PET and fMRI methodology are organized here into three sections that describe the physical, social, and inferential contexts in which imaging studies are conducted. The first section covers the physical basis of PET and fMRI imaging. This section describes the physics of each technique, what each measures, aspects of data processing, current limits of resolution, and a comparison of the relative advantages and disadvantages of these two techniques. The second section concerns aspects of neuroimaging related to social issues. In this section, we explore the kinds of questions that might be fruitfully addressed using imaging, human factors considerations when designing imaging studies, and a “road map” of an imaging experiment. The third section deals with inference in neuroimaging. It contains a review of types of experimental designs, analysis strategies and statistics, and localization of neuroimaging results in the brain. The statistical part of the section reviews the General Linear Model (GLM; the most commonly used analysis framework), hierarchical and robust extensions to the GLM that are increasingly applied to neuroimaging data, and the most commonly used multivariate analyses. In this section we also address group analyses and multiple comparisons, and pitfalls in the use of the various analysis techniques.

Although we review the physics underlying PET and fMRI here, we would like to emphasize that much of the material in the remainder of the chapter can stand on its own; the reader need not have a thorough grasp of the physics before proceeding to other sections. An outline of the major topics covered is as follows:

- I. Physical context
 - What PET and fMRI can measure
 - PET physics
 - MRI physics
 - Bold physiology
 - Arterial spin labeling (ASL)
 - Limitations of PET and fMRI
- II. Social and procedural context
 - Uses of data from functional neuroimaging
 - Human factors in functional neuroimaging
 - Data Preprocessing
- III. Inferential context
 - Forward and reverse inference
 - Types of experimental designs
 - Techniques for contrasting experimental conditions
 - The general linear model (GLM) in neuroimaging
 - GLM model-building in fMRI
 - Extensions of the GLM
 - Group analysis
 - Statistical Power
 - Bayesian inference
 - Multivariate analysis
 - Thresholding and multiple comparisons

I. PHYSICAL CONTEXT

Imaging methods for human studies include a number of alternatives: fMRI, PET, single positron emission computerized tomography (SPECT), event-related potentials (ERP), electroencephalography (EEG), magnetoencephalography (MEG), and near-infrared spectroscopy. A number of other brain-imaging techniques are available for use in animals using radiolabeling, histological, or optical

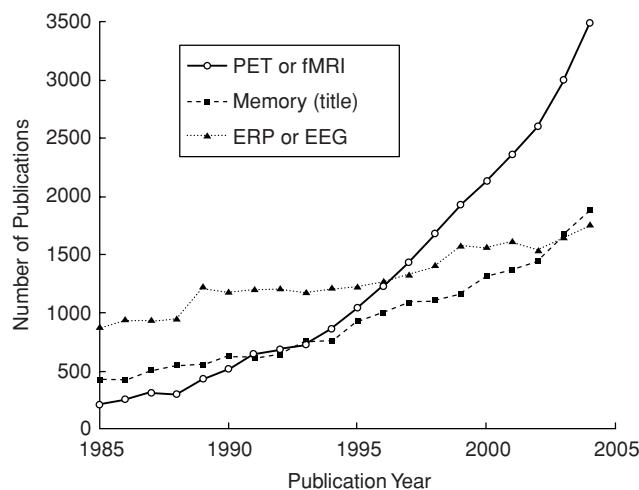

Figure 2.1. Publications by year indexed in Medline for PET and fMRI studies. Neuroimaging studies were identified by inclusively combining the search terms fMRI, PET (but not animal or companion), positron emission tomography, functional magnetic resonance imaging, or brain imaging, limited to human studies. Memory publications were identified using a title search for the word “memory,” and ERP/EEG publications were identified by using an inclusive search for these terms.

imaging techniques. Each of these techniques has advantages and disadvantages, and provides a unique perspective on the functions of mind and brain.

We focus chiefly on PET and fMRI because of their popularity and because of their potential for combining with psychological methods to unravel aspects of mind and brain. PET and fMRI offer a balance between spatial resolution and temporal resolution – in contrast to EEG and MEG, which provide millisecond timing information but with uncertain spatial localization. Finally, PET and fMRI can be used to create dynamic (over time) images of the whole brain, including deep subcortical structures whose activity is largely undetectable with EEG and MEG. This last feature offers great potential for synergy with animal research: animal electrophysiology and lesion experiments often focus on isolated brain regions or pathways, whereas imaging can assess global function and interactions across diverse brain systems.

What PET and fMRI can measure

The number of techniques for imaging brain processes with PET and fMRI is growing. Although a thorough discussion of all of these is beyond the scope of this chapter, we provide a brief summary of them here. In the remainder of the chapter, we focus most intensively on measures of regional brain “activation” or “deactivation.” We will use these terms to refer to a local increase or decrease, respectively, in signal linked to local blood flow and/or oxygen concentration. Activation and deactivation in PET and fMRI reflect changes in neural activity only indirectly. Table 2.1 shows a summary of the various methods available using PET and fMRI as measurement tools. Following is a brief description of each method. In addition, a summary of the relative advantages and disadvantages of fMRI and PET is provided in Table 2.2.

Structural scans. Although we are largely concerned here with functional studies, we note that MRI by itself can provide detailed anatomical scans of gray and white matter with resolution well below 1 mm³. This can be useful if one expects structural differences between two populations of individuals, such as schizophrenics versus normal controls (Andreasen et al., 1994), or changes in gross brain structure with practice or some other variable. An example is a recent study that reported larger posterior hippocampi in London taxi drivers who had extensive training in spatial navigation (Maguire et al., 2000).

Anatomical connectivity. Another structural scanning technique is diffusion tensor imaging. This technique allows one to identify white-matter tracts (such as corpus callosum) in the human brain and changes in these structures as a function of some variable, such as age or training. Although not a technique to image brain function, “tractography,” most often performed using diffusion tensor imaging (DTI) in MRI, is a technique that allows the investigator to map the white matter tracts that connect regions of the brain and hence determine the physical connectivity network underlying brain activity (Peled, Gudbjartsson, Westin, Kikinis, & Jolesz, 1998). MR images can

Table 2.1. Summary of PET and fMRI methods

What is imaged	PET	fMRI
Brain structure		Structural T1 and T2 scans
Regional brain activation	Blood flow (¹⁵ O) Glucose metabolism (¹⁸ FDG) Oxygen consumption	BOLD (T2*) Arterial spin labeling (ASL) FAIR
Anatomical connectivity		Diffusion tensor imaging
Receptor binding and neurochemistry	Benzodiazapines, dopamine, acetylcholine, opioids, other neurochemicals Kinetic modeling	MR spectroscopy
Gene expression	Various radiolabeling compounds	MR spectroscopy with kinetic modeling

Table 2.2. Relative advantages of PET and fMRI

PET	fMRI
Mapping of receptors and other neuroactive agents	Repeated scanning
Direct measurement of glucose metabolism	Single subject analyses possible
No magnetic susceptibility artifacts; better signal around brain sinuses	Higher spatial resolution
Quiet environment for auditory tasks	Higher temporal resolution
Easily combined with ERP and other measurements because there is no magnetic field	Single trial designs; image events within trials
Quantitative baseline possible for measuring resting-state metabolism, comparing scans across days, comparing across long time periods within a session	Estimation of hemodynamic response and separation of stimulus and task set related variables Measure dynamic connectivity (correlations) among brain regions Lower cost

be made sensitive to the spontaneous diffusion of water. Near a white matter tract, water diffuses most easily along the tract, producing a diffusion tensor (a generalization of a vector) that is large along the axis of the tract and small in the other dimensions. In the published literature, diffusion tensor images are usually labeled with different colors for the x, y, and z components of motion; a solid block of one color indicates fiber tracts running along either the x, y, or z-axis of the image.¹

DTI can be used to study the structure of fiber tracts in healthy or patient populations, or they can be used in combination with functional imaging studies. For example, a recent implementation of this approach used DTI to define adjacent regions of the anterior cingulate that receive different projections from other brain regions (Johansen-Berg et al., 2004). Subsequent fMRI imaging showed that these adjacent subregions responded to different psychological tasks.

Regional brain activation. Perhaps the most frequent use of both PET and fMRI is the study of metabolic

and vascular changes that accompany changes in neural activity. With PET, one may separately measure glucose metabolism, oxygen consumption, and regional cerebral blood flow (rCBF). Each of these techniques allows one to make inferences about the localization of neural activity based on the assumption that neural activity is accompanied by a change in metabolism, in oxygen consumption, or in blood flow.

Functional MRI using the Blood Oxygen Level Dependent method (BOLD) measures the ratio of deoxygenated to deoxygenated hemoglobin in the blood across regions of the brain. The rationale is that (a) more oxygenated blood in an area causes a decrease in BOLD signal, and (b) oxygen consumption is followed by an overcompensatory increase in blood flow, which dilutes the concentration of deoxygenated hemoglobin and produces a relative increase in signal (Hoge et al., 1999); (Kwong et al., 1992); (Kwong et al., 1992). The BOLD effect is a complex interplay between oxygen consumption, blood flow and blood volume, and it is described in more detail in the following section.

Cerebral perfusion can be measured using MRI rapidly and noninvasively by using arterial spin labeling (ASL). These measurements are a more direct, and quantitative measure of brain activity (Duong et al., 2002) but they present some technical challenges that will be discussed in later sections.

Receptor binding. The affinity of particular chemicals for specific types of neurotransmitter receptors offers researchers a leverage point for investigating the functional neurochemistry of the human brain. Radioactive labels are attached to compounds that bind to receptors in the brain. Labeled compounds are injected into the arteries of a subject by either a bolus (a single injection) or continuous infusion of the substance until the brain concentrations reach a steady state. This method can be used to image the density of a specific type of receptor throughout the brain. It can also be used to image the amount of binding to a particular type of receptor that accompanies performance of a task, as it was used in one study of dopamine binding during video game playing (Koepf, 1998).

The most common radioligands and transmitter systems studied are dopamine (particularly D2 receptors) using [¹¹C]raclopride or [¹²³I]iodobenzamide, muscarinic cholinergic receptors using [¹¹C]scopolamine, and benzodiazepines using [¹¹C]flumazenil. In addition, radioactive compounds that bind to serotonin, opioid, and several other receptors have been developed. Because the dynamics of radioligands are complex, a special class of mathematical models, called kinetic models, have been developed to explain the dynamic action of the labels. Kinetic modeling can allow a researcher to estimate how much of the radiolabeled compound is in the vasculature as opposed to in the brain, how much is freely circulating in brain tissue, how much is bound to the specific

¹ A standard convention, which we adopt throughout this chapter, is to refer to locations in the brain according to their relative position from the anterior commissure. Coordinates are recorded in three dimensions: lateral (negative x values are in the left hemisphere, positive in the right), rostrocaudal (positive is anterior), and dorsal-ventral (positive is superior), referred to as x, y, and z, respectively.

receptor-type under investigation, and how much is bound to nonspecific sites in the brain. Estimation of these parameters requires a detailed knowledge of the properties of the specific substances used, and how they act in the brain over time.

Having provided a brief summary of these techniques, we shall now concentrate on PET and fMRI as they are used to measure changes in blood flow and oxygenation. In the following sections, we describe the basics of what PET and fMRI measure, and how these measurements are made.

PET physics

Positron Emission Tomography provides a three-dimensional (3-D) image of blood flow, glucose consumption, or neurotransmitter receptor binding by detecting positrons emitted by a radioactive tracer. Positrons are subatomic particles having the same mass but opposite charge as an electron – they are “anti-matter electrons.” The most common radioactive tracers are ^{15}O , “oxygen-15,” commonly used in blood-flow studies, ^{18}F (fluorine), used in deoxyglucose mapping, and ^{13}C (carbon) or ^{123}I (iodine), used to label raclopride and other receptor agonists and antagonists. The decay rate of such isotopes is quite fast, and their half-lives vary from a couple of minutes to a few hours, which means that a cyclotron must be available nearby in order to synthesize the radioactive tracer minutes before each PET scan.

The tracer is injected into the subject’s bloodstream in either a bolus or a constant infusion that produces a steady-state concentration of tracer in the brain. As the tracer decays within the blood vessels and tissue of the brain, positrons are emitted. The positrons collide with nearby electrons (being oppositely charged, they attract), annihilating both particles and emitting two photons that shoot off in opposite directions from one another. The photons are detected by photoreceptive cells positioned in an array around the participant’s head. The fact that matched pairs of photons travel in exactly opposite directions and reach the detectors simultaneously are important for the tomographic reconstruction of the 3-D locations where the particles were annihilated. Note that the scanner does not directly detect the positrons themselves; it detects the energy that results from their annihilation.

Depending on the design, most PET scanners are made up of an array of detectors that are arranged in a circle around the patient’s head, or in two separate flat arrays that are rotated around the patient’s head by a gantry. To detect simultaneously occurring pairs of photons, each pair of detectors on opposite sides of the participant’s head must be wired to a “coincidence detector” circuit, as illustrated in Figure 2.2. Small tubes (called “septa” or “collimators”) are placed around the detectors to shield them from radiation from the sides and help prevent coincidences due to background radiation.

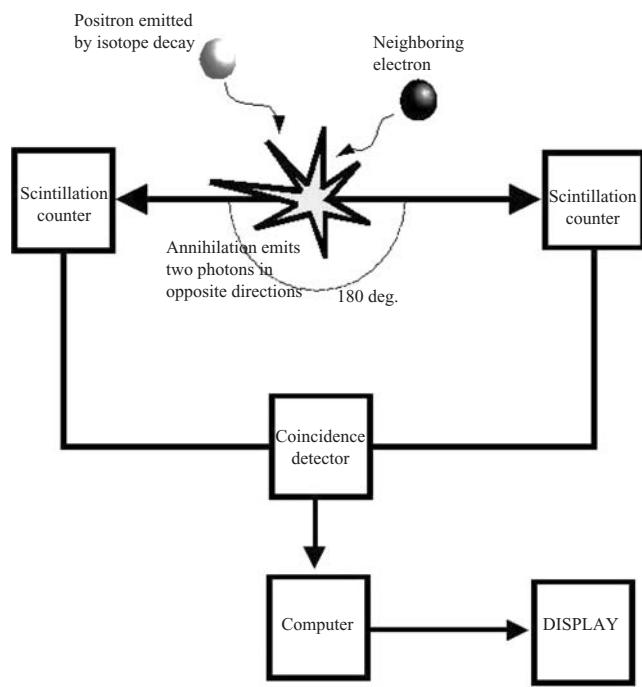

Figure 2.2. A schematic diagram of the main components of a PET scanner.

The injected tracer will be distributed throughout the blood vessels and tissue of the brain (indeed, throughout the rest of the body as well). The goal of *image reconstruction* is to determine the density of radioactive counts, and thus the amount of radioactively labeled substance, in each location within the brain. Here, we describe this process for a single two-dimensional (2-D) slice through the brain. Using mathematical notation, we use the letter **R** to refer to the location in 2-D space within the slice, and the density of tracer in each location as a 2-D function **D(R)**. The goal of reconstruction is to find **D(R)**. Each pair of coincidence detectors counts the number of positrons **P** emitted (plus error) at a particular angle throughout the entire brain slice. Positrons annihilated at a subset of locations **R** will yield coincidence counts on a particular pair of detectors. In mathematical terms, the positron count **P** at each detector is equal to the sum of the positron densities over all locations lying between the detectors:

$$P(\theta) = \sum_r D(r) \cdot \Delta r \quad (2.1)$$

It’s useful to think of **P** as a 1-D projection, or shadow, of the 2-D densities in the brain slice. The counts at each pair of detectors around the head are a projection at a different angle. For instance, in the image in Figure 2.3A there is a low-intensity gray circle that represents the brain, and a higher density dark circle that represents a tracer-rich area in the brain. The two detectors each contain a projection of the image (imagine a light placed behind the “brain” in Figure 2.3A) at a different angle. A simple way to think of

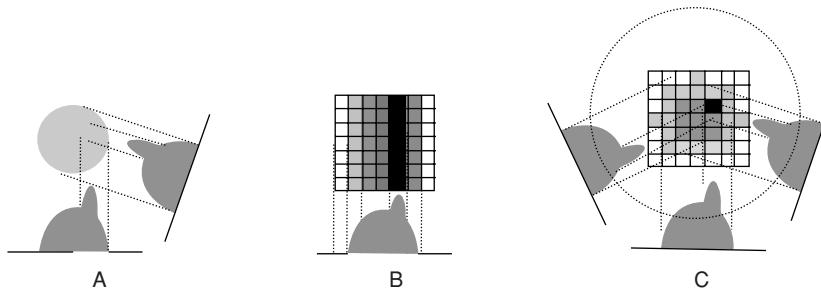

Figure 2.3. PET image reconstruction. The raw data are a set of projections (sums) at different angles, as shown in A. “Backprojecting” the raw data onto the image means adding the numbers of counts in the projection to the pixels that are aligned with each point in the projection, as shown in B. An image can be obtained after the data from all the projections has been added, as shown in C.

reconstruction is to take each detector and assign the number of counts found at that detector to each location \mathbf{r} that could have produced the counts, as shown for one detector in Figure 2.3B. Summing the reconstructed image over detectors at different angles (Figure 2.3C) yields an estimate of the original densities $\mathbf{D}(\mathbf{R})$. As the number of projections is not infinite, and neither is the number of pixels in the image, some severe artifacts will occur in the image, and they must be compensated for by applying different filters to the data. This method is referred to as filtered backprojection.

In practice, this procedure is usually implemented by treating the projections as one-dimensional (1-D) representations of the spatial frequency of the image. Spatial frequencies can be translated into image intensities using the inverse Fourier transform. A Fourier transform is an operation that re-expresses a signal (data collected over time or space) in terms of the power in the signal at different frequencies (spatial or temporal), and it plays an important role in both PET and fMRI data analysis. The inverse Fourier transform, FT^{-1} , expresses frequency-domain signals back in the spatial (or temporal) domain. Thus, the tracer density $\mathbf{D}(\mathbf{R})$ can be estimated by taking the inverse 2-D Fourier transform of the count data:

$$D(R) = \text{FT}^{-1} \{ R \cdot P(\theta) \} \quad (2.2)$$

A more complete explanation of filtered backprojection and other methods can be found in several good texts (Bendriem, 1998; Sandler, 2003).

What do PET counts reflect? The answer depends, of course, on what molecule the label is attached to and where that molecule goes in the brain. Ideally, for ^{15}O PET, counts reflect the rate of water uptake into tissue. ^{18}F -fluorodeoxyglucose (FDG) PET measures glucose uptake, whereas ^{13}C Raclopride PET measures dopamine binding. However, in practice the observed level of signal depends on a number of factors, including the concentration of the radiolabeled substance in the blood, the blood flow and volume, the binding affinity of the substance to receptors, the presence of other endogenous chemicals that compete with the labeled substance, the rate of dissociation of the

substance from receptors, and the rate at which the substance is broken down by endogenous chemicals.

Estimation of all these parameters requires detailed knowledge of the properties of the specific substances and how they act in the brain over time. *Kinetic models* have been developed to estimate how much tracer is contained in different categories, or *compartments*, of blood and tissue. Different forms of kinetic modeling have different numbers of compartments; for example, a two-compartment model estimates how much of the radiolabeled compound is

in the vasculature as opposed to in the brain. A three-compartment model used in receptor binding studies estimates tracer quantities in blood, “free” tracer in tissue, and label bound to receptors. Often a reference region with few or no receptors (i.e., the cerebellum for dopamine) is used to model the separation of free from bound tracer; this requires the assumption that none of the signal in the reference region comes from “bound” tracer. A four-compartment model additionally separates tracer bound to receptors of a specific type (called specific binding) from those bound to other receptors (called nonspecific binding).

MRI physics

The raw signals in both NMR and MRI are produced the same way. As we will soon explain in more detail, a sample (e.g., a brain) is placed in a strong magnetic field and radiated with a radiofrequency (RF) electromagnetic field pulse. The nuclei absorb the energy only at a particular frequency, which is dependent on their electromagnetic environment, and then return it at the same frequency. The returned energy is detected by the same antenna that produced the RF field. Pulse sequences, or particular patterns of manipulations of the RF pulse and other magnetic fields, are used to acquire data that can be localized in the 3-D space of the brain.

The human body is made mostly of water, whose two hydrogen atoms are each made up of a single proton and a single electron. Every proton has its own magnetic dipole moment, represented mathematically by a vector in 3-D space. The magnetic moment is the amount of “magnetization” of an object, and it determines how strongly it interacts with magnetic or electric fields (a bar magnet is a dipole, and a very strong one would have a very large dipole moment).

The main magnetic field of an MRI scanner, usually labeled \mathbf{B}_0 , is extremely powerful – anywhere from 1.5 Tesla (the standard magnet used for clinical scans, 30,000 time stronger than the magnetic field of the earth) to 8 T. To achieve such high magnetic fields requires very high electric currents. Thus, MRI magnets are typically

superconducting closed loops of wire that carry a large current. The magnet's current is loaded ("ramped") when it is initially installed, and then it is simply allowed to flow along the closed loop perpetually. Due to the superconductive state of the coils, the magnet is always on, although no electricity is being applied to it. The drawback of this is that the magnet requires liquid helium to maintain the superconductive state, and that the perpetual field requires that the operator be constantly vigilant for safety hazards that might arise from inappropriate materials being in the environment of the magnet. Note that the potential for hazard is present even when the rest of the scanner hardware and software is turned off, because the magnetic field is always turned on. The field is most homogenous, or uniform, in the **bore** of the magnet, the hollow core in which the participant's head is situated.

When they are placed in the \mathbf{B}_0 field, the precession, or "spins," of a portion of the protons will align with or against the magnetic field. Being aligned with the magnetic field takes less energy than being aligned against it, so a greater number of the spins will be aligned in the direction of the field. The overall net magnetization of the spins in a piece of brain tissue is the *net magnetization vector*. We shall call the net magnetization vector \mathbf{M} . The larger the magnetic field, the greater the proportion of spins that are aligned, and the easier the magnetization vector is to detect.

The net magnetization vector *precesses* around the axis of the \mathbf{B}_0 field, parallel to the long axis of the bore of the magnet. Precession is a movement that looks like a spinning top: The origin of the vector stays fixed, while the end of the vector, describing the net magnetization of the spins in 3-D space, describes a circle around the axis of the \mathbf{B}_0 field, as shown in Figure 2.4. One of the most important equations in NMR physics is that describing the rate or angular velocity of precession, also called the *resonance frequency*, ω_0 (pronounced omega-naught):

$$\omega_0 = \gamma B_0 \quad (2.3)$$

The rate of precession equals the magnetic field \mathbf{B}_0 , multiplied by a constant, γ (gamma), called the gyromagnetic ratio. The gyromagnetic ratio is specific for the nucleus in question; γ for hydrogen nuclei is 42.58 MHz/Tesla. By introducing systematic local variations in the magnetic field, called *gradients*, the spins precess at different frequencies at different spatial locations. This information is critical to localizing an NMR signal in space. NMR spectroscopy takes advantage of the fact that the number of electrons present, the proximity of other nuclei, and other factors can change the local \mathbf{B}_0 field, thus altering ω_0 . Certain molecules can be identified by the pattern, or spectrum, of resonance frequencies in a piece of tissue.

The MRI signal is generated by introducing a second magnetic field, which we refer to as \mathbf{B}_1 . This second field is applied by an antenna and it rotates at the same rate of precession as the magnetization vector. This rate is typi-

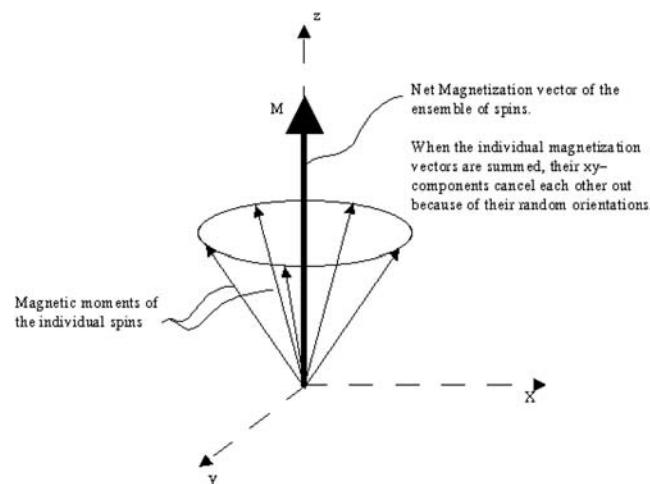

Figure 2.4. The magnetic spin ensemble in MRI.

cally in the radio frequency range, so these pulses are also referred to as "RF pulses." The RF pulse is applied in a direction perpendicular to the main magnetic field.

Physicists typically describe precession by referring to a "rotating frame of reference." This means that the vectors are considered from the point of view of an observer who is rotating along with the \mathbf{B}_1 field. To such an observer, the net magnetization vector (\mathbf{M}) and the RF field (\mathbf{B}_1) are stationary and perpendicular to each other, but the rest of the world is spinning. In this frame of reference, the effect of a magnetic field on a magnetic dipole is a rotation of the dipole toward the transverse plane. Thus, by applying the pulse at the frequency ω_0 , the pulse tips the net magnetization vector, increasing the "wobble" in the precessing vector. The degree of tipping is called the flip angle. If the flip angle is 90 degrees, as is shown in Figure 2.5, the net magnetization vector will be rotating in a plane transverse

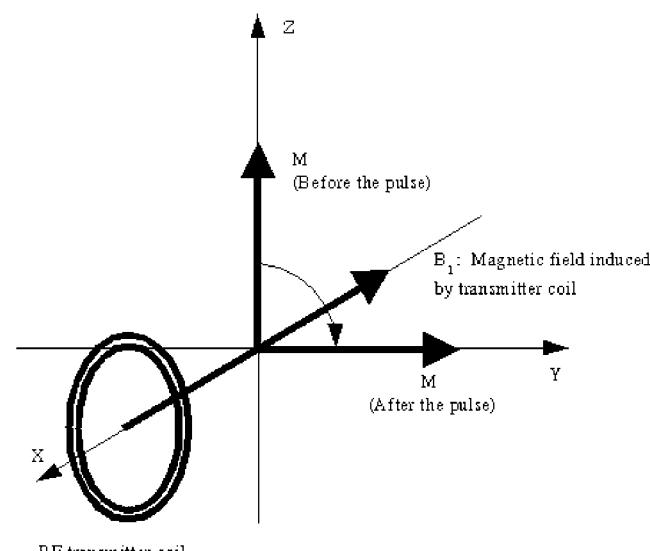

Figure 2.5. Tipping the magnetization vector from the z-axis onto the xy-plane. The duration and strength of the \mathbf{B}_1 field determine how far the vector is tipped (the "flip angle").

to the direction of \mathbf{B}_0 . We'll call the \mathbf{B}_0 direction \mathbf{z} , and the axes of the transverse plane \mathbf{x} and \mathbf{y} .

Changes in a magnetic field will induce electrical currents in a wire coil. The antenna used for transmission of the RF pulse is such a coil, and the rotation of \mathbf{M} through the plane of the antenna coil induces a current in the coil. This current induced in the coil is the NMR signal that we observe. The current oscillates at the resonance frequency, and the power (amplitude) of the signal is proportional to the degree of magnetization in the transverse plane.

When the RF pulse is turned off, the magnetization vector will "relax" back to its equilibrium position in line with \mathbf{B}_0 . This relaxation happens through several mechanisms: "Spin-lattice" relaxation occurs as the spins give away their energy, and they return to their original quantum state. The time this takes is called the T_1 relaxation time, and it depends on the density of the microscopic environment of the water protons (hence the protons in hydrogen) in the imaged tissue. This, in turn, will be reflected in differences in brain structure such as gray matter, which has a high water content versus white matter, which has a lower content. Pulse sequences sensitive to differences in T_1 relaxation time are called "T₁-weighted" images, and they are commonly used for high-resolution structural scans.

Spin-spin relaxation happens along the transverse (i.e., on the x - y plane) component of the magnetization vector. Recall that the magnetization vector that gives rise to the signal is made up of the sum of an ensemble of dipoles that precess at a given rate. Spin-spin relaxation is due to some of the spins rotating faster than others in the transverse plane. When this happens, the ensemble of spins get out of phase with each other and thus decrease magnetic coherence and reduce the net magnetization vector, as illustrated in Figure 2.6. The driving mechanism for this kind of relaxation is collisions between molecules that cause them to get out of phase with each other. The rate at which this happens is called the T_2 relaxation rate. Structural images that are sensitive to the differences in T_2 relaxation rates among different tissue types can also be acquired; these are called "T₂-weighted" images.

Another kind of relaxation is caused by local inhomogeneities in the magnetic field. These variations cause some protons to precess faster than others. Over the course of a few milliseconds, the protons will fall out of phase with each other, and the transverse-plane component of \mathbf{M} will shrink faster than expected due to simple T_2 . This change is referred to as T_2^* (pronounced 'T2 star'). A major reason for differences in T_2^* signal over the brain is variation in the local ratio of oxygenated to deoxygenated hemoglobin. A major cause of this variation is differences in regional brain metabolic processes, a signal of interest to neuroscientists. Thus, T_2^* weighted images are a reflection of changes in brain metabolism, and they are the "functional" brain images collected in fMRI BOLD (Blood Oxygen Level Dependent) imaging.

An example of the same slice of tissue imaged with T_1 and T_2 weighting can be seen in Figure 2.7. The images look

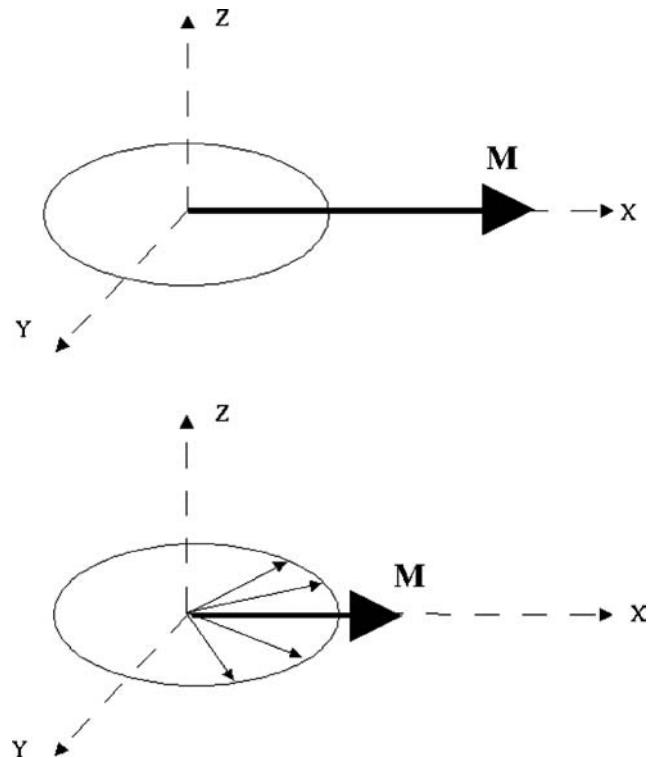

Figure 2.6. The dephasing process occurs because all the spins in the ensemble do not precess at the exact same rate. Some of them get a head, and some of them lag behind. The net effect is that they start canceling each other out, shortening the length of the magnetization vector.

strikingly different. Changing the contrast mechanism can be very useful in differentiating brain structures or lesions because some structures will be apparent in some kind of images but not in others. For example, multiple sclerosis lesions are virtually invisible in T_1 weighted images, but appear very brightly in T_2 weighted images.

The differences between T_1 , T_2 , and T_2^* weighted images lie in the construction of the pulse sequence, the pattern of RF excitations and data collection periods. A thorough discussion of pulse sequences is beyond the scope of this chapter because few neuroscientists or psychologists will ever program one. Rather, this is the province of physicists and bioengineers, and this division of labor is a key indication of how the discipline of neuroimaging is a truly interdisciplinary venture. For a more detailed introduction to types of pulse sequences, we refer the reader to Huettel, Song, & McCarthy (Huettel, 2004).

Now that we have a rough idea of how a signal is produced, let us take a look at how we can extract spatial information from it so that we can form an image. Localization of the signal in 3-D space in the brain is no easy task: it requires producing changes in the signal that vary systematically with location in the x , y , and z direction. MRI and fMRI images are usually acquired slice-by-slice in the z direction; thus, localization in the z direction is handled with *slice selection*, the process of selectively

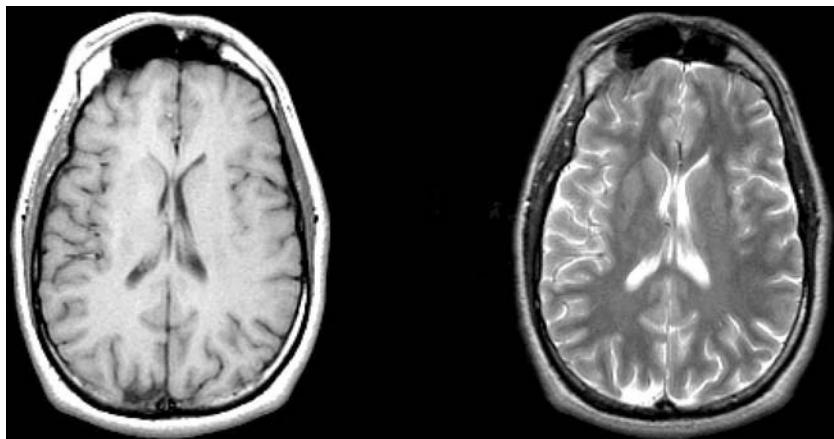

Figure 2.7. The same slice of brain tissue can appear very different, depending on which relaxation mechanism is emphasized as the source of the contrast in the pulse sequence. Using long echo times emphasizes T2 differences between tissues, and shortening the repetition time emphasizes T1 differences in tissue. Left: one slice of a T1 image. Right: the same slice acquired as a T2 image.

exciting one slice of brain tissue at a time. Signal is localized within a slice, in the x and y directions, by *frequency-encoding*, respectively. These are described in the following sections. We mentioned above that the precession frequency of the spins (and thus their resonance frequency) was proportional to the strength of the magnetic field. Now, consider what happens when we apply a *gradient* – another magnetic field in the direction of \mathbf{B}_0 , except that this field varies linearly in intensity with location along the x -axis (This is called the x -gradient). Because the magnetic field strength varies with position in space, so does the rotational frequency of the magnetization vector, and consequently, the frequency of the detected signal. Hence, the power of the signal collected by the RF antenna at each frequency tells us the power of the signal source at each location along the direction of the applied gradient. This technique is called “frequency encoding.” As with PET, the Fourier transform plays a role in reconstructing the image intensities from a frequency encoded signal. In MR image reconstruction, a Fourier transform of the frequency-encoded signal will result in an intensity image. The intensity is the amount of power, or “signal,” at each position along the direction of the frequency-encoding gradient.

In reality, things are a bit more complex. Because the spins at different locations along the x -axis are precessing at different rates in the presence of the gradient, their magnetization vectors get out of phase with each other, causing the net transverse magnetization (the overall signal) to decay quickly. The spins can be refocused in two different ways. One could apply a gradient of equal but opposite intensity to undo the phase gain caused by the first gradient, such that the spins will regain their phase coherence and form what’s called a “gradient-echo.” Alternatively, one could also apply another, “refocusing” RF pulse to rotate the magnetization 180 degrees, and then re-apply the original x gradient so that the spins regain

their phase coherence. This technique is called “spin-echo,” and both techniques are illustrated in Figure 2.8. Most BOLD pulse sequences employ the gradient echo technique.

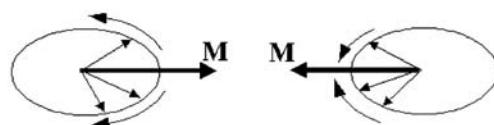

To encode the spatial location along the y -axis, we *briefly* apply a gradient along the y direction prior to applying the frequency encoding gradients. The result of this gradient is a brief change in the spins’ precession rate, and they end up a little bit ahead or behind the others depending on where they are along the y -axis. In other words, they gain or lose a little bit of phase relative to the vectors rotating at the resonant frequency, depending on their position along the y -axis and the strength of the applied gradient. This is called phase encoding because the phase gained by the signal is determined by its position in space. This procedure is repeated over a range of gradient amplitudes, so that we obtain a set of signals with a *distribution* of phases along one axis and a distribution of frequencies along the other axis.

It is important (albeit difficult to visualize) to notice that obtaining a distribution of phase gains along the y -direction (phase encoding) is equivalent to frequency encoding, and vice versa. Effectively, there are now two spatial frequency axes, commonly referred to as k_x and k_y . You may find yourself wondering why one doesn’t just apply simultaneous frequency encoding gradients along x and y directions. The answer is that doing so would result in a gradient that runs along the diagonal instead because gradients add linearly as vectors.

k_x and k_y data are arranged in “k-space,” a 2-D matrix whose rows and columns contain the power in the signal

Gradient Echo technique: A gradient in the magnetic field causes the spins to lose phase coherence. Reversal of the gradient causes them to regain it.

Spin Echo technique: spins are dephased by the gradient. After application of a 180 degree pulse, all the spins are rotated about the y -axis, and the application of the same gradient causes the spins to regain coherence along the negative x -axis.

Figure 2.8. Refocusing of spins in MR imaging by Gradient Echoes and Spin Echoes.

at each frequency. The two-dimensional Fourier transform of the k-space data is an image of the signal contribution from each location in the slice.

Up to this point, we have given a brief description of one of many techniques for generating an MR image. For more in-depth information, we refer the reader to a very approachable text by Elster (1994).

We mentioned earlier that BOLD imaging uses a T_2^* -weighted signal that depends on the oxygenation of hemoglobin. As neural activity increases, so does metabolic demand for oxygen and nutrients. Capillaries in the brain containing oxygen and nutrient-rich blood are separated from brain tissue by a lining of endothelial cells, which are connected to astroglia, a major type of glial cell that provides metabolic and neurochemical-recycling support for neurons. Neural firing signals the extraction of oxygen from hemoglobin in the blood, likely through glial processing pathways (Shulman, Rothman, Behar, & Hyder, 2004; Sibson et al., 1997). As oxygen is extracted from the blood, the hemoglobin becomes paramagnetic – iron atoms are more exposed to the surrounding water – which creates small distortions in the \mathbf{B}_0 field that cause the T_2^* effect. Increases in deoxyhemoglobin can lead to a decrease in BOLD signal, often referred to as the “initial dip.” The initial decrease in signal (whose existence is controversial) is followed by an increase, due to an overcompensation in blood flow that tips the balance towards oxygenated hemoglobin (and less signal loss due to dephasing). It is this that leads to a higher BOLD signal. Initially, fMRI was performed by injection of contrast agents (such as iron) with paramagnetic properties, but the discovery that the T_2^* relaxation rate of oxygenated hemoglobin was longer than that of deoxygenated hemoglobin led to BOLD imaging as it is currently used with humans, without contrast agents (Kwong et al., 1992; Ogawa, Lee, Kay, & Tank, 1990).

BOLD physiology

How well does BOLD signal reflect increases in neural firing? The answer to this important question is complex, and understanding the physiological basis of the BOLD response is currently a topic of intense research (Buxton & Frank, 1997; Buxton, Uludag, Dubowitz, & Liu, 2004; Vazquez & Noll, 1998; Heeger, 2002). Some relationships among factors that contribute to BOLD signal are summarized in Figure 2.9.

Essentially, the BOLD signal corresponds relatively closely to the local electrical field potential surrounding a group of cells – which is itself likely to reflect changes in post-synaptic activity – under many conditions. Demonstrations by Logothetis and colleagues have shown that high-field BOLD activity closely tracks the position of neural firing and local field potentials in cat visual cortex, even to the locations of specific columns of cells responding to particular line orientations (Logothetis, 2001). However, under other conditions, neural activity and BOLD signal may become decoupled (Disbrow, 2000). Thus, for these

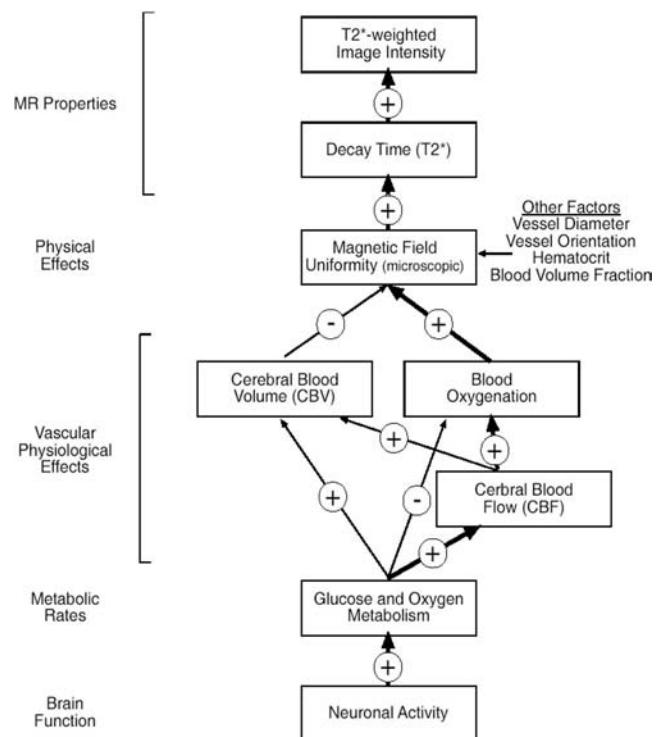

Figure 2.9. Influences on T_2^* -weighted signal in BOLD fMRI imaging. Courtesy Dr. Doug Noll.

reasons and others, BOLD signal is only likely to reflect a portion of the changes in neural activity in response to a task or psychological state. Many regions may show changes in neural activity that is missed because they do not change the net metabolic demand of the region.

Another important question is whether BOLD signal increases reflect neural excitation or inhibition. Some research supports the idea that much of the glucose and oxygen extraction from the blood is driven by glutamate metabolism, a major (usually) excitatory transmitter in the brain. Shulman and Rothman (Shulman & Rothman, 1998) suggest that increased glucose uptake is controlled by astrocytes, whose end-feet contact the endothelial cells lining the walls of blood vessels. Glutamate, the primary excitatory neurotransmitter in the brain, is released by some 60–90% of the brain’s neurons. When glutamate is released into synapses, it is taken up by astrocytes and transformed into glutamine. When glutamate activates the uptake transporters in an astrocyte, it may signal the astrocyte to increase glucose uptake from the blood vessels. Although it remains plausible that some metabolic (and BOLD) increases could be caused by increased *inhibition* of a region, in many tasks where both BOLD studies and neuronal recordings have been made, BOLD increases are found in regions in which many cells increase their activity. This is true in studies of eye movements, task switching, working memory, food reward, pain, and other domains.

Arterial spin labeling (ASL)

Blood Oxygenation Level Dependent (BOLD) fMRI is currently the dominant technique for functional imaging and

has produced a wealth of information about the brain's cognitive and affective functions. However, BOLD signal is difficult to quantify in a physically meaningful way because it is a non-linear function of many physiological parameters as well as the scanner's own characteristics (Figure 2.9). An alternative is to measure cerebral perfusion (or cerebral blood flow, CBF), a quantifiable physiological measure that may be more directly related to neuronal metabolism than BOLD. Recent animal imaging studies have indicated that CBF changes are more localized to gray matter than are BOLD changes, consistent with the notion that the BOLD effect is more weighted toward draining veins (Duong et al., 2002; Pfeuffer et al., 2002).

Perfusion imaging, unlike BOLD, may be used to study baseline activity (i.e., the resting state) without comparison to an active state. This type of measurement is particularly desirable for studies concerned with pathological states and/or testing the effects and specificity of different drugs, and in longitudinal studies. Even in non-quantitative studies (relative CBF), it has been shown that the variance of ASL perfusion studies across scanning sessions is dramatically less than that of BOLD, making studies that span days or even months feasible (Wang, Aguirre, Kimberg, & Detre, 2003).

In the pursuit of a practical cerebral perfusion measurement, there has been extensive work toward the development of arterial spin labeling techniques (Alsop & Detre, 1996; Kim, 1995; Wong, Buxton, & Frank, 1997) which employ magnetically labeled arterial water as an endogenous tracer. In typical ASL experiments, two images are collected: one following a tagging period, and the other after a control period during which the tag clears and the system is allowed to return to equilibrium. Subtraction of these two images yields a signal that is proportional to the amount of tag that is in the tissue, and can be used to quantify the perfusion rate.

There are numerous ASL schemes, but they all rely on the same principles and can be categorized as one of two approaches: the label is applied in either a "pulsed" or a "continuous" manner. The pulsed approach is carried out by applying a fast magnetic inversion pulse over a region outside the tissue of interest (e.g., the neck), thus creating a bolus of inverted spins that are allowed to flow into the tissue of interest, where they are detected. The continuous approach, on the other hand, uses a long RF pulse in combination with a magnetic field gradient along the direction of flow that results in the inversion of the spins that flow through the inversion plane. The inversion pulse is usually applied until the tissue of interest is saturated with tagged spins (Williams, Detre, Leigh, & Koretsky, 1992). Whereas the pulsed approach only requires 1–2 seconds for the label to reach its maximum concentration in the tissue, the continuous approach requires approximately 3 seconds before a steady state is reached. However, because of the longer inversion times of the continuous labeling scheme, the amount of tag to be detected is much larger

and thus, the SNR of the method is also larger (Wong, Buxton, & Frank, 1998).

One issue plaguing the BOLD effect technique is that because the BOLD effect is based on sensitivity to local changes in magnetic susceptibility, artifacts due to susceptibility gradients are also greatly exacerbated. These artifacts are especially problematic in areas of the brain that lie near air spaces, such as the roof of the mouth, nose and ear canals, as well as the sinuses. Such air-tissue interfaces create local field gradients that accelerate T_2^* dephasing (Bardgettini, Wong, Hinks, Tikofsky, & Hyde, 1992); (Kwong et al., 1992); (Ogawa, Lee, Kay, & Tank, 1990). Arterial spin labeling techniques do not require T_2^* weighting, so one can use standard Spin Echo imaging techniques to collect image data and avoid susceptibility artifacts. Functional imaging studies of the basal forebrain and orbitofrontal cortex would, thus, benefit from such techniques.

BOLD effect imaging remains the dominant technique for fMRI because arterial spin labeling techniques also pose a number of challenges. The techniques suffer from low SNR because less than 10% of the water in a given voxel is contributed by blood (Pawlik, Rackl, & Bing, 1981) and the label decays at a quick rate. This problem can be alleviated by increasing the amount of label that is introduced into the tissue, i.e., using longer RF labeling pulses until the tissue of interest becomes saturated with labeled blood (this approach is referred to as "continuous arterial spin labeling," or CASL). Collecting multi-slice data can also be challenging because the imaging RF pulses can interfere with the inversion label of the arterial water (Silva, Zhang, Williams, & Koretsky, 1995). The technical development of ASL techniques for use in functional MRI is an active field of research, and an increasing number of studies are being carried out with ASL.

Limitations of PET and fMRI

Spatial limitations

There are limitations restricting what both PET and fMRI can measure. Neither technique is good for imaging small subcortical structures or fine-grained analysis of cortical activations. The spatial resolution of PET, on the order of 1–1.5 cm^3 , precludes experiments testing for neural activity in focused areas of the brain (e.g., mapping receptive fields of cells in visual cortex). fMRI has a greater spatial resolution, as low as 1 mm^3 but often on the order of 3 mm^3 for most whole-brain functional studies. Careful work in individual participants has demonstrated the imaging of ocular dominance columns in humans (Cheng, 2001).

However, the high potential resolution is limited by several factors. First, fMRI researchers typically smooth (blur) the data before analysis, and some inferential methods (i.e., Gaussian Random Field Theory used in SPM, discussed later) require a high degree of blurring to be valid. Second, making inferences about populations of subjects requires analyzing groups of individuals, each with a different brain. The *normalization* procedures often

used to warp individual brains into a common “reference space” introduce spatial imprecision and blurring in the group data. Third, larger activated areas are commonly taken as stronger evidence for activation – an assumption that may be misleading for small anatomical structures! Larger areas of activation often also mean less precise localization. Thus, the effective spatial resolution of both PET and fMRI is likely to be limited not only by the technology itself, but by these other considerations. One impact of spatial limitations and intentional data-blurring is that activation in small structures, particularly compact subcortical nuclei, may be missed entirely or mislocalized. A fruitful approach for those interested in particular subcortical structures is to optimize both the physical acquisition and analysis to detect signal in these regions.

Acquisition artifacts

Artifactual activations (i.e., patterns that appear to be activation arising from non-neural sources) may arise from a number of sources, some unexpected. An early study, for example, found a prominent PET activation related to anticipation of a painful electric shock in the temporal pole (Reiman, Fusselman, Fox, & Raichle, 1989). However, it was discovered some time later that this temporal activation was actually located in the *jaw* – the subjects were clenching their teeth in anticipation of the shock!

Functional MRI signals are especially susceptible to artifacts near air and fluid sinuses and at the edges of the brain. Testing of hypotheses related to activity in brain regions near these sinuses – particularly orbitofrontal cortex, inferior temporal cortex, hypothalamus and basal forebrain, and amygdala – is problematic using fMRI, though a number of groups have used optimized acquisition and analysis schemes to deal with susceptibility. Spiral imaging sequences generally lead to signal loss (dropout) in susceptible regions, causing signal loss, whereas echo planar sequences (EPI) may lead to spatial distortion of the image and mislocalization of signal. The essential problem is that the fluid spaces cause distortions, or inhomogeneities, in the local magnetic field that are different for each participant. Some approaches are to use “z-shimming” during acquisition to make the field more homogenous (Constable & Spencer, 1999), improved reconstruction algorithms (Noll, Fessler, & Sutton, 2005), “unwarping” algorithms that measure EPI distortion by measuring inhomogeneity in the magnetic field and attempting to correct it (Andersson, Hutton, Ashburner, Turner, & Friston, 2001), and use of magnetic inserts in the mouths of participants that act as shims (Wilson & Jezzard, 2003).

Functional MRI also contains more sources of signal variation due to noise than does PET, including a substantial slow drift of the signal in time and higher frequency changes in the signal due to physiological processes accompanying heart rate and respiration (the high frequency noise is especially troublesome for imaging the brainstem). The low-frequency noise component in fMRI

can obscure results related to a psychological process of interest and it can produce false positive results, so it is usually removed statistically prior to analysis.

A consequence of slow drift is that it is often practically unfeasible to use fMRI for designs in which a process of interest only happens once or unfolds slowly over time, such as drug highs or the experience of strong emotions (though there are some examples of such studies). The vast majority of fMRI designs use discrete events that can be repeated many times over the course of the experiment – for example, the most common method for studying “emotion” in fMRI is to repeatedly present pictures with emotional content.

Temporal resolution and trial structure

Another important limitation of scanning with PET and fMRI is the temporal resolution of data acquisition. The details of this are discussed in subsequent sections, but it is important to note here that PET and fMRI measure very different things, over different time scales. Because PET computes the amount of radioactivity emitted from a brain region, at least 30 seconds of scanning must pass before a sufficient sample of radioactive counts is collected. This limits the temporal resolution to blocks of time of at least 30 seconds, well longer than the temporal resolution of most cognitive processes. For glucose imaging (FDG) and receptor mapping using radiolabeled ligands, the period of data collection for a single condition is much longer, on the order of 30–40 minutes.

Functional MRI has its own temporal limitation due largely to the latency and duration of the hemodynamic response to a neural event. Typically, changes in blood flow do not reach their peak until several seconds after local neuronal and metabolic activity has occurred. Thus, the locking of neural events to the vascular response is not very tight. Because of this limitation, a promising current direction is the estimation of the onset and peak latency of fMRI responses, and other parameters, averaged over many trials (Menon, Luknowsky, & Gati, 1998). We provide a more thorough discussion of this and related issues in the General Linear Modeling section.

II. SOCIAL AND PROCEDURAL CONTEXT

Uses of data from functional neuroimaging

A fundamental question in neuroimaging research is what one hopes to achieve with the chosen method. We begin our discussion of the social context of neuroimaging with a discussion of the types of questions that neuroimaging is and is suited to answer. Embarking on neuroimaging research requires a solid grasp of what kinds of imaging results would constitute evidence for a psychological or physiological theory, and a grounded understanding of what kinds of results are likely to be obtainable. Following this discussion, we provide a road map of the stages of an

fMRI experiment and some of the human factors issues involved in conducting an fMRI study.

Brain mapping: Learning about the brain. Perhaps the most obvious rationale for conducting functional neuroimaging experiments is to correlate structure with function. Through a combination of animal, human patient, neuroimaging, and neurophysiology, we now know that there is substantial localization of many functions in the neural tissue of the brain.

The majority of neuroimaging studies to date may be classified as brain mapping studies, in which investigators are exploring the patterns of activity elicited by a particular psychological process or condition. Brain mapping has been used to investigate virtually every field of study in human psychology and psychiatry, including (for example) attention, perception, memory, learning, emotion, reward, depression and other mood disorders, psychopathy, and Parkinson's and other neurological disorders. Recently, this trend has broadened to include mapping of social processes such as representations of the "self" and of others' intentions, economic principles such as expected utility and risk, and emotional self-regulation. Another approach particularly relevant here is the mapping of brain regions that correspond with changes in the autonomic and endocrine systems as measured by heart rate (Critchley, 2003), electrodermal responses (Critchley, 2000), pupil dilation (Siegle, 2003), and cortisol release (Dedovic, 2005; Oswald, 2005).

Although data are typically analyzed and described in terms of activation changes corresponding to a psychological process region-by-region in the brain (e.g., the "role of the insula in process X"), a more comprehensive view is that psychological processes arise from interactions among distributed networks of neurons. It is quite possible that patterns of *functional connections* among different brain regions may best characterize tasks, and multivariate brain mapping is likely to become more prevalent in the future (Penny, Stephan, Mechelli, & Friston, 2004; Roebroeck, Formisano, & Goebel, 2005; Beckmann, 2005; Calhoun, 2005).

Overall, the sort of behavioral neurology that is provided by studies of functional neuroimaging is quite helpful on several fronts. A detailed mapping of the functions of various brain structures will give us solid evidence about the primitive psychological processes of the brain. It will also provide detailed information for neurosurgical planning. Thus, if there were no other reason to conduct studies that use functional neuroimaging, mapping the brain would be sufficient reason. However, there are other reasons as well. Two major ones include psychological inference and prediction of future brain and psychological states.

Psychological inference: Learning about psychology. For reasons that we discuss more extensively in the following section, brain mapping can teach us much about the gross organization of the brain, but it isn't likely in and of itself to be very informative about *psychological mechanisms*. For example, researchers may want to know *how* people make decisions, whether there are *different kinds* of cognitive

control processes and how they are organized, or whether there are *distinct mechanisms* for different kinds of memories. Much of cognitive psychology has focused on identifying the component parts of systems such as decision making, attentional control, and memory, among other topics. This has been approached in two major ways: by trying to identify behavioral dissociations in performance between different processes, and by trying to identify the similarities in performance between different processes. The logic of both approaches can also be applied to measures of brain activation.

Studies of dissociations and associations include assessment of two or more tasks studying the same experiment. In a dissociation design, researchers test whether particular brain regions are more active in one condition than in another. A double dissociation occurs when manipulation A affects Task 1 more than Task 2, whereas manipulation B affects Task 2 more than Task 1. In a brain imaging study attempting to establish a double dissociation, investigators might look for two regions, one of which is more active in Task 1 than Task 2, and the other of which is more active in Task 2 than Task 1. Of course, a region need not be limited to one coherent piece of brain tissue; it might well consist of a network of brain areas. Finding a dissociation of this sort is typically considered evidence for separability of the two tasks, in that they each engage component processes differentially.

A recent study in our laboratory illustrates this approach. We sought to discover whether different kinds of shifts of attention activate different brain areas. One kind of attention-shift is required when one must change which of several objects is currently relevant for behavior. For example, an airline pilot may be monitoring the cockpit windshield, and shift attention to the radar display to check for other nearby objects. Another type of attention-shift is between attributes of objects: a pilot may switch attention from the location of objects on the radar to their apparent velocity. In addition to the object and attribute switching described above, the study also manipulated whether attention-switching was performed on items stored in working memory ("internal" representations) or whether they were available on-screen ("external" representations). Figure 2.10 shows results from different types of attention shift in a group of 38 participants.

In a double-dissociation design, investigators might want to know whether there are areas that respond more to object-switching than to attribute-switching, or vice versa. For instance, in Figure 2.10, the region in left inferior frontal gyrus shown in blue responds more to switches between internal than external representations. The extrastriate region shown in yellow, by contrast, responds more to switches of external representations than internal ones. We may conclude from this finding that the two types of attention-switches involve some different processes. There are limitations to this kind of inference, and we discuss them in the following section.

An alternative way to learn about the relationships among different tasks from brain imaging is to examine

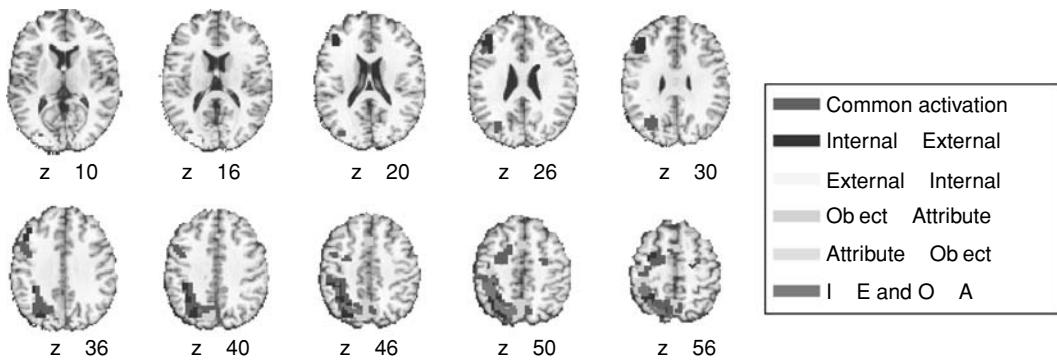

Figure 2.10. Axial slices showing brain regions responsive to different types of switching and their overlap, from Wager et al. (2005). All voxels identified show significant switch costs in at least two switch-no switch contrasts ($p < .05$ corrected in each). Thus, many regions not shown here may also show brain switch costs at less stringent thresholds. Regions colored in red are *common activations* that show no significant differences among costs for different types of switch (at $p < .05$ uncorrected). Other regions show evidence for greater activation in some switch types than others, as indicated in the legend. I, internal; E, external; O, object; A, attribute switch types.

the similarity of activation patterns across tasks. The logic is that the more similar the activation maps are for a pair of tasks or states, the more components the tasks have in common. This logic has been used in studies of individual differences in performance (Miyake, 2000). For example, if math scores and reading scores are highly correlated across individuals, then math and reading are assumed to share some common underlying performance components. In the brain imaging study on attention switching, one might examine the activation patterns for different kinds of task switching and quantify the degree of overlap among them. In this case, the substantial overlap in activations among all four types of attention switching suggests that common mechanisms are shared across all the tasks (red in Figure 2.10). Qualitative analyses of the similarities among activation patterns across tasks are common in the literature. What is critical is to have quantitative analyses of those similarities so that one can determine just how much overlap there is in brain activation between two tasks.

A third approach to use neuroimaging data is to study a psychological process by studying a physiological marker for that process. This approach has been taken in the psychophysiological literature – using cardiovascular responses as a marker for discrete or diffuse affective processes – although many researchers in that field are well aware of the problems in equating a physiological process with a psychological one. We discuss issues with this kind of psychological inference more extensively in the following section.

Human factors in functional neuroimaging

Many types of studies are not easily adaptable to the neuroimaging environment. Here, we briefly discuss human factors limitations and some safety issues to consider when embarking on a neuroimaging study. A complete review of safety concerns is beyond the scope of this chapter (see Elster, Link, & Carr, 1994 for more detail), but we cover a few of the basics here.

First, the MR environment is highly magnetic, and the magnetic field in the scanner is always on (barring unusual events that may require a shutdown). The strength of pull of ferromagnetic objects toward the bore of the magnet increases with the *square* of the closeness to the magnet, and the force increases with the mass of the object. Metal objects can fly out of hands or pockets as one moves closer to the bore, and larger objects pose a serious health hazard because they become missiles in the MR environment. Metallic objects in and around the participant's body can become dislodged in the intense magnetic field and cause serious injury or death. Because of the intensity of the magnetic field, participants who have implants that have any chance of being metallic (e.g., pacemakers or any electronic implants) are to be kept out of the magnetic environment. In addition, the presence of metal otherwise in the body (as in metal workers who may have tiny metallic shreds in their eyes) is a strict contraindication for scanning.

Electromagnetic fields can cause heating of tissue if applied with sufficient intensity and over enough time. This is typically not an issue, as most MRI scanners have built-in safeguards to prevent too much RF power deposition into the subject. However, should there be any metal conductors inside the RF coil, they can become quite hot because of induced currents, and they cause burns even at RF power levels that would otherwise be harmless to the participant. This is the same principle that underlies the production of sparks when you put metal objects in the microwave oven. Third, in some rare instances, changes in the magnetic field produced by the gradient coils can induce electric currents in long nerves causing them to depolarize and produce mild twitching. This is referred to as peripheral nerve stimulation (PNS) and occurs only rarely during fast imaging sequences but is more likely at higher field strength.

A safety concern particular to the PET environment is radiation exposure, which is limited by FDA regulations of 5 rem per session or 15 rem annually. NIH

guidelines are 3 rem within 13 weeks or 5 rem annually (http://www.cc.nih.gov/ccc/protomechanics/chap_6.html)

In addition to safety precautions, there are other considerations that one must address to protect the integrity of the acquired data. For both PET and fMRI, the participant must remain motionless for the duration of the session, but particularly while imaging data are being collected. PET tolerances for head movement are generally higher, but task-correlated head movement can be a serious confound in either modality. In fMRI, head motion is particularly problematic, as it induces changes in the local magnetic field. Although linear motion-correction algorithms generally do a reasonable job at correcting for gross displacement of the head, they do not correct for the more complex artifacts created with movement. Participants' heads are usually restrained with a vacuum bag (a soft pillow that becomes hard when air is pumped out of it), a forehead strap and foam pads, a bite bar, or some combination of these restraints. Participants who move too much are excluded from analysis.

The restrictiveness of the scanning environment means that it is not generally advisable to use neuroimaging for tasks in which head movement is unavoidable (e.g., studies involving overt speech or pain studies involving sudden-onset electric shocks). Researchers have partially circumvented the problem and collected vocal responses during tasks by pausing data collection during verbalization or including a set of regression predictors to account for motion artifacts (Frackowiak, 1997), but the latter in particular may be only a partial solution.

The enclosed MR environment can also be a problem for individuals with claustrophobia. It is a good idea for groups working with special populations – children and individuals with psychiatric disorders – to familiarize participants in a mock-scanning environment (including an enclosed bore and simulated scanner noise) before they enter the magnet proper.

Functional MRI scanning creates repeated loud tapping and buzzing noises (approximately 100dB at the patient's location), which makes auditory presentation of stimuli more difficult than presentation in other sensory modalities. The noise can be reduced with earplugs and shielded earphones, and so some kinds of auditory studies are possible. However, earphones, like other electrical and electronic devices that may be present in the scanner room, may cause magnetic susceptibility artifacts in the images.

For visual stimulation participants in PET and fMRI scanners typically view a visual display either projected by an LCD display onto a screen in the magnet room, on a shielded in-scanner LCD display, or projected onto each eye with fiber optics or LCD screens mounted in goggles. The screen is often projected onto participants' retinas through small mirrors mounted in the head coil (in MRI). The visual angle of presentation is often limited to about 15 degrees. The contrast and display image quality should be assessed before imaging, particularly for tasks that require the viewing of photographs or other fine-grained visual discriminations.

Response devices vary from scanner to scanner, but often the options are limited because in-scanner devices must be adequately RF-shielded. Responses are often limited to pressing buttons, making eye movements (several manufacturers provide scanner-compatible eye trackers), and moving joysticks or trackballs.

In general, any device that has wires or ferromagnetic parts can induce artifacts into the images because they distort the magnetic field. If severe, these artifacts may be visible as stripes or distortions in the structural (T1 or T2) images. However, T_2^* contrast is much more sensitive to artifacts, so distortions may not be visible in the structural scans but present in the functional data. Such artifacts have been observed (in our experience) with electrodermal response (EDR) leads, earphones, joysticks, mice, and keyboards in the scanning room. Some of these were not designed for use in the scanning environment, so there is no surprise that these result in artifacts. However, other commercial products intended to be RF-shielded for fMRI use also may lead to artifacts in images. In general, it is advisable to look carefully at structural and functional scans (and do a complete analysis of a simple paradigm such as visual stimulation) with and without any new piece of equipment in the room.

RF artifacts can also be caused by improper shielding of electrical cables running through the wall from the control room into the scanner room, and even by the use of hair products and makeup that contain ferrous material (not uncommon!). The closer a metallic object is to the patient's head, the greater the potential for artifacts. Jewelry, watches, and credit cards should never be taken into the MR environment (electronics are likely to be destroyed). Small metallic objects far from the participant's head, such as buttons on jeans, haven't presented a problem in our experience.

Another concern is that the neuroimaging environment itself may change performance of the task and other physiological measures. Changes may be due to anxiety about the scanning environment, changes in temperature (many scanner rooms are chilly), changes in posture that induce physiological changes (lying down reduces orthostatic load), practice, a response to the medical context presented by imaging suites, or other variables. It is advisable to test paradigms outside the scanner, and use objective measures of performance and other behaviors whenever possible.

Data preprocessing

Neuroimaging, and particularly fMRI, data undergo substantial processing before data analysis. There are several conditions about the fMRI images that must be met in order to carry out a successful data analysis. Most analyses are based on the assumption that all the voxels in any given image were acquired at the same time. Second, it is assumed that each data point in the time series from a given voxel were collected from that voxel only (i.e., that the participant did not move). Third, it is assumed that the residual variance will be constant over time and have

a Gaussian distribution. Additionally, when carrying out analyses across different subjects, we assume that each voxel occupies the same location within the brain for all the subjects in the study. Without any pre-processing, none of these assumptions are entirely true, and the assumptions will introduce errors in the results. Here, we describe preprocessing for an fMRI experiment; other types of neuroimaging will require different steps.

Reconstruction. Images are reconstructed from data in k-space and transformed into image space. Raw and reconstructed data are stored in a variety of formats, but reconstructed images are generally composed of a 3-D matrix of data, containing the signal intensity at each “voxel” or cube of brain tissue sampled in an evenly spaced grid, and a *header* that contains information about the dimensionality, voxel size, and other image parameters. A popular format is Analyze, also known as AVW, which uses a separate header file and image file for each brain volume acquired. Other formats, such as AFNI, are also gaining popularity. A series of images describes the pattern of activity over the course of the experiment. It is also common to store images in a 4-D matrix, where the fourth dimension is time.

Slice timing. Statistical analysis assumes that all the voxels in an image are acquired at the same time. In reality, the data from different slices are shifted in time relative to each other – because most BOLD pulse sequences collect data slice-by-slice, some slices are collected later during the volume acquisition than others. Thus, we need to back calculate what the signal intensity of all the slices would have been at the same moment in the acquisition period. This is done by interpolating the signal intensity at the chosen time point from the same voxel in previous and subsequent acquisitions. A number of interpolation techniques exist, from bilinear to sinc interpolations, with varying degrees of accuracy and speed. Sinc interpolation is the slowest, but generally the most accurate.

Realignment. A major problem in most time-series experiments is movement of the subject’s head during acquisition of the time series. When this happens, the image voxels’ signal intensity gets “contaminated” by the signal from its neighbors. Thus, one must rotate and translate each individual image to compensate for the subject’s movements.

The coordinates of a point in space can be expressed as a vector. It can be shown that the coordinates of a given point in space after any given translation, rotation, or combination of both, can be calculated by multiplying a matrix by the original vector. Such a matrix is called an *affine transformation* matrix. Multiplying all the voxel coordinates of an image by the same matrix will rotate and translate the entire image. Thus, in order to undo the rotation and translation of the head, we begin with a reference image (popular choices are the first image or the mean image) and transform all the other images in the time series to match it. For each image in the times series,

we calculate the elements in a six-parameter affine transformation matrix that corresponds to the displacement (x, y, z) and rotation (roll, pitch, yaw) of the head relative to the reference image. Usually, this is done by a least squares approximation that will minimize the difference between the image to be corrected and the reference. Multiplying by the matrix of best-fitting affine parameters applies the transformation and adjusts the image so that it matches the reference. Realignment corrects adequately for small movements of the head, but it does not correct for the more complex spin-history artifacts created by the motion. The parameters at each time point are saved for later inspection and are often included in the analysis as covariates of no interest.

Smoothing. Currently, many investigators apply a spatial smoothing kernel to the functional data, blurring the image intensities in space. This is ironic, given the push for higher spatial resolutions and smaller voxels – so why does anyone do it? One reason is that in a group analysis, voxels are assumed to occupy the same brain space across individuals. Smoothing can help minimize errors in inter-subject registration and normalization (see the following section). A second reason is that a popular choice for correcting for multiple comparisons, Gaussian Random Field Theory, assumes that the signal over space is a continuous field, and that the images have normally distributed noise. This is not the case in most experiments because the signal is often correlated among different voxels, especially in fMRI experiments. In order to make the noise in the images meet the assumption, the images are convolved with a Gaussian kernel (a 3-D normal probability density function), which gives the noise a more Gaussian distribution. The kernel is often described by the full width of the kernel at half its maximum height (“FWHM”) in mm. One estimate of the amount of smoothing required to meet the assumption is a FWHM of 3 times the voxel size (e.g., 9 mm for 3 mm voxels).

Acquiring an image with large voxels and acquiring with small voxels and smoothing an image are not the same thing. The signal-to-noise ratio during acquisition increases as the square of the voxel volume, so acquiring small voxels means that signal is lost that can never be recovered. Thus, it is optimal from a signal-detection point of view to acquire voxels at the desired resolution and *not* smooth the images, using other methods (e.g., the non-parametric methods described in the following section) in the statistical analysis.

Coregistration. Because the high-resolution structural images contain so much more anatomical information than the functional images, it is useful for localization and inter-subject normalization to make sure that the image locations correspond to the same brain regions in both structural and functional images. A problem is that the functional and structural images are collected with different sequences and in different image dimensions. This means that though the images correspond closely, the

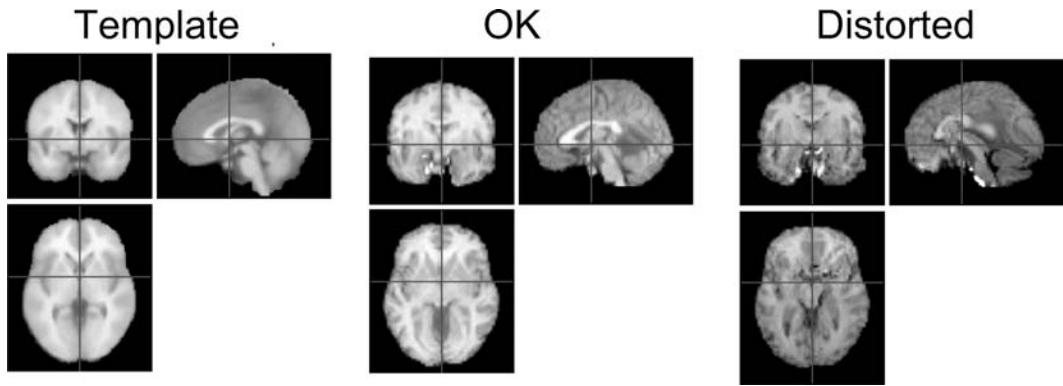

Figure 2.11. Left: the Montreal Neurological Institute average of 152 brains, used here as a spatial normalization template. Center: a subject that turned out OK. Right: a problematic normalization.

intensity values between the two images do not map in a monotonically increasing fashion. For example, the brightness (intensity) of gray, white, and ventricular tissue types may be ordered W – G – V in the T_2^* images, and V – G – W in a T2 image. Minimizing squared errors is inappropriate in this case, but an affine transformation matrix is often estimated by maximizing the *mutual information* among the two images, or the degree that knowing the intensity of one can be used to predict the intensity of the other (Cover, 1991). Often, a single structural image is co-registered to the first or mean functional image. Other schemes co-register a high-resolution structural image to an in-plane structural image (in the same image space as the functional images) acquired immediately before acquisition of the functional images.

Normalization or warping. In order to make quantitative comparisons across subjects, the corresponding brain structures must have the same spatial coordinates in the images. Of course, this is usually not the case because each individual has a uniquely shaped brain. We can however, stretch and compress the images in different directions so that the brain structures are in approximately the same locations. Usually we normalize all the brain images so that they will match a standard *template* (or target) brain (e.g., the Montreal Neurological Institute brain templates).

Whereas the realignment and co-registration procedures perform a *rigid body* rotation, normalization can stretch and shrink different regions of the image to achieve the closest match. The warping is described by a set of cosine basis functions, whose coefficients must be estimated by a least squares error-minimization approach. How closely the algorithm attempts to match the local features of the template depends on the number and spatial frequency of basis functions used. Often, warping that is too flexible (many basis functions) can produce gross distortions in the brain, as local features are matched at the expense of getting the right overall shape, as shown in Figure 2.11. This happens essentially because the problem space is too complex, and the algorithm can settle into a “local minimum”

solution that is not close to the global optimal solution (Frackowiak, 1997).

Following preprocessing, statistical analysis can proceed. The next section describes task design and statistical analysis in more detail. Together, these comprise the inferential context for neuroimaging.

III. INFERENTIAL CONTEXT

The inferential context for neuroimaging studies includes how tasks are designed (including special considerations for neuroimaging studies), how data analysis is conducted, and how results are interpreted in light of other findings – sometimes converging ones from other methodologies. We begin with a discussion of the logic and limitations of psychological inference from brain imaging studies, and we then return to issues of task design and analysis. We believe it is important to begin at the end, so to speak, because limitations in the kinds of inferences that can be made are a major constraint on choices of designs and analyses.

Forward and reverse inference

Once brain mapping has revealed a set of regions that are consistently activated by a task, it is tempting for scientists and lay people alike to believe that this is a brain network that implements the psychological processes involved. Two kinds of inferences emerge from this belief. First, researchers may conclude from a set of data that some brain regions are activated by a task. This is *forward inference*, inference about the brain given a particular psychological manipulation. The second inference is that activation of some regions implies that a particular psychological process has occurred. This is *reverse inference*, inference about psychology given brain activation.

Reverse inference treats a brain region – the anterior cingulate for pain or the caudate for reward – as a marker for a psychological process. That is, if one observes activity in a region, then the corresponding psychological process is assumed to have been engaged. A number of theoretical and practical problems with making reverse inferences

about psychology have been described (Sarter, Berntson, & Cacioppo, 1996). However, the temptation to make premature inferences about psychology from brain activations is strong, because the major motivation for conducting research on the brain and behavior is to learn about psychological processes.

Researchers have inferred that romantic love and retribution involve “reward system” activation because these conditions activate the caudate nucleus (Aron et al., 2005; de Quervain et al., 2004), that social rejection is like physical pain because it activates the anterior cingulate (Eisenberger, Lieberman, & Williams, 2003), among countless similar conclusions. The trouble is that both these regions are involved in motor control and cognitive planning and flexibility in a wide range of tasks, including basic shifting of attention, working memory, and inhibition of simple motor responses (Bush, Luu, & Posner, 2000; Kastner & Ungerleider, 2000; Paus, 2001; Wager, Jonides, & Reading, 2004; Wager, Jonides, Smith, & Nichols, 2005). One meta-analytic review concluded that cingulate activity was related most reliably to “task difficulty” In a large range of tasks (Paus, Koski, Caramanos, & Westbury, 1998). Thus, the assumption that one can make reverse inferences in this case is seriously flawed.

These kinds of inferential difficulties are not unique to the brain imaging community. Current issues raised in interpreting brain imaging studies seem eerily similar to the debates over electrical brain stimulation in the 1950s. In a famous case, Jose Delgado claimed that he had identified the aggression centers of the brain (also, incidentally, in the caudate nucleus), and by remote-control stimulation of an implanted electrode could make a raging bull as passive as a gentle lamb. Delgado demonstrated his findings by placing himself in a ring with a Spanish bull and using his device to pacify the animal in mid-charge (Valenstein, 1973). The experiment worked: the bull stopped – but not likely because he was truly pacified. Valenstein (1973) recounts that the electrodes were placed in motor-control regions of the caudate that forced the bull to turn in one direction (and probably confused the animal as well!).

It is useful here to analyze what went wrong in formal terms. What Delgado observed in the previous example is the disruption of aggressive behavior (B), which is “consistent with” the hypothesis that brain circuits for aggression were stimulated (A). That is, there is a high probability of observing B, given the truth of hypothesis A, or $P(B | A) \rightarrow 1$. But “consistent with” is not good enough. He made an erroneous inference about the probability of hypothesis A given the data B, and concluded that $P(A | B)$ is high. According to probability theory, these two statements are not equivalent, but rather $P(A | B)$ depends on $P(B | A)$, and also on the base rates (prior probabilities) of A and B, as stated by Bayes’ Theorem:

$$P(A | B) = \frac{P(A | B)P(A)}{P(B)} \quad (2.4)$$

In ignoring what else besides A might have disrupted behavior, they ignored the base rate of B, and reached a false conclusion.

In our brain imaging example, if the base rate of anterior cingulate activation across studies is high – if it’s activated in every study – then its activation tells us very little about the engagement of any particular psychological process.

Types of experimental designs

Neuroimaging designs require making tradeoffs. One basic tradeoff is between experimental power and the ability to make strong inferences from results. Some types of designs, such as the simple blocked design, often yield high experimental power, but they provide imprecise information about the particular psychological processes that activate a brain region. Event-related designs allow brain activation to be related more precisely to particular cognitive processes engaged in particular types of trials, but they are often less powerful and require additional assumptions about the underlying hemodynamics of the brain. Researchers may also choose to focus intensively on testing one comparison of interest, maximizing power to detect an effect, or they may test multiple conditions in order to draw inferences about the generality of a brain region’s involvement in a class of similar psychological processes. We describe some types of designs and the uses to which they are best suited in the following section.

Blocked designs

Because long intervals of time (30 seconds or more) are required to collect sufficient data in a PET experiment to yield a good image, the standard experimental design used in PET-activation studies is the blocked design. A blocked design is one in which different conditions in the experiment are presented as separate blocks of trials, with each block representing one scan during an experiment. To image a briefly occurring psychological process (e.g., the activation due to attention switching) using a blocked design, one might repeat the process of interest during an experimental block (A) and not during a control block (B). The A – B comparison is a simple *contrast* across experimental conditions; contrasts of various types are used in all kinds of experimental designs. Given the temporal limitation of this technique, PET is not well suited to examining the fine time course of brain activity that may change within seconds or fractions of a second.

The blocked structure of PET designs (and blocked fMRI designs) imposes limitations on the interpretability of results. Activations related to slowly changing factors such as task-set or general motivation are captured well by blocked designs. However, if one wishes to image the neural responses to individual stimuli, blocked designs are not well suited to that goal. In addition, the A – B contrast does not permit the researchers to infer if a region is activated in A but not B, deactivated in B but not A, or shows a combination of both effects. The use of multiple controls

and comparison conditions can ameliorate this problem to some degree.

One advantage to a blocked design is that it offers more statistical power to detect a change. Under ideal conditions, blocked designs can be over 6 times as efficient as randomized event-related designs (Wager & Nichols, 2003). Generally, theory and simulations designed to assess experimental power in fMRI designs point to a 16–18 s task/16–18 s control alternating-block design as optimally statistically powerful (Liu, 2004; Skudlarski, Constable, & Gore, 1999; Wager & Nichols, 2003). However, it is worth noting that this is not always true; the relative power of a blocked design depends on whether (a) the target mental process is engaged relatively continuously in A and not at all in B, and (b) imposing a block structure changes the nature of the task. On this latter point, it is easy to imagine that blocking some variable may fundamentally alter the strategy that subjects apply to the task.

Event-related fMRI

To take advantage of the rapid data-acquisition capabilities of fMRI, event-related fMRI designs and analyses have been developed. These designs, when employed judiciously, allow one to estimate the fMRI response evoked by specific stimuli or cognitive events within a trial (Rosen, Buckner, & Dale, 1998). A sample of the MRI signal in the whole brain can be obtained in 2–3 seconds on average (the TR, or repetition time of image acquisition), depending on the way the data are acquired and depending on the required spatial resolution of the voxels that are imaged. The limiting factor in the temporal resolution of fMRI is generally not the speed of data acquisition, but the speed of the underlying evoked hemodynamic response to a neural event (or the hemodynamic response function, HRF), which begins within a second after neural activity occurs and peaks 5–8 seconds after that neural activity has peaked (Aguirre, Zarahn, & D'Esposito, 1998; Friston, Frith, Turner, & Frackowiak, 1995).

Although event-related designs are attractive because of their flexibility and the information they provide about the individual responses, they require more caution in the design and analysis of the experiment. It is quite common to assume an ideal or “canonical” hemodynamic response function (HRF) in order to generate linear models for statistical analyses (the fitted curves shown by the dashed lines in Figure 2.12). This procedure requires a realistic model of the shape and timing of the HRF. Notably, the canonical estimates typically used come from studies of brief visual and motor events. In practice, however, the timing and shape of the HRF are quite variable across the brain within an individual and across individuals (Aguirre, Zarahn, & D'Esposito, 1998; Schacter, Buckner, Koutstaal, Dale, & Rosen, 1997). Part of the variability among shapes of the HRF is due to the underlying configuration of the vascular bed, which may cause differences in the HRF across brain regions in the same task for purely physiological reasons. Another source of variability in the shape of the HRF is dif-

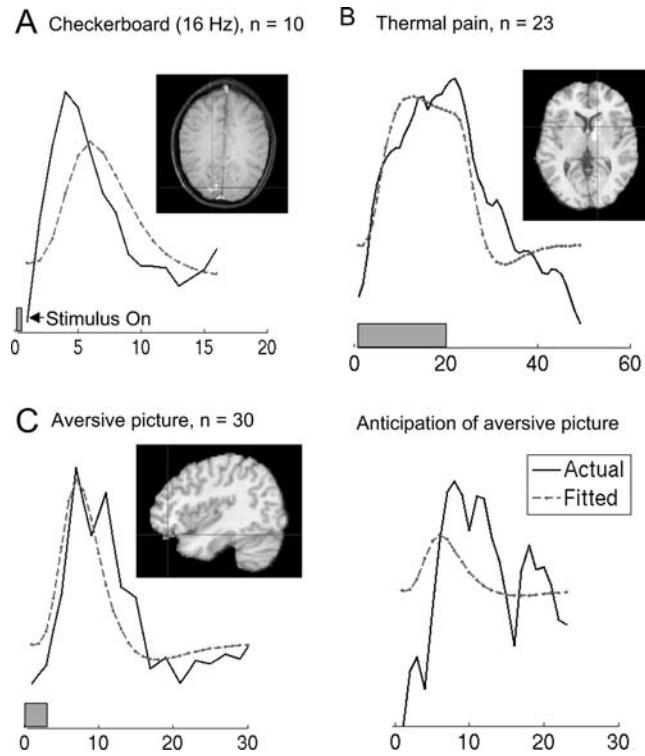

Figure 2.12. Examples of hemodynamic response functions (HRFs) derived from different brain regions in different studies. The brain region for each HRF is shown in the inset panels. The gray boxes at lower left in each panel show the duration of stimulus presentation. Solid lines show group-averaged high-resolution HRF estimates derived using a finite impulse response model. Dashed lines show the fitted responses using the canonical SPM HRF, composed of two gamma functions. The impulse HRF was convolved with a boxcar function equal to the stimulus duration in A and D, providing linear predictions for the response to the epoch. The impulse HRF was fitted to the briefly presented events in B and C.

ferences in the pattern of evoked neural activity in regions performing different functions related to the same task.

Figure 2.12A shows an example of an average response in left visual cortex, identified on an individual basis in 10 participants (scanning time was approximately 60 minutes per participant, with one stimulus every 30 s) (Wager, Vazquez, Hernandez, & Noll, 2005). The figure shows that the HRF peaks earlier than the canonical model, and the magnitude of activation is thus underestimated by about 30% in this group of subjects. Blocked designs are less sensitive to the variability of the HRF because they are dependent on the total activation caused by a *train* of stimulus events (though this depends on the density of psychological activity during the block (Price, Veltman, Ashburner, Josephs, & Friston, 1999)!). For example, Figure 2.12B shows the responses to a 20 s epoch of thermal pain in the right thalamus and caudate, averaged over 23 subjects (Wager et al., 2004). The predicted model of this longer period of stimulation is also based on the canonical HRF. Specifically, the model is generated by convolution of the HRF with a 20-s long step-function representing the

stimulation period. The canonical model fits reasonably well in this case.

On the other hand, Figure 2.12C shows a problematic case. The orbitofrontal cortex response to a 3 s presentation of an aversive visual stimulus is somewhat prolonged relative to the model, but the estimated magnitude is reasonably accurate (unpublished data). The right panel, on the other hand, shows the response in the same brain region to anticipation of viewing an aversive picture. In this case, the timing and duration of the cognitive activity are unknown – the activity could occur at the onset of the cue, throughout the anticipation epoch, or with increases proportional to the proximity of the picture. The model fits poorly in this case, illustrating the importance of knowing the onset and duration of the stimulation for linear model analyses.

In a single-trial event-related design, events are spaced far apart in time (every 20–30 s is considered sufficient). fMRI signal can be observed on single trials if the eliciting stimulus is very strong (Duann et al., 2002), permitting the possibility of fitting models at the level of an individual trial (Rissman, Gazzaley, & D'Esposito, 2004). This promising technique enables the testing of relationships between brain activity and trial-level performance measures such as reaction time and emotion ratings for particular stimuli (Phan et al., 2004).

Early studies frequently employed selective averaging of activity following onsets of a particular type (Aguirre, Singh, & D'Esposito, 1999; Buckner et al., 1998)(Menon, Luknowsky, & Gati, 1998)). However, even brief events (e.g., a 125-ms visual checkerboard display) have been shown to affect fMRI signal more than 30 s later (Wager, Vazquez, Hernandez, & Noll, 2005). Because the selective averaging procedure does not take stimulus history into account, it must be used with caution when responses to different events may overlap in time. Because of this, the majority of analyses, including those that estimate the shapes of HRFs, are currently done within the GLM framework (described in the following section).

Reports that the fMRI BOLD response is linear with respect to stimulus history (Boynton, Engel, Glover, & Heeger, 1996) encouraged the use of more rapidly-paced trials (Zarahn, Aguirre, & D'Esposito, 1997), spaced less than 1 s apart in extreme cases (Burock, Buckner, Woldorff, Rosen, & Dale, 1998; Dale & Buckner, 1997). Linearity in this context means that the magnitude and shape of the HRF does not change depending on the preceding stimuli. Studies have found that nonlinear effects in rapid sequences (1 or 2 s) can be quite large (Vazquez & Noll, 1998; Birn, Saad, & Bandettini, 2001; Friston, Mechelli, Turner, & Price, 2000; Wager, Vazquez, Hernandez, & Noll, 2005), but that responses are roughly linear if events are spaced 4–5 s apart (Miezin, Maccotta, Ollinger, Petersen, & Buckner, 2000).

To get an intuition about how rapid designs allow one to discriminate the effects of different conditions, consider this: With a randomized and jittered design, some-

times several trials of a single type will occur in a row, and because the hemodynamic response to closely spaced events sums in a roughly linear fashion, the expected response to that trial type will build to a high peak. Introducing longer delays between some trials and shorter ones between others allows peaks and valleys in activation to develop that are specific to particular experimental conditions. Thus, it is critical either to systematically intermix events of different types in a rapid event-related design or to vary (jitter) the inter-stimulus interval (ISI) between trials.

Suppose, for example, you have a rapid sequence with two types of trials – say, attention switch trials (S) and no-switch trials (N) as in task switching experiment described above (Figure 2.10). Randomly intermixing the trials with an ISI of 2 s will allow you to compare responses to S with those to N; that is, you will be able to estimate the difference $S - N$. However, you will not be able to tell if S and N activate or deactivate relative to some other baseline. If you vary the inter-stimulus intervals randomly between 2 and 16 s, you'll be able to compare $S - N$ (albeit with less power because there will be fewer trials), but you'll also be able to test whether S and N show positive or negative activation responses. This ability comes from the inclusion of inter-trial rest intervals against which to compare S and N, and the relatively unique signature of predicted responses to both S and N afforded by the random variation in ISIs.

The advantages of rapid pacing – including trial pacing comparable to other experiments, reduced boredom, and sometimes increased statistical efficiency – must be weighed against potential problems with nonlinearity, multicollinearity, and model misfitting when very rapid designs are used. A current popular choice is to use jittered designs with inter-stimulus intervals of at least 4 s, with exponentially decreasing frequencies of delays up to 16 s.

Techniques for contrasting experimental conditions

Thus far, we have alluded to a simple kind of contrast between two conditions, the subtraction of a control condition (B) from an experimental one (A). Such contrasts are critical because any task, performed alone, produces activation in huge portions of the brain. To associate changes in brain activation with a particular cognitive process requires that we isolate changes related to that process from changes related to other processes.

The simple contrast discussed above was the first method used to make inferences about psychological processes from neuroimaging data (Petersen, Fox, Posner, Mintun, & Raichle, 1988; Posner, Petersen, Fox, & Raichle, 1988). It is called the subtraction method, the logic of which is this: If one tests two experimental conditions that differ by only one process, then a subtraction of the activations of one condition from those of the other should reveal the brain regions associated with the target process. This

subtraction is accomplished one voxel at a time throughout brain regions of interest. Together, the results of the voxel-wise subtractions yield a 3-D matrix of the difference in activation between the two conditions throughout the scanned regions of the brain, or *contrast images*. T-tests can be performed for each voxel to discover where in the brain the difference is reliable. The resulting parametric map of the t-values for each voxel shows the reliability of the difference between the two conditions throughout the brain. Figures of activation maps in publications, such as those shown in Figure 2.10, generally show images of voxels whose t-values or comparable statistics (z or F) exceed a statistical threshold for significance.

Subtraction logic rests on a critical assumption, what has been called the assumption of “pure insertion” (Sternberg, 1969). According to this assumption, changing one process does not change the way other processes are performed. Thus, by this assumption, the process of interest may be “purely” inserted into the sequence of operations without altering any other processes. Although violations of subtraction logic have been demonstrated experimentally (Zarahn, Aguirre, & D’Esposito, 1997), the logic is still widely used because it greatly simplifies the inference-making process. However, if the two tasks studied differ in more than one overt (e.g., visual stimulation) or covert process (e.g., attention, error checking, subvocalization, attention shifts), the results will be ambiguous. With only two tasks or conditions, this is very often the case.

One way to constrain the interpretation of brain activity and strengthen the credibility of subtraction logic is to incrementally vary a parameter of interest across several levels – essentially performing multiple subtractions on a single variable. An example is a study of the Tower of London task (Dagher, Owen, Boecker, & Brooks, 1999), which requires subjects to make a sequence of moves to transfer a stack of colored balls from one post to another in the correct order. The experimenters varied the number of moves incrementally from 1 to 6. Their results showed linear increases in activity in dorsolateral prefrontal cortex across all 6 conditions, suggesting that this area served the planning operations critical for good performance. The contrast tested in this condition is a *linear contrast*. We provide a mathematical explanation of how exactly this and other contrasts are performed in the section on linear modeling. Other contrasts, such as quadratic or monotonic contrasts, can also be specified.

Another extension of subtraction logic is the factorial design. The study of task switching presented in the introduction to this chapter serves as an example. Consider the comparison in this study of two types of switching, each varied independently: switching among objects and switching among attributes of objects. This design is a simple 2×2 factorial, with 2 types of trials (switch vs. no switch) crossed with 2 types of judgments (object/attribute). This design permits the testing of three contrasts: (a) a main effect of switch versus no switch; (b) a main effect of task type; and (c) the interaction between the two, which tests whether the switch versus

non-switch difference is larger for one task-type than the other. Factors whose measurements and statistical comparisons are made within subjects, as are those described above, are *within-subjects* factors, and those whose levels contain data from different individuals (e.g., depressed patients vs. controls) are *between-subjects* factors. Within-subjects factors generally offer substantially more power and have fewer confounding issues (e.g., differences in brain structure and HRF shapes) than between-subjects factors.

Factorial designs allow one to investigate the effects of several variables on brain activations. They also permit a more detailed characterization of the range of processes that activate a particular brain region – attention switching in general, or switching more for one task-type than the other. Factorial designs also permit one to discover double dissociations of functions within a single experiment. In our example (Figure 2.10), a factorial design was required in order to infer that a manipulation (e.g., object-switching) affected dorsolateral prefrontal cortex, but a second manipulation (e.g., attribute switching) did not.

Factorial designs also provide some ability to test for brain regions activated in common by a set of related tasks or uniquely by only certain tasks (Fan, Flombaum, McCandliss, Thomas, & Posner, 2003; Wager, Jonides, Smith, & Nichols, 2005; Wager et al., 2005). An important note in this regard is that inferring that an area responds, say, to “task switching in general” requires more than just a significant main effect of switching, but rather a *conjunction* across object and attribute switching. That is, each effect must be independently significant to conclude that both effects were present in a region (T. Nichols, Brett, Andersson, Wager, & Poline, 2005).

Also of great interest to psychologists and neuroscientists is the *specificity* of regional activation to one particular psychological process. An activated region or pattern of activations specific to a process is activated by *only* that process. If such specificity exists, then that pattern may serve as a marker for the psychological process, and reverse inference becomes possible. In general, if such inferences can be made at all, it seems practical to compare across a great many studies using a meta-analysis (Wager, Jonides, & Reading, 2004) – because establishing a marker requires determining which tasks do not activate the region. However, a problem with meta-analyses is their poor spatial resolution compared with individual studies.

One productive line of research attempting to address specificity within individual studies has been pursued by Kanwisher and colleagues in the study of face recognition (Kanwisher, McDermott, & Chun, 1997). In this study and many subsequent ones, they identified an area in the fusiform gyrus that responded to pictures of faces and drawings of faces, but not to houses, scrambled faces, partial faces, facial features, animal faces, and other control stimuli. By presenting a large number of control stimuli of various types, Kanwisher et al. (1997) were able to infer that the brain area they studied, which they called the Fusiform Face Area (FFA), was specific to the perception

of faces. They tested both for the types stimuli that elicited an FFA response and for those that did *not* elicit a response. In addition, because this region lies in slightly different locations across different participants, they performed separate “localizer” scans to locate the functionally face-selective region within individual participants.

The general linear model (GLM) in neuroimaging

The techniques described above can be understood mathematically in terms of the GLM framework. GLM is a linear analysis method that subsumes many basic analysis techniques, including t-tests, ANOVA, and multiple regression. In neuroimaging designs, analyses of both blocked and event-related designs are most frequently carried out in the GLM framework, though with some extensions that we describe in the following section. The GLM can be used to estimate whether the brain responds to a single type of event, to compare different types of events, to assess correlations between brain activity and behavioral performance or other psychological variables, and for other tests.

The GLM is appropriate when multiple predictor variables – which together constitute a simplified *model* of the sources of variability in a set of data – are used to explain variability in a single, continuously distributed outcome variable. In a typical neuroimaging experiment, the predictors are related to psychological events, and the outcome variable is signal in a brain voxel or region of interest. In analysis with the “massively univariate” GLM approach commonly used in brain imaging, one performs a separate regression analysis at every voxel in the brain.

In a single-subject fMRI analysis, the GLM assumes that the observed signal time series in a voxel is the sum of the activity evoked by a number of independent processes. Some of these processes are of interest, but others are nuisance contributions to the overall signal (e.g., apparent activation due to movement of the head). Activity evoked by each process is modeled with by constructing a predictor, or estimate of the predicted brain response, for each process. The amplitudes (weights) of the predictors, which reflect the magnitudes of the evoked activity for each process, are unknown. The GLM estimates these magnitudes and determines whether they are significantly different from zero at each voxel in the brain.

By convention, predictors are arranged in columns. The *design matrix*, X , describes the model. It contains a row for each of n observations collected (subjects or samples) and a column for each of k predictors. The data, y , are modeled as a linear combination of the predictors (i.e., a weighted sum) plus error, ε . The GLM framework is described by the equation:

$$y = X\beta + \varepsilon \quad (2.5)$$

where β is a $k \times 1$ vector containing the predictor weights (also called regression slopes or parameter estimates). The equation is in matrix notation. Thus, X is an $n \times k$ model matrix, y is an $n \times 1$ vector containing the observed data, and ε is an $n \times 1$ vector of unexplained error values. Error

values are assumed to be independent and to follow a normal distribution with mean 0 and standard deviation σ . The β weights in a neuroimaging experiment correspond to the *estimated magnitude of activation* for each psychological condition described in the columns of X .

The model is fit to the data by finding the weights (β) that minimize the squared distance between the vector of fitted values, $X\beta$, and the data. One of the advantages of the GLM is that there is an algebraic solution for the β s that minimizes the squared error:

$$\hat{\beta} = (X^T X)^{-1} X^T y \quad (2.6)$$

where $\hat{\beta}$ are the estimates of the true regression slopes. In algebraic terms, the GLM projects data (y) in an n -dimensional space (n independent data observations) onto a k -dimensional model subspace (k predictors). The matrix product $(X^T X)^{-1} X^T$ is the matrix of the orthogonal projection onto the reduced-dimensional space of X .

Inference is generally conducted by comparing the $\hat{\beta}$ s with their standard errors and using classical inferential procedures to estimate the likelihood of the estimates under the null hypothesis. The standard errors of the estimates are the diagonal elements of the matrix:

$$se(\hat{\beta}) = (X^T X)^{-1} \hat{\sigma} \quad (2.7)$$

The ratio of betas to their standard errors follows a t-distribution with $n - k$ degrees of freedom. Notably, the error term is composed of two separate terms from different sources. σ is the error variance, and $(X^T X)^{-1}$ depends on the design matrix itself. If the matrix contains high values, the estimates will be less precise, and statistical power will decrease. If X is scaled appropriately, $X^T X$ is the variance-covariance matrix of X . Low values on the diagonal of $X^T X$ (low predictor variability) and high off-diagonal elements (high collinearity) will both cause $(X^T X)^{-1}$, and the variability of the estimates, to grow.

Contrasts

Contrasts across conditions can be easily handled within the GLM framework. Mathematically, a contrast is a linear combination of predictors. The contrast (e.g., $A - B$ in a simple comparison, or $A + B - C - D$ for a main effect in a 2×2 factorial design) is coded as a $k \times 1$ vector of contrast weights, which we denote with the letter c . For example, the contrast weights for a simple subtraction are $c = [1 - 1]^T$, where T indicates the transpose operator. A single contrast for a linear effect across four conditions might be $c = [-3 - 1 1 3]^T$. A set of contrasts can be simultaneously tested by concatenating the contrasts into a matrix. Thus, the main effects and interaction contrasts in a 2×2 factorial design can be specified with the following matrix:

$$C = \begin{bmatrix} 1 & 1 & 1 \\ 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 1 \end{bmatrix};$$

For the contrast to be orthogonal to the intercept, contrast weights must sum to zero. If the weights do not sum to zero, then the contrast values partially reflect overall scanner signal intensity. It is worth going into this level of detail here because contrast weights in statistics packages used with imaging data are often specified by the analyst, rather than being specified automatically as they might be in standard statistical programs such as SPSS or SAS. The true contrast values $C^T \beta$ can be estimated using $C^T \hat{\beta}$, where $\hat{\beta}$ is obtained using Equation (6). The standard errors of each contrast are the diagonals of:

$$se(C^T \hat{\beta}) = C^T (X^T X)^{-1} C \hat{\sigma} \quad (2.8)$$

Most imaging statistics packages write a series of images to disk containing the betas for each condition throughout the brain, and another set of contrast images containing the values of $C^T \hat{\beta}$ throughout the brain. As the latter images contain estimates of activation differences across conditions, these are typically used in a group analysis. A third set of images contain t-statistics, or the ratio of contrast estimates to their standard errors.

Assumptions

The model-fitting procedure assumes that the effects due to each of the predictors add linearly and do not change over time (i.e., a linear, time-invariant system). The inferential process assumes that the observations are independent, that they all come from the same distribution, and that the residuals are distributed normally and with equal variance across the range of predicted values. All of these assumptions are violated to a degree in at least some brain regions in a typical imaging experiment, which has prompted the development of a number of important extensions. Violations of the assumptions are not merely a theoretical nuisance. They can make the difference between a valid finding and a false positive result, or between finding meaningful activations in the brain and wasting substantial time and money.

Diagnostic tools have been developed for exploring the data, looking for artifacts, and checking a number of assumptions about the data and model (Luo, 2003), and like many tools developed by members of the neuroimaging community, they are freely available on the internet. The quantity of data – for example 100,000 separate regressions on 1000 data points per subject \times 20 subjects – and the software and data structures that support its analysis makes it very difficult to examine assumptions and check the data, which makes such diagnostic tools all the more important.

Another active area of research concerns strategies for dealing with some known violations of assumptions, described in the following section. Violations of independence can be handled in a limited way using generalized least squares. Violations of equality and normality can be dealt with by using nonparametric permutation tests to make statistical inferences (Nichols, 2002), or, if they

result from the presence of outliers, by robust regression techniques (Wager, 2005). Free implementations of each of these extensions are available, and we return to a description of them after providing additional background on application of the GLM to imaging experiments.

GLM model-building in fMRI

Perhaps the most challenging task in linear regression analysis is the creation of a *realistic* model of the signal. This model constitutes the matrix X in the general linear model equation. In a neuroimaging study, researchers typically build a model of the predicted brain response to each psychological event-type or condition. A stimulus or psychological *event* that elicits a brief burst of neural activity in an area typically produces a prolonged HRF that peaks 5–6 s later (but may vary across brain regions, as described above!) PET images integrate across many such events, and each brain image (an image containing one data observation at every voxel) reflects overall activity in a particular condition. Thus, much of the remainder of this section does not apply to PET analyses.

Accounting for the delayed hemodynamic response

A popular method of forming a prediction about BOLD activity is to assume that the response to a brief event will follow a canonical shape, such as that shown in Figure 2.12A and the center panel of Figure 2.13, for every event-type and every voxel in the brain. To build the model, researchers start with an “indicator” vector representing the neuronal activity for each condition sampled at the resolution of the fMRI experiment. This vector has zero value except during activation periods, when the signal is assigned a unit value. To form the predicted response in a condition, the indicator vector for that condition is convolved with the assumed HRF, and the result forms a column of the design matrix.

The process, shown in Figure 2.13 for an event-related design with four trial types (A–D), is similar for both blocked and event-related fMRI designs. The left panel shows the indicators, with rows of the plot corresponding to the four conditions. Each of the indicator vectors is convolved with the canonical HRF, shown in the center panel, to yield the predictors shown in the rows of the next panel. The image of the design matrix, a commonly used presentation format in imaging experiments, is shown in the rightmost panel.

If the assumed HRF does not fit, there is at best a drop in power to detect a response. At worst, model misspecification can produce false positive results. Say, for example, the HRF peaks at the expected time in condition B, but later in A. Because the shape is fixed, the amplitude of the fit for B will be greater than A. Without some additional diagnostic tests, one might falsely infer that B activates the brain region more than A.

Comparing groups of individuals (e.g., older versus younger adults, or patients and normal controls) can also

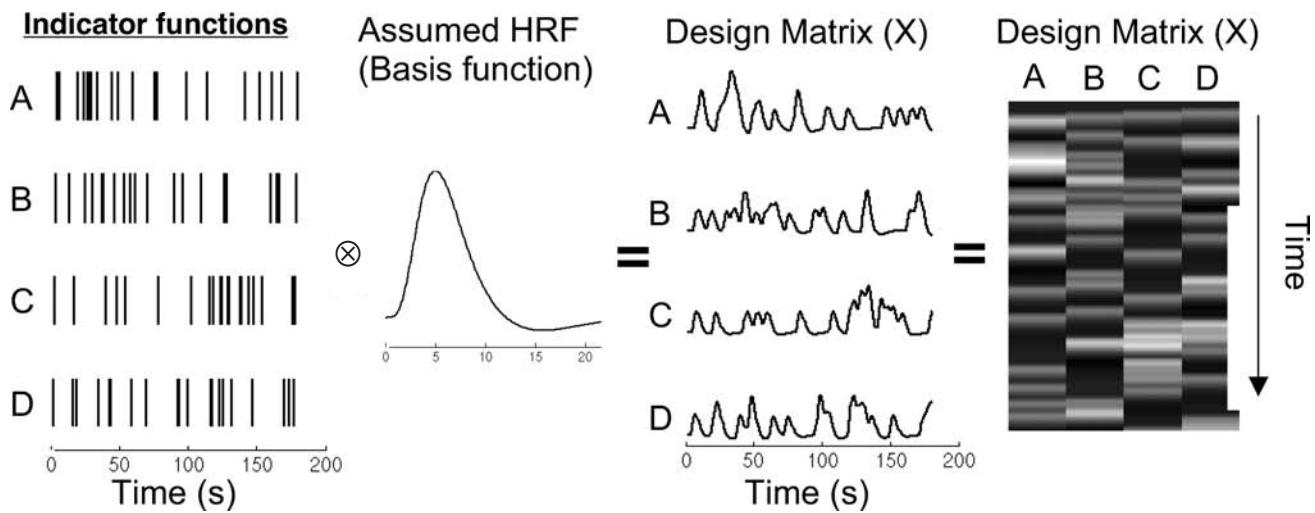

Figure 2.13. Construction of an event-related fMRI design matrix with four event types, using the canonical SPM HRF.

be especially problematic. If one finds differences between Task A and Task B in evoked response magnitude, are those differences caused by differences in neural activity, or by differences in how well subjects' responses fit the canonical, assumed shape? Elderly subjects, for example, have reduced and more variable shapes of their HRFs compared to younger subjects (D'Esposito, Zarahn, Aguirre, & Rypma, 1999).

One approach that has been used to avoid this problem is the measurement of hemodynamic responses in visual and motor cortex for each individual subject (Aguirre, Zarahn, & D'Esposito, 1998). This approach may work for brain regions whose HRF shapes match those in sensorimotor cortex. An alternative approach is to use a more flexible model of the HRF, which we describe in the following section.

Basis sets

In the previous discussion, responses to each psychological event-type or condition are modeled by only one linear regressor, which allows one to estimate only the fitted amplitude of the response. If more than one regressor is used to model each event-type, then the regressors can model different components of the response. The same onsets are convolved with different canonical functions that together can model a range of different HRF shapes. These canonical functions are called basis functions, and the group of basis functions chosen to model the response is called a basis set. Fitting a basis set at each voxel means that the fitted shape of the HRF is allowed to vary across brain regions.

Basis sets vary in the number of parameters estimated per event-type and in the shapes of the basis functions. A flexible basis set will be able to model more different HRF shapes, but generally at the cost of statistical power (more parameters means more variability in parameter estimates). A popular choice is to use a canonical HRF and its derivatives with respect to time and dispersion

(we use TD to denote this hereafter (Friston et al., 2002; Friston, Josephs, Rees, & Turner, 1998). Other choices include basis sets composed of principal components (Aguirre, Zarahn, & D'Esposito, 1998; Woolrich, Behrens, & Smith, 2004), cosine functions (Zarahn, 2002), radial basis functions (Riera et al., 2004), and spectral basis sets (Liao et al., 2002).

One of the most flexible models, a finite impulse response (FIR) basis set, contains one free parameter for every time-point following stimulation in every cognitive event-type that is modeled (Glover, 1999; Goutte, Nielsen, & Hansen, 2000; Ollinger, Shulman, & Corbetta, 2001). Using such a model makes minimal assumptions about the shape of the HRF – in fact, the set of parameter estimates (betas) from this model constitute an estimate of what the shape of the HRF looks like when sampled at the frequency of data collection (the TR).

Figure 2.14 shows fits to some empirical data from our laboratory using three popular basis sets with different degrees of flexibility. The “actual” HRF in these plots (solid lines in the right panels) comes from a region of the right thalamus that responds to viewing aversive emotional pictures. They are estimates using an FIR model with 1 s time bins, so they are the most assumption-free estimates we can obtain of the true response in this region. The SPM2 canonical HRF, composed of two summed gamma functions, is shown in the top-left panel. The image of the basis set is shown in the center panel, and the fit of the basis set to the data is shown in the rightmost panel. As the figure shows, the fit leaves much to be desired, and the height of the response is substantially underestimated, because the actual HRF peaks later and shows a much larger undershoot than the model. The second row of panels shows a plot of the basis set of the SPM2 canonical HRF with its derivatives with respect to time and dispersion (left), the image of the basis set (center), and the fitted response (right). The fit is substantially better, and would probably be adequate in this case to capture the positive-going lobe

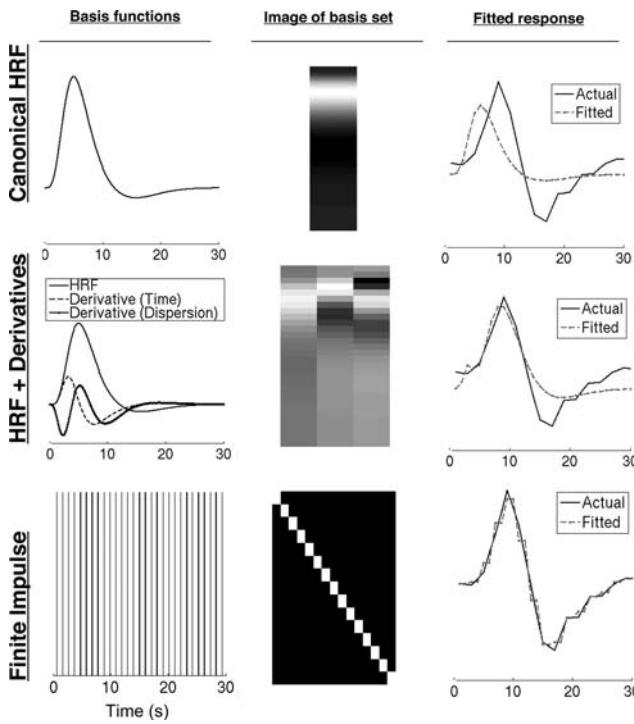

Figure 2.14. Basis functions (left panels), their intensity-mapped images (center), and fitted responses to data for three popular basis sets. Solid lines show group-averaged HRF estimates using a 1-s resolution FIR model. Dashed lines show the fitted response.

of the evoked activation. An FIR model is a linear model too, and the bottom panels show the same results for an FIR model with one estimate every 2 s.

Whatever basis set is used, statistical comparisons across event types must be made. The advantage of assuming a canonical shape is that because beta values represent response amplitudes for different conditions, the differences between betas represent differences in activation across psychological tasks or states. It is thus relatively straightforward to assess contrasts in a subtraction, parametric, or factorial design.

With more flexible basis sets, the parameters for each event-type combine – sometimes in complex ways – to model the HRF, and the betas for one condition cannot simply be subtracted from another. An omnibus F-test in repeated-measures ANOVA can be used to look for parameter \times condition interactions (implemented in some neuroimaging statistics packages, such as SPM2), if care is taken to account for the correlations among parameter estimates. However, this approach carries a cost in power and a problem in interpretability: A significant test statistic implies that the conditions differ in some way, but does not specify in what way (amplitude, latency, shape) they are different. For this reason, one-parameter canonical models remain popular despite their problems – but more sophisticated approaches, such as measuring the height and peak/onset delay from estimated HRFs, have been developed and may be implemented in popular packages soon.

Physiological noise and covariates of no interest

In both PET and fMRI designs, additional predictors are typically added to account for known sources of noise in the data. These are covariates of no interest, and they are included to reduce noise and to prevent signal changes related to head movement and physiological (e.g., respiration) artifacts from influencing the contrast estimates. In PET, a common covariate is the global (whole-brain) mean signal value for each subject, included to control for differences in amount of radioactive tracer in circulation.

In fMRI, the signal can drift slowly over time, as shown in Figure 2.15A. These signals were extracted from the ventricles during an fMRI scan, where there is no tissue, and thus no task-related activation. Though there is noise at all frequencies, the noise has greater amplitude at low frequencies, as shown in the spectral plot of the Fourier transform in Figure 2.15B. The Fourier transform of fMRI noise shows an inverse relationship with the noise frequency, and can be approximated by a $1/f$ (1/frequency) function. Also apparent in these data are spikes of high-power at about 0.15 Hz and 0.34 Hz. These frequencies may correspond approximately to average heart rate and respiration rate aliased back into the task frequencies. Aliasing occurs when a true signal (blue in Figure 2.15C) occurs at more than twice the sampling frequency (red circles in Figure 2.15C), and the apparent frequency (e.g., of the red curve) is “reflected” back to a lower value. The power spectra of the original and aliased signals are shown in Figure 2.15D. In fact, much of the autocorrelated noise in fMRI may come from aliased physiological artifacts (Lund, 2005).

Because of slow drift, it is advantageous to filter out low-frequency noise with a *high-pass filter*. This filtering is often performed in the GLM, by adding covariates of no interest (e.g., low-frequency cosines). Such filtering precludes using designs that vary the task condition at low frequencies. To the degree that the task frequencies overlap with the filtered frequencies, the filter will remove the signal of interest from the data! A good practice is to set the lowest period of the cosine functions modeling the drift to twice that of the experimental period. Other types of commonly used covariates of no interest include the estimated movement parameters and their derivatives/squared values, as well as signals from pulse and respiration sensors.

Extensions of the GLM

Autocorrelation and generalized least squares

One issue with the use of the GLM to analyze imaging data is that it assumes that the observations (images) are all independent of one another. In an fMRI time series, the data are correlated across time and space. This means that the activity in a voxel at one time can be partially determined from the preceding activity, and that there are fewer error degrees of freedom than used in the GLM calculations. Such temporal autocorrelation causes apparent p-values from the GLM to be much smaller than they

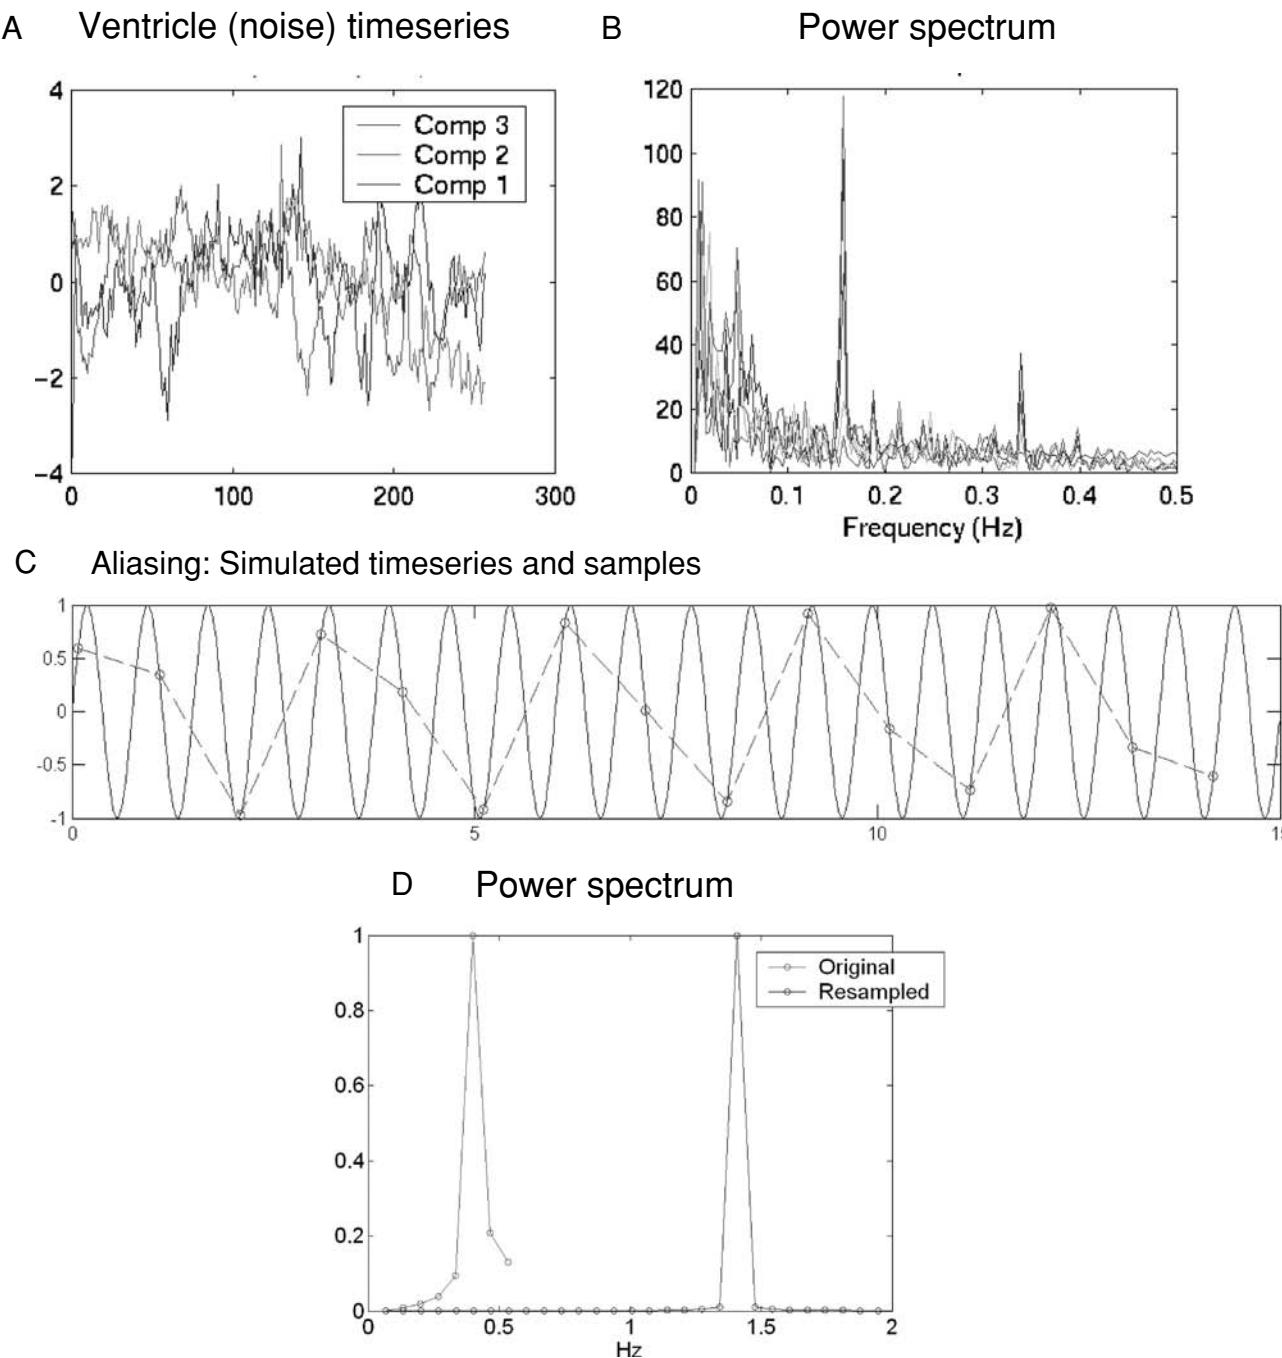

Figure 2.15. (A) Principal components of fMRI noise extracted from the ventricles (fluid spaces) of a single subject. (B) The power spectrum of each component, with frequency on the x-axis and energy on the y-axis. (C) A true signal sampled at a lower temporal resolution (circles), illustrating aliasing. (D) The power spectra of original and estimated signals.

actually are. As a result, inferences about individual subjects cannot be made without correcting for autocorrelation. Group analyses will not be biased by the existence of autocorrelation within individuals, but they will be less powerful than they would be if an appropriate model were used, because the subject-level parameter estimates will be more variable.

There are two basic ways to handle autocorrelation. One way is to estimate the autocorrelation and reduce

the degrees of freedom appropriately, for example via the Satterwaite correction (Neter, 1996). A popular approach using the SPM99 toolbox was to apply temporal smoothing to the data (a low-pass filter, which *introduces* autocorrelation), and then reduce the degrees of freedom based on the applied smoothing. However, a more popular approach recently has been to estimate the autocorrelation and remove it from the data during model fitting. This is called prewhitening because it is an attempt to create “white

noise" without temporal structure, and it is statistically efficient (high power) if the autocorrelation is modeled correctly, but it can introduce false positives under certain conditions if the autocorrelation estimates are in error (Friston, 2000).

Prewhitenning works by pre-multiplying both sides of the general linear model equation (Eq. 5) by the square root of a filtering matrix W , to create a new design matrix $W^{1/2}X$ and whitened data $W^{1/2}y$. W can stand for 'whitening matrix,' or, as we will see later, more generally for weighting matrix. Just as a properly designed matrix can apply a high-pass or low-pass (smoothing) filter, here the matrix can be used to remove autocorrelation. One way to understand this is to notice that $W^{1/2}X$ is a new linear combination, or weighting, of the predicted values (rows) of X based on the columns of $W^{1/2}$. If the initial predicted responses at each time (in a column of X) are themselves a weighted combination of the current stimulus and past history, then W is designed so that the weights (values) in its rows are the *inverse* of the estimated weights that produced the correlation. Thus, applying $W^{1/2}$ weights the observations so that the autocorrelation is removed. The estimates of the activation magnitudes in this case become:

$$\hat{\beta} = (X^T W X)^{-1} X^T W y \quad (2.9)$$

This equation describes activation parameter estimation in the generalized least squares (GLS) framework. Several other applications of GLS, including to hierarchical modeling, are described in the following section. The crux of the issue for dealing with autocorrelation is designing the matrix W so that the autocorrelation is removed. A popular approach in SPM2 is to use an AR1 model, which assumes each observation is a weighted combination of the current level of activity plus carryover from the previous time point. This model can account for smooth drift, but not sinusoidal or other oscillating noise structures. Other models allow for influences farther back in time (AR2 for two time-points, AR3 for three, and so forth). An approach implemented in VoxBo software is to use an empirically determined autocorrelation function from visual and motor cortex during separate localizer scans to prewhiten the data (Aguirre, 1997). One observation to note is that SPM2 assumes that the autocorrelation (and other parameters such as the covariance and spatial smoothness of the data) is the same everywhere in the brain. FSLs approach implements local (region-by-region) autocorrelation estimates and prewhitening. In principal, if the covariance of the data is given by V , then one should choose $W = V^{-1}$ as the whitening matrix.

We described the W matrix as a weighting matrix above because the form of Equation 9 is not only appropriate for whitening time series data, but it is generally useful whenever cases (observations) should be weighted. Consider the case of the group analysis, in which some subjects' estimates may be much more reliable than others. This may be because the "good" subjects showed consistent task performance, they had strong or regularly shaped HRFs,

the scanner noise was low on the day they were tested, their time series data were more independent of physiological confounds, or for other reasons. In such a case, the $\hat{\beta}$ s will be better estimates of the true β s for those subjects, and it is advantageous to weight those cases most highly in the group analysis.

The ability to weight cases based on the intra-subject variance is a primary advantage of using a hierarchical model over the two-level summary statistic approach. Once the intra-subject error terms have been estimated, the individuals with the least certain estimates can be down-weighted in the group analysis. In this case, W is a diagonal matrix whose diagonal elements are $(1/\sigma_G^2 + \sigma^2)$, or the inverse of the sum of intra- and inter-subject variance estimates. The off-diagonals are zero because we assume subjects are independent of one another (the prewhitening matrix has high off-diagonal entries to the degree that the time series is autocorrelated). Group $\hat{\beta}_G$ s are estimated using weighted least squares as in Equation 9.

Outliers, artifacts, and robust regression

Statisticians almost universally agree that when performing statistical tests, the data must be examined for outliers and for violations of the statistical assumptions required for inference. Because outliers are far from the group values and the fitting procedure in the GLM minimizes the sum of squared errors, outliers have a disproportionate influence on the group parameter estimates, and they can create violations of the other assumptions. Ideally, the analyst carefully examines the pattern of data and deals with potential outliers on a case-by-case basis.

A major challenge in neuroimaging is that thousands of statistical tests are typically run in parallel, and assumptions are often not checked. Is this a problem? Outliers can cause both null results and false positives, and they may be much more common in imaging data than in many other kinds of data. Simulations performed in our laboratory show that a small proportion of outliers (10% of the sample) can cause a 50% reduction in power over what could be obtained using one of the improved methods described in the following section (Wager, Keller, Lacey, & Jonides, 2005).

Outliers in imaging experiments come from many sources. As mentioned above, some subjects' activation estimates may be more variable than others for a variety of reasons, and some of this variability may be reflected or not in the intra-subject variance. For example, outliers in the individual time series data are regionally specific, very common, and can dramatically influence activation estimates for an individual. These outliers are likely to produce corresponding increases in the variance for that subject. By contrast, errors in the process of normalization, or warping brains into a standard anatomical space, will produce outliers in the group data for a brain region without influencing the intra-subject variance.

Robust regression techniques are a class of statistical tools designed to provide estimates and inferential

statistics that are relatively insensitive to the presence of one or more outliers in the data (Huber, 1981; Hubert, 2004; Neter, 1996). They are most appropriate when a large number of regressions are tested and assumptions cannot be evaluated for each individual regression, such as with neuroimaging data. In our work we have compared a number of simple techniques for eliminating or reducing the impact of outliers, focusing mostly on the group analysis level (Wager, Keller, Lacey, & Jonides, 2005). One technique that works well in a variety of situations is iteratively re-weighted least squares (IRLS). It is based on the principle that outliers can be down-weighted rather than dropped altogether, and that outliers can be identified based on how far away they are from the “center of mass” of the data (after accounting for variability explained by the model). The algorithm uses the same weighting scheme used in Equation 9. As with the hierarchical model, the matrix W is a diagonal matrix containing weights for each subject. The regression line and computation of weights based on residual values is iterated until convergence.

Robust regression is a practical tool for group imaging analysis. First, it does not increase the false positive rate under the variety of conditions and types of outliers encountered in imaging studies; and false positive rates are lower than those of the ordinary GLM under some particularly problematic conditions (Wager, Keller, Lacey, & Jonides, 2005). If there are no outliers in a particular brain region, then there is a small cost in power, because the weighting scheme effectively reduces the error degrees of freedom; but the cost is generally relatively minimal compared to the benefits in regions containing outliers. Although running such an analysis on the computers of the 1990s would have been prohibitive in terms of computation time, a consumer-model computer in 2005 can run IRLS on every voxel in the brain in a typical group imaging study in a matter of several hours.

Group analysis

The analysis described so far has been, for fMRI datasets, an analysis of data from a single subject. However, researchers are often interested in making inferences about a population, not just about a single subject or even a set of individual subjects, which requires a group analysis.

There are two main approaches to group analysis that differ in the underlying assumptions that they make and the conclusions that may be drawn from the results of the analysis. The *fixed-effects model* does not model variability across subjects, and the *mixed-effects* (often erroneously referred to as random-effects) *model* provides for inter-subject variability. Only mixed-effects models allow population inference.

Fixed versus mixed effects

Fixed-effects models assume the signal strength is identical in all subjects and the only variation present between subjects is due to measurement error. Early approaches in brain imaging collapsed data across multiple observations

within a group of subjects into one large GLM analysis. This approach is a fixed-effects model, because the error variance across subjects is assumed to be fixed rather than modeled as a random variable. The hypothesis tests performed are therefore only about the acquired data and cannot be generalized to a wider population. Early PET analyses seem to have taken a wrong turn early on because of the novelty of the data management problem, but fixed effects analyses are rarely used or considered valid now.

The alternative is to treat the subjects as a random effect, meaning that different subjects may actually respond to the experimental task in a different manner. Mixed effects models assume that the signal strength varies across subjects. In these models there are two sources of variation, the first due to measurement error (as in the fixed-effects model) and the second to differences in the individual's response magnitude. Taking this approach, each subject has a random magnitude that is considered to be drawn from a population with a fixed population mean. By testing observed activation values against estimates of the between-subjects error, can provide a traditional test of significance in a population.

Mechanics of mixed effects and hierarchical models

Both PET and fMRI studies nearly always involve collecting more than one image per subject, and testing for the significance of effects in a group of subjects. The full model can be viewed as being hierarchical in nature, with observations (fMRI signal or PET images) nested within subjects, which are in turn nested within a group, and different random variance components are introduced at each level. In fMRI, typically, separate GLM analyses are conducted on the time series data for each subject at each voxel in the brain to estimate the magnitude of activation evoked by the task. This is called a first-level analysis. These estimates are carried forward and tested for reliability across subjects in a second-level group analysis.

In the *summary statistics* approach, used in SPM99, VoxBo, FSL, AFNI, and often SPM2, a model is fit for each subject. After the effect of interest is defined, a contrast image is constructed for each subject corresponding to this effect. In the second level, a voxel-wise t-test is performed across all of the contrast images. If we have two populations of interest, then a two-sample t-test can be applied at the second level. This approach is simpler than the full hierarchical model, in that it does not explicitly model error at both levels in the second-level analysis. However, it assumes balanced design matrices (e.g., the same design for each subject) and that the within-subject variance is homogeneous across subjects (i.e., no “noisy” subjects). If these assumptions do not hold, a full hierarchical model, discussed in the following section, is more appropriate.

Mathematically, we can describe the second-level analysis in the same way as the first-level GLM discussed earlier. We use X_G to refer to a series of between-subjects predictors. The intercept of this model, which is always included, reflects the mean activity in a population when all other predictors are at zero. If the other predictors are

mean-zero, the intercept parameter is the mean activation across subjects. Other predictors in X_G are used to model inter-individual differences (e.g., patients vs. controls, differences in trait anxiety, performance measures, etc.). The vector of the regression slopes (magnitudes) for these effects is β_G , and ε_G is a vector of individual differences not explained by the model. The true activation contrast values for the first-level analysis for each subject are thus a combination of a true population effect plus unexplained individual differences among subjects. The full two-level model can be written:

$$\begin{aligned} Y &= X\beta + \varepsilon \\ \beta &= X_G\beta_G + \varepsilon_G \end{aligned} \quad (2.10)$$

In particular, note that there are now two sources of noise present in the model, one within subjects and one between subjects.

In the summary statistics approach, we assume that the activation estimates $\hat{\beta}$ are equal to the true values of β . We then run a second GLM, this time with the $\hat{\beta}$ s for each subject as the dependent variable and the between-subjects design matrix X_G as predictors. Here the estimate of β_G is dependent on the intermediate estimate $\hat{\beta}$. In the simplest case, a one-sample t-test, $\hat{\beta}$ is an N (subjects) $\times 1$ vector of estimated activation magnitudes for a condition in one voxel (the group data), X_G is an $N \times 1$ column of ones (an intercept), and β_G is a single true group activation parameter.

However, in reality $\hat{\beta}$ is not the same as β , because the estimates $\hat{\beta}$ are influenced by the within-subjects (sampling) error as well. To get the full model, we can replace individual subjects' β s (Eq. 5) by a group model consisting of a population parameter β_G plus individual differences ε_G , so that $\beta = X_G\beta_G + \varepsilon_G$. Thus, the full model that relates the predictors to the data for the group of subjects is:

$$\begin{aligned} y &= XX_G\beta_G + X\varepsilon_G + \varepsilon \\ &= \tilde{X}\beta_G + \gamma \end{aligned} \quad (2.11)$$

where $\tilde{X} = XX_G$ and $\gamma = X\varepsilon_G + \varepsilon$. The error γ is now composed of two parts – individual difference values ε_G that cannot be explained by the model and error values ε based on the sampling error within subjects. Collecting more data per subject can minimize the within-subjects error variance σ^2 , (based on ε) but cannot reduce the between-subjects error variance σ_G^2 , based on ε_G . Collecting more subjects can reduce the standard error based on ε_G .

If we solve the equation above for β_G , in the full model we get a solution that depends directly on the data y , and not on the intermediate values $\hat{\beta}$. It can be shown that a single-level GLM can be decomposed into an equivalent two-level version if both the $\hat{\beta}$ s and their covariance are passed down from the first level. Beckmann et al. (Beckmann, Jenkinson, & Smith, 2003) have applied hierarchical modeling to fMRI, and it is implemented in the increasingly popular FILM (fMRIIB Improved Linear Model) package as part of the fMRIIB Software Library

(FSL; Smith et al., 2004). Hierarchical modeling is also possible in SPM2, though the summary statistics approach is often used in practice (Friston, Stephan, Lund, Morcom, & Kiebel, 2005).

In practice, the relative contribution of the within- and between-subjects error is unknown, and variance components must be estimated. In SPM2 the variance components are estimated using Restricted Maximum Likelihood (ReML). The ReML estimates are calculated using only data from responsive voxels, which are voxels with large F-statistics in a standard pre-analysis of the data, and pooled across those voxels.

Statistical power and sample size

Statistical power rests on having a large activation response (high contrast values) and a low standard error. In a group study, the standard error comes from two sources: variability across subjects (ε_G) and the variability within each subject (ε). At the group level, power can be increased by increasing the sample size, improving methods for selecting comparable brain regions across subjects (e.g., normalization, ROI selection), or testing a more homogeneous population (at the cost of generalization to other populations).

What sample size is adequate? This depends on the effect size in the group and scanner noise and signal optimization, and it is different for each task and each brain voxel (Zarahn & Slifstein, 2001); (Desmond & Glover, 2002). Using a large group effect size by conventional standards (Cohen's $d = 1$) and a simple Bonferroni correction for multiple comparisons (described in the following section) over 30,000 voxels, we can get an idea of what sample size is adequate. As Figure 2.16 shows, the chances of finding a truly activated voxel with $n = 10$ are virtually zero. With $n = 20$, power is still less than 10%, but with 30 and 40 subjects, the power increases to .35 and .7, respectively.

For a given true group effect size and sample size, power depends on the within-subjects standard error, ($se(C^T\hat{\beta})$). As shown in Equation 8, the within-subjects standard error depends on the design matrix (X) and the residual variance, σ . σ can be reduced by optimizing data collection (e.g., pulse sequences and hardware) and in the study design by maximizing the engagement of subjects in the tasks.

However, because the standard error depends on the design matrix (X), power can also be substantially increased by carefully choosing the number, sequence, and spacing of events to minimize the design-related component of the standard error, $C^T(X^T X)^{-1}C$ in Equation 8. Variance in the predicted response and orthogonality in the predicted responses for different events both make a statistically powerful experimental design (Liu, 2004). This is particularly critical in event-related fMRI, where delayed HRFs, overlapping responses, and autocorrelation contribute in complex ways to the overall error. It is possible to build a design in which effects can never be

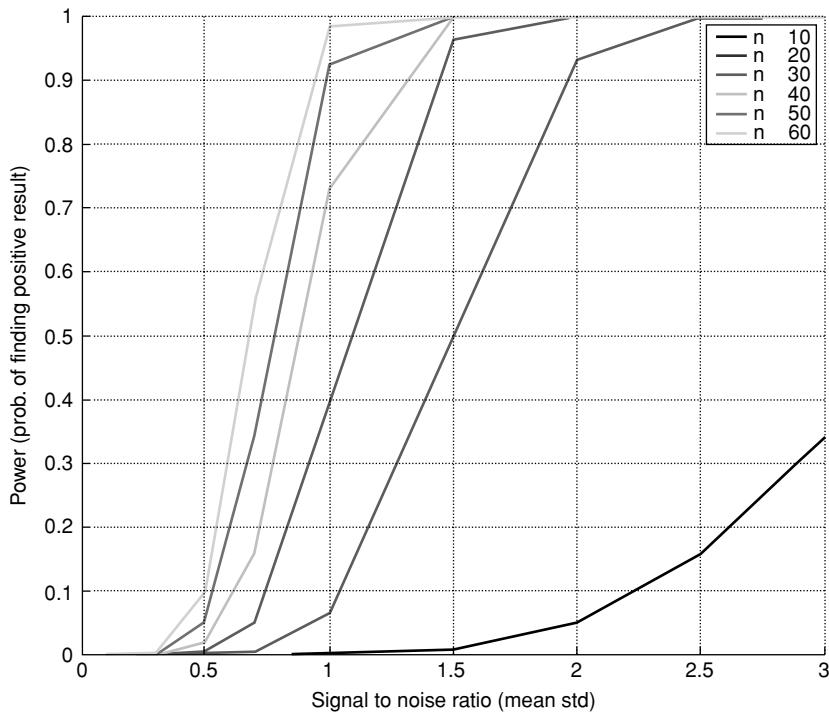

Figure 2.16. Power, or the probability of detecting activation in a truly activated voxel, as a function of effect size (Cohen's d , x-axis) and sample size (lines), using Bonferroni correction for 30,000 voxels. The search area corresponds roughly to a whole-brain search over gray matter only with $3.5 \times 3.5 \times 5$ mm voxel sizes.

detected, even if they actually exist! For this reason, many researchers choose to use computer-aided designs to optimize sequences of trials so that the power to estimate contrasts of interest may be maximized (Buracas & Boynton, 2002; Wager & Nichols, 2003).

Both theory and simulations show that there is a substantial tradeoff in power between *detecting* activation differences between conditions using an assumed HRF shape and estimating the *shape* of evoked activations with a more flexible model (Liu, 2001). This tradeoff is shown in Figure 2.17, in which shape-estimation power is shown on the x-axis and contrast-detection power is shown on the y-axis. The points in the model represent designs with different sequences and timing of events. Blocked designs have the highest detection power, but provide little information about the shape of the response. M-sequences, or sequences that are orthogonal to themselves shifted in time, provide optimal shape estimation power (the nonoptimality in the figure is due to truncation of the m-sequences so they are imperfect), but low detection power (Buracas & Boynton, 2002). Random event-related designs are in between. As the Figure shows, designs optimized with a genetic algorithm (Wager & Nichols, 2003) can produce substantially better results than random designs on both measures.

Bayesian inference

Recently, Bayesian methods have received a great deal of attention in fMRI literature. Bayesian inferential methods are now key components in several major fMRI analysis software packages (e.g., SPM and FSL). Harkening back to our discussion on inference, we made the

point that $P(\text{Activation}|\text{Task state})$, or the probability of observing activation given a task state, is not the same as $P(\text{Task}|\text{Activation})$. Bayesian statistics differ from classical statistics in that the unknown true population parameters β are considered to be random variables rather than fixed constants, and what is assessed is $P(\beta|y)$, where y is the observed data. According to Bayes's rule (Eq. 4), the probability of activation $P(\beta|y)$ is a combination of the likelihood of observing the data and a subjective prior belief about the parameter. This combination is called the posterior distribution, and can be written:

$$P(\beta|y) \propto P(y|\beta)P(\beta) \quad (2.12)$$

Here $P(\beta|y)$ denotes the posterior, $P(\beta)$ the prior and $P(y|\beta)$ the likelihood function. Because these are probability distributions, and β takes on a distribution of values, specifying priors involves specifying multiple parameters of the prior distribution, such as the mean and variance, as well as its distributional form. Note that if we were simply to find the values of $\hat{\beta}$ that maximize the likelihood of the observed data, we would obtain the maximum likelihood estimator (MLE) used in classical inference.

The posterior mean or mode is often used as a parameter estimate, that is, we can estimate β using $\hat{\beta} = E(\beta)$, where E denotes expected value. However, it is often difficult to calculate the exact form of the posterior distribution, and Bayesian inference therefore often requires the numerical evaluation of complicated integrals or sums. Techniques such as Markov-chain Monte-Carlo (MCMC) and Variational Bayes (VB) are used to make relevant numerical calculations about the posterior (Penny et al. 2003, Penny et al. 2004, Woolrich et al. 2005). An excellent overview

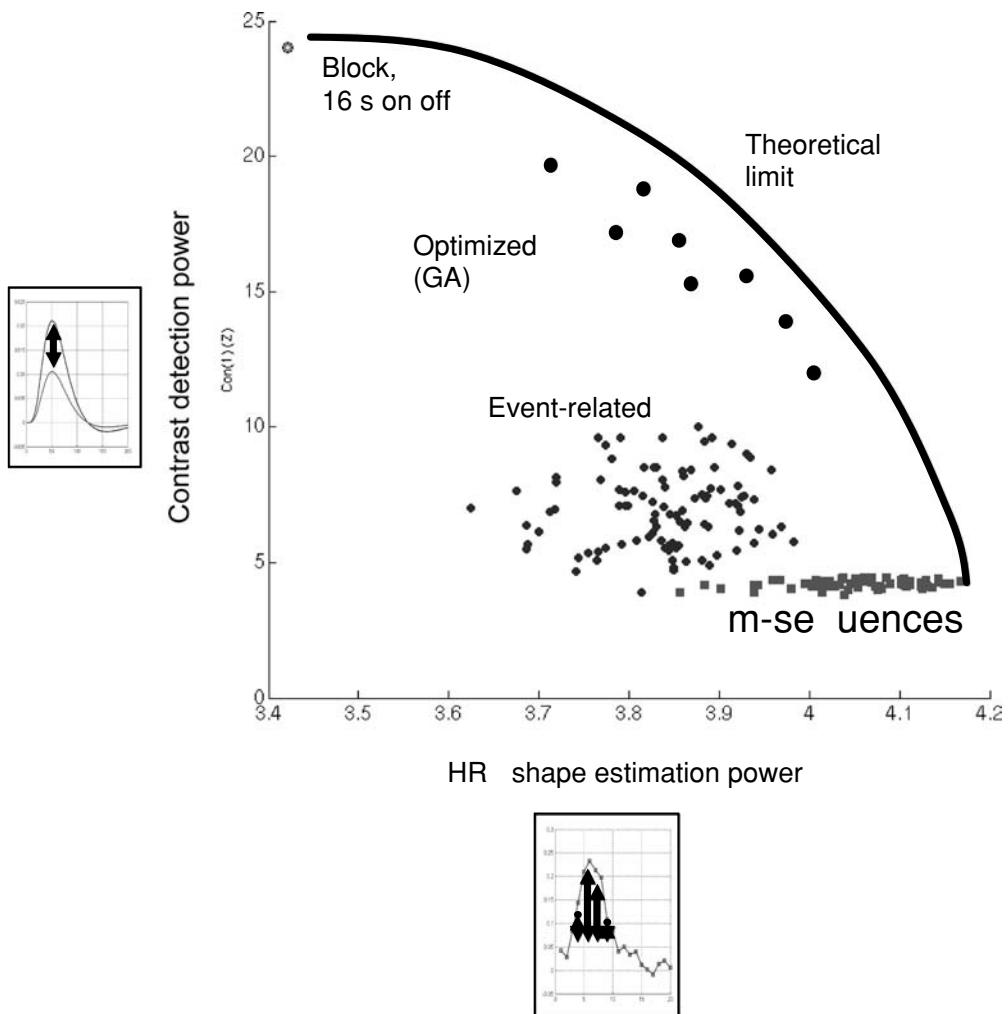

Figure 2.17. The tradeoff between contrast detection and HRF shape estimation power, and the performance of different types of designs on each. Power is expressed here in terms of z-scores in a simulated group analysis ($n = 10$, effect sizes estimated from visual cortex data in Wager et al., 2005). Yellow circle: an optimal-periodicity block design is shown in yellow. Blue circles: Randomized event-related designs. Red squares: m-sequences. Open circles: genetic algorithm (GA) optimized designs.

of Bayesian statistics can be found in Gelman et al. (2004).

As mentioned above, Bayesian methods require the definition of prior probabilities, and the choice of priors is crucial. Inference is based on a combination of evidence from the observed data and pre-existing beliefs. If strong priors are chosen, the resulting activation maps may reflect prior beliefs more than the story told by the data. If one does not want to impose such beliefs, then it is possible to use *non-informative priors*. This is an approach taken by some neuroimaging applications, for example, FSL, which implements a fully Bayesian approach towards multi-subject analysis with non-informative priors (Woolrich, 2004). For the single-level model this leads to parameter estimates that are equivalent to those obtained using classical inference. Without informative priors, it is unclear whether the Bayesian approach confers an advantage over the classical approach, although the ability to specify priors makes the Bayesian framework more flexible. Another way to choose

prior beliefs is by estimating them from data. This is the empirical Bayes approach. It is a hybrid between classical and Bayesian inference that is used in the SPM2 software (Friston, 2002; Friston, 2002).

Taking a Bayesian approach allows us to calculate the probability that the activation exceeds some specific threshold, given the data (Penny, 2003). Posterior probability maps (PPMs), for example in SPM2, are images depicting these probabilities. In a fully Bayesian framework, there is no hypothesis test and there are no false positives or multiple comparisons problem because one never rejects a null hypothesis. However, if PPM maps are thresholded (e.g., at 0.95) and one wants to infer that some voxels were actually activated by the task, then a hypothesis test is conducted and false positives again become an issue. It is hard to imagine a case where researchers would not want to conclude that some regions were activated by a task, so this theoretical advantage does not translate into a practical advantage.

One place Bayesian methods may be advantageous is in specifying spatial priors on the regression coefficients (Penny, 2005) that incorporate prior knowledge that the evoked responses are both spatially contiguous and locally homogenous.

Multivariate analysis

The massively univariate GLM approach treats each voxel as a separate dependent measure, but it is perhaps more natural to think of brain activity in terms of time-varying processes that are distributed across the brain. Likewise, it seems natural to think of psychological processes as emerging from the *interactions* among a set of brain regions – a concept that is not captured in the univariate approach. Multivariate methods such as those described in the following section generally model the data by decomposing a large dataset (1000 time points \times $100,000$ voxels \times 20 subjects) into a smaller set of *components* and a series of *weights*. The components may be canonical patterns of activity across time and the weights their distribution across brain space, or the other way around.

Such approaches include Principal Components Analysis (PCA), Independent Components Analysis (ICA), Canonical Variate Analysis (CVA), Partial Least Squares (PLS), Factor Analysis, and the Multivariate Linear Model (MLM). They all share the common core idea of decomposition into simpler components that maximize the amount of variability explained by the model. The approaches differ in the criteria used to select and rotate components, and in whether the experimental design is included as part of the data to be modeled.

In practice, an additional important distinction is whether the techniques are used to model the timeseries data within a participant, trials within a participant, or the individual differences in activation across participants. The interpretation of the results is very different depending on which of these types of data is used. Timeseries data can provide evidence on dynamic functional and effective connectivity across time (Mechelli, Penny, Price, Gitelman, & Friston, 2002). Trial-level data can be used to relate brain activity with performance or emotion within subjects (Rissman, Gazzaley, & D'Esposito, 2004). And individual difference data can characterize patterns of individual differences across the brain, that is, the tendency of a particular type of subject to activate a distributed attention network (Habeck et al., 2005; Lin et al., 2003). (As a note of caution, such data is often misinterpreted as reflecting dynamic connectivity).

Though the potential for new information offered by dynamic connectivity makes this type of analysis very appealing, special concerns must be taken to prevent observed patterns from being dominated by timeseries artifacts (Lund, 2001). In addition, for most dynamic connectivity applications, it is critical to provide population-level inference by treating subjects as a random effect, as in the GLM above. Freely available toolboxes exist that

can perform this type of analysis – two notable ones are the GIFT package (Calhoun, Adali, & Pekar, 2004) and the tensor-ICA routines in FSL (Beckmann & Smith, 2005).

Another important distinction is between *hypothesis-driven* and *data-driven* approaches. The GLM approach is hypothesis driven, because one seeks to find regions that fit a particular predicted model. Most multivariate approaches (e.g., PCA, ICA, FA) are data-driven, in that they simplify or reduce the data into components without reference to a predictive model (i.e., the design matrix, X). Usually, the multivariate analysis is used to generate components, and then those components are tested for relationships with X (Beckmann & Smith, 2004).

Another approach is to include X in the set of data to be reduced, or to decompose the covariance between the data and the model into components. This approach has the potential to pick out specifically those components that are task-related, but has the potential to capitalize on chance variations in the signal, and thus simulations or permutation methods must be used to control the false positive rate. Partial least squares (McIntosh, Chau, & Protzner, 2004) and semi-blind ICA are examples of this approach (Calhoun, Adali, Stevens, Kiehl, & Pekar, 2005).

Mechanics of multivariate analysis

Each technique described in this section decomposes a matrix of data, Y, into a set of spatial and temporal components. Y is a $[t \times v]$ matrix, with t time points (observations) and v voxels. Each column of Y is the timeseries of one voxel in the brain.

Principal Components Analysis (PCA) decomposes the data by finding linear combinations of timeseries, each a column in matrix U (also of dimension $t \times v$), such that each column of U is uncorrelated with (orthogonal to) every other column of U. The columns of U, called components, are arranged in order of variance explained: the first component explains the most variance possible in Y, the second component explains the maximal amount of remaining variance, and so forth. Together with their spatial maps and variances (described in the following section) these v components perfectly reproduce the data, but most of the total variance is usually captured in just the first few components of U. Thus, the first components are a compressed representation of the data.

Because each component is a weighted sum across timeseries of different voxels, another matrix V (of dimension voxel \times component, $[v \times v]$) contains columns of voxel weights used to create each component in U. For example, the first column of V shows how to weight each of the v voxel timeseries in order to capture the most variance in Y, and represents the spatial distribution of the first component. Thus, the columns of U are the temporal components (the canonical timeseries) and those of V are the spatial components (the maps across brain voxels) of these timeseries.

If we think of each voxel as being a variable with its own axis, the weights V describe a rotation of the data Y

such that the columns of YV – the new component scores – fall along the axes of greatest covariance across voxels. An algebraic solution for V is given by the eigendecomposition of the covariance matrix of Y , which finds a matrix of eigenvectors V and eigenvalues (weights for V) λ such that $\text{cov}(Y)V = \lambda V$. That is, rotating V by $\text{cov}(Y)$ is equivalent to scaling V by scalar weights λ , because V lie along the principal axes of $\text{cov}(Y)$. The weights λ are the variances of each component.

In neuroimaging, the components are usually calculated through singular value decomposition (SVD) of the centered (mean-zero) data. SVD is a more general form of PCA that decomposes the data into temporal components U and spatial components V such that:

$$Y = USV^T \quad (2.13)$$

With centered (mean-zero) data, S is a diagonal matrix (only the diagonal elements are non-zero) whose entries are the singular values, the sums of squared deviations explained by each component. These are related to the eigenvalues such that $\lambda = S^2/(t - 1)$. The columns of V are the eigenvectors, as in the eigendecomposition described above, and US are the component scores (components scaled by the amount of variability they explain), equal to YV in the eigendecomposition. A thorough treatment of eigenvectors, eigenvalues, and SVD is provided by Strang (1988).

Once one grasps the central idea of data decomposition into spatial and temporal components, many other techniques can be understood as variations on this theme. Independent Components Analysis (ICA), for example, is a variant of this technique. Rather than maximizing explained variance, the components are chosen to maximize the statistical independence of the components in a more general sense. The components are not required to be orthogonal; rather, the constraint is that the distribution of one component cannot be predicted from the values of the other, and the joint probability $P(A,B)$ of components A and B is equal to $P(A)P(B)$. In the Infomax variant, mutual information between components (a general measure of relationship that is not necessarily linear or monotonic) is minimized (McKeown 1998a). In broad terms, ICA assumes that Y , is a weighted sum of a number of source signals (timeseries), contained in X . The data Y is a linear mixture of these source components described by the weighting or *mixing matrix* of spatial weights M :

$$Y = MX \quad (2.14)$$

There is no algebraic solution, so iterative search algorithms are used to estimate both M and X . An alternative decomposition is to transpose the data matrix and treat the spatial components as sources and the temporal components as mixing weights. For more details, we refer the reader to (Bell & Sejnowski, 1995; McKeown & Sejnowski, 1998; McKeown et al., 1998; Petersson, Nichols, Poline, & Holmes, 1999b; Petersson, Nichols, Poline, & Holmes, 1999a).

Both PCA and ICA simply reduce the data to a simpler (lower-dimension than that of the v voxels) space by capturing the most prominent variations across the set of voxels. The components may reflect signals of interest or they may be dominated by artifacts, and it is up to the user to determine which are of interest (e.g., task-related). In ICA the order of importance of the independent components cannot be determined. Hence, it is necessary to sift through all of the components to search for ones that are task-related or otherwise of interest. However, both ICA and PCA assume all variability results from signal (noise is not modeled). A popular variant in the social sciences literature is factor analysis, which additionally fits a parameter for the noise (unexplained) variance at each voxel. However, a disadvantage of factor analysis is that the solution is *rotationally indeterminate*, and thus a number of combinations of spatial and temporal components can explain the same variability in the data. Although both ICA and PCA are not rotationally indeterminate, there is some question as to what the “right” rotation is (in PCA it is determined by variance explained). Interpreting thresholded component maps, as is commonly done, depends critically on establishing a rotation that is meaningful and reliable across studies.

These techniques as described so far model only a single subject’s data. In a group study there is the additional complexity of making population inference. It is not correct to treat all the data as coming from one super-subject and decomposing the group data matrix, for the same reasons that fixed effects analyses in the GLM are not appropriate. One approach is to decompose the group matrix, and subsequently back-reconstruct or estimate spatial weights for each subject for a component of interest (Calhoun, Adali, Pearlson, & Pekar, 2001). The spatial weights at each voxel across subjects are treated as random variables, and one-sample t-test is conducted to test whether that voxel loaded significantly on that component in the group. Another approach, called *tensor ICA*, is to use a three-way decomposition, using the group data to estimate temporal components and weights for each subject and each voxel (Beckmann & Smith, 2005). The subject weights at each voxel are then tested for significance.

Thresholding and multiple comparisons

As discussed above, the massively univariate approach requires fitting a model at each of many voxels throughout the brain (often 100,000 or more), and constructing maps of the activation statistics and reliability over the brain (statistical parametric maps, or SPMs). In a typical behavioral experiment, test statistics whose p-values are below 0.05 are considered sufficient evidence to reject the null hypothesis, with an acceptable false positive rate (α) of 0.05. However, in a neuroimaging experiment, many such tests (e.g., 100,000) are conducted, and a voxel-wise α of 0.05 means that 5% of the voxels on average will show false positive results. In our example, that turns

out to be 5,000 false positive results. Thus, even if an experiment produces *no true activation*, there is a good chance that without a more conservative correction for multiple comparisons, the activation map will show a number of activated regions, leading to erroneous conclusions.

Many researchers use a more stringent, but arbitrary, threshold of 0.005 or 0.001 to help reduce false positives. The problem with this approach is that the chances of finding at least one false positive is very high, and its exact probability is unknown. It is generally considered desirable to limit the chances of finding a false positive somewhere in the brain to 0.05. This is the family-wise error rate (FWER), the rate at which a statistical test would be expected to produce one or more false positives among a family of tests, under the null hypothesis.

Commonly, researchers impose an additional threshold on extent of activation, requiring k (for example, 5) or more contiguous voxels to be significant at .005 (for example) before considering a region to be significant. This approach does not necessarily control the FWER either. The assumption that the chances of observing 5 contiguous voxels at $p < .005$ is .005⁵ (true for independent voxels) is erroneous because imaging data are correlated (“smooth”) across space. Without estimating the spatial *smoothness*, one cannot tell what the true probability of observing a contiguous activated cluster of k voxels is under the null hypothesis. Smoothness, number of subjects, and the size of the search volume vary across studies, so the FWER corrected threshold will also be different for different studies.

Another kind of control of the false positive rate is to use the false discovery rate (FDR) control. Imagine that we conduct a study on 100,000 brain voxels at alpha = .001 uncorrected, and we find 300 significant voxels. We expect 100 of them or 33% of our significant discoveries, to be false positives. But which ones they are we cannot tell, and 33% is a substantial proportion. We may want to set a threshold such that only 5% of the significant voxels are expected to be false positives. This is FDR control at the 0.05 level. In this case, we might argue that most of the results are likely to be true activations; however, we will still not be able to tell which voxels are truly activated and which are false positives.

A review of the PET and fMRI literature shows that many investigators use uncorrected thresholds; this is likely because these studies do not have the statistical power to correct for multiple comparisons and still detect a reasonable number (or, indeed, any) of the truly activated areas. This is because as the false positive rate is controlled more conservatively, statistical power decreases. However, from the standpoint of making inferences about regional activation within a study, correcting for multiple comparisons is critical. Without correcting, any of the activations in the study might be simply false, and many such false positive regions are expected. Methods for controlling the FWER and FDR are described briefly in the following section, along with a popular alternative, region-of-interest testing.

FWE correction. The simplest way of controlling the FWER is to use the Bonferroni correction, in which the alpha value is divided by the total number of statistical tests performed (i.e., voxels). However, if there is spatial dependence in the data (as there would be because of spatial smoothing) this is an unnecessarily conservative correction that leads to a decrease in the probability of detecting truly active voxels.

Gaussian Random Field Theory (RFT), used in SPM software, is another approach towards controlling the FWER. If the image is smooth and the number of subjects is relatively high (around 20), RFT is less conservative and provides control closer to the true false positive rate than the Bonferroni method. However, with small samples, RFT is often more conservative than the Bonferroni method. It is acceptable to use the more lenient of the two, as they both control the FWER, which is what SPM currently does. In addition, RFT is used to assess the probability of k contiguous voxels exceeding the threshold under the null hypothesis, leading to a cluster-level correction. Nichols and Hayasaka (T. Nichols & Hayasaka, 2003) provide an excellent review of FWER correction methods, and they find that whereas RFT is overly conservative at the voxel level, it is somewhat too liberal at the cluster level with small sample sizes.

RFT correction begins by estimating the spatial smoothness of the data and the consequent number of independent statistical tests, or *resels* (resolution elements). The number of clusters that should be found solely by chance at a given threshold is known as the Euler characteristic (EC) of the data. The RFT method assumes that the statistic maps are continuous random 3-D fields of values, and so spatial smoothing is often applied (some estimates are three times the voxel dimensions) to satisfy this assumption. In SPM, it also assumes that the smoothness is stationary (does not vary) throughout the brain – an assumption that is often violated.

Both methods described above for controlling the FWER assume that the error values (estimated by the residuals) are normally distributed, and that the variance of the errors is equal across all values of the predictors. Nonparametric methods instead use the data themselves to find the distribution. Using such methods can provide substantial improvements in power and validity, particularly with small sample sizes, and we regard them as the “gold standard” for use in imaging analyses. Thus, these tests can be used to verify the validity of the less computationally expensive parametric approaches.

A popular package for doing non-parametric tests in group analyses, SnPM or Statistical Non-Parametric Mapping (T. E. Nichols & Holmes, 2002), is based on the use of permutation tests. Under the null hypothesis for a one-sample t-test, the signs (+ or -) of the activations are distributed symmetrically around 0. In SnPM, the signs of betas across subjects are permuted, and t-statistics are computed throughout the brain. The maximum t-value from this permuted null hypothesis map is saved, and the

simulation is repeated many times (e.g., 10,000) to simulate a distribution of the maximum t-value under the null hypothesis. The 95th percentile of this distribution of maxima is a threshold that provides FWER control at $p < .05$. Similar permutation tests are available for a variety of types of test, including multiple-condition tests (e.g., ANOVA) and brain-behavior correlations.

FDR control. The false discovery rate (FDR) is a recent development in multiple comparison problems developed by Benjamini and Hochberg (1995). Whereas the FWER controls the probability of any false positives, the FDR controls the proportion of false positives among all rejected tests.

The FDR controlling procedure is adaptive in the sense that the larger the signal, the lower the threshold. If all of the null hypotheses are true, the FDR will be equivalent to the FWER. Any procedure that controls the FWER will also control the FDR. Hence, any procedure that controls the FDR only can be less stringent and lead to a gain in power. A major advantage is that because FDR controlling procedures work only on the p-values and not on the actual test statistics, it can be applied to any valid statistical test.

ROI analysis. Because of the difficulty in preserving both false positive control and power without many subjects, researchers often specify regions-of-interest (ROIs) in which activation is expected before the study is conducted. ROI analyses are conducted variously over the average signal within a region, the peak activation voxel within a region, or – a preferred method – on individually defined anatomical or functional ROIs. Another technique involves testing every voxel within an ROI (e.g., the amygdala) and correcting for the number of voxels in the search volume. This is often referred to as a small-volume correction.

Two important cautions must be mentioned. First, conducting many ROI analyses increases the false positive rate. Although it may be philosophically sound to independently test a small number of areas in which activation is expected, testing many such regions violates the spirit of a priori ROI specification and will lead to an increased false positive rate. Small volume corrections in multiple ROIs also do not preserve the false positive rate across ROIs.

Second, although activated regions can be used as ROIs for subsequent tests, the test used to define the region must be *independent* of the test conducted in that region. Acceptable examples include defining a region based on a main effect and then testing to see if activity in that region is correlated with performance, or using the main effect of $(A + B)$ to define a region and then testing for a difference $(A - B)$. Problematic examples are defining a region activating in older subjects and then testing to see if its activity is reduced in younger subjects or defining a region based on activity in the first run of an experiment and then testing whether it shows less activity in subsequent runs. Both of these are not valid tests because they do not control for regression to the mean.

A final note about uncorrected thresholds. From the standpoint of accumulation of evidence across studies, when testing large samples is impractical, using low thresholds and then using meta-analysis to see which areas are reliably activated makes some sense. Imagine that there are 20 activated regions in a task, and that 50 studies are conducted of the same task. If each study uses FWE correction, the power in each study might be 5%. Each study might be expected to activate 1 of the 20 regions, which one selected at random, and the result would be a literature of 50 papers that show different results, allowing little meaningful aggregation across those studies. Thus, it is a good idea to report results at a reasonable uncorrected threshold (e.g., $p < .001$ and 10 contiguous voxels) for archival purposes, in addition to reporting corrected results.

ACKNOWLEDGMENTS

We would like to thank Dr. Doug Noll for providing Figure 2.9, and Brent Hughes and Matt Keller for helpful editing.

Electroencephalography and High-Density Electrophysiological Source Localization

DIEGO A. PIZZAGALLI

1. INTRODUCTION

In 1924, Hans Berger, a German psychiatrist, performed the first electroencephalographic (EEG) recording in humans (Berger, 1929), a discovery that was initially greeted with great skepticism by the scientific community. By recording from one electrode placed over the forehead and one over the occipital cortex, Berger discovered the existence of rhythmic activity oscillating at approximately 10 Hz, particularly during relaxed wakefulness and in the absence of sensory stimulation or mental activity. In this landmark discovery, Berger described for the first time what would become known as alpha waves. As a result, Berger was among the first to suggest that the periodic fluctuations of the human EEG may be associated with mental processes, including arousal, memory, and consciousness. Over the years, developments in data collection and analyses transformed EEG into one of the prime techniques for studying the human brain. Table 3.1 summarizes selected landmark discoveries and developments that have shaped EEG field throughout the century.

The past two decades in particular have witnessed unparalleled progress in our ability to image human brain function noninvasively. Different imaging techniques are currently available to investigate brain function based on hemodynamic (functional magnetic resonance imaging, fMRI), metabolic (positron emission tomography, PET), or electromagnetic (electroencephalography, EEG; magnetoencephalography, MEG) measurements. In order to investigate spatiotemporal dynamics of brain activity, methods that directly assess neural activity are required. By measuring electrical activity of neuronal assemblies with millisecond temporal resolution, EEG and MEG, unlike hemodynamic techniques, offer the possibility of studying brain function in real time. Unfortunately, as will be discussed in this chapter, the spatial resolution afforded by EEG/MEG is constrained by several factors. The most important of these factors are the distorting effects of the head volume conductor,¹ low signal-to-noise

ratios, and limited spatial sampling due to practical limits on the numbers of electrodes that can be utilized. More importantly, it soon became evident that the neuroelectromagnetic “inverse problem” (the attempt to identify generating sources of measured, scalp-recorded EEG signals) is fundamentally ill-posed. As first described in 1853 by Helmholtz, there are an infinite number of source configurations that can explain a given set of scalp-recorded potentials. Thus, at a first glance, the quest for the development of methods combining millisecond temporal resolution with millimeter spatial resolution appears to be a lost cause. Fortunately, solutions to the inverse problem can be found by postulating physiologically and anatomically sound assumptions about putative EEG sources and by mathematically implementing established laws of electrodynamics.

The main purpose of the present chapter is to review recent advances in the EEG field (event-related potentials, ERPs, will not be discussed here, as they are reviewed elsewhere in this volume). To understand these developments it will first be necessary to detail the physiological basis of the EEG signal. Subsequently, important issues associated with data acquisition, signal processing, and quantitative analyses will be discussed (see Davidson, Jackson, & Larson, 2000; Pivik et al., 1993; Gasser & Molinari, 1996; Nunez et al., 1997; Nuwer et al., 1999; Thakor & Tong, 2004 for more comprehensive reviews of these topics). The largest portion of the chapter will be devoted to reviewing emerging source localization techniques that have been shown to localize EEG activity without postulating a priori assumptions about the number of underlying sources (Baillet et al., 2001; Michel et al., 2004). As we will discuss, perhaps the greatest advancements in the EEG field in the last 5–10 years have been achieved in the development of these localization techniques, in particular when used in concert with high-density EEG recording, realistic head models, and other functional neuroimaging techniques. The picture emerging in light of these achievements reveals that the spatial resolution of the EEG may be substantially higher than previously thought, thus opening exciting and new opportunities for investigating spatiotemporal

¹ Volume conduction refers to the process of current flow from the electrical generator to the recording electrode (Fisch, 1999).

Table 3.1. Selected historical landmarks in electroencephalography (adapted from Maurer & Dierks, 1991 and Neidermeyer, 1993)

Year	Name	Description
1875	R. Caton	First tracing in animals of fluctuating potentials that constitute the EEG
1924	H. Berger	First human EEG measurement
1929	H. Berger	First human EEG publication in <i>Archive für Psychiatrie und Nervenheilkunde</i>
1932	J. T. Toennies	First ink-writing biological amplifier
1932	G. Dietrich	First application of Fourier analyses on human EEG
1934	F. Gibbs	First systematic application of the EEG to epilepsy
1935	A. L. Loomis	First systematic application of the EEG to sleep
1936	W. G. Walter	Discovery of slow (delta) activity in the presence of tumors
1942	K. Motokawa	First EEG brain map
1943	I. Bertrand and R. S. Lacape	First book on EEG modeling
1947		American EEG Society is founded
1947	G. D. Dawson	First demonstration of human evoked potential responses
1949		<i>Electroencephalography and Clinical Neurophysiology</i> , the first EEG journal, is launched
1952	A. Remond and F. A. Offner	First topographic analyses of occipital EEG
1952	M. A. B. Brazier and J. U. Casby	Introduction of auto- and cross-correlation function
1955	A. Remond	Application of topographical EEG analyses
1958	H. Jasper	Introduction of 10–20 system for standardized electrode placement
1960	W. R. Adley	Introduction of Fast Fourier Transformation (start of computerized spectral analyses)
1961	T. M. Itil	Application of EEG analyses for classification of psychopharmacological agents
1963	N. P. Bechtereva	Localization of focal brain lesions by EEG
1965	J. W. Cooley and J. W. Tukey	Introduction of fast Fourier algorithm
1968	D. O. Walter	Introduction of coherence analyses for the human EEG
1970	B. Hjorth	Development of new quantitative methods, including source derivation
1971	D. Lehmann	First multichannel topography of human alpha EEG fields
1973	M. Matousek and I. Petersen	Development of age-corrected EEG spectral parameter for detecting pathology (qEEG)
1977	E. R. John	Introduction of “neurometrics” (standardized qEEG analyses with normative databases)
1978	R. A. Ragot and A. Remond	EEG field mapping
1979	F. H. Duffy	Introduction of brain electrical activity mapping (BEAM)

dynamics of brain mechanisms underlying mental processes and dysfunctions in psychopathology, bringing us closer to fulfillment of Berger’s dream that EEG will open a “window to the mind.”

2. PHYSIOLOGICAL BASIS OF THE EEG

2.1. EEG generation: I. The role of post-synaptic potentials in cortical pyramidal neurons

In the central nervous system, when a neuron is activated by other neurons through afferent action potentials, excitatory post-synaptic potentials (EPSPs) are triggered at its apical dendrites. When this occurs, the membrane of the

apical dendrites becomes depolarized and electronegative, compared to the cell soma (Baillet et al., 2001; Speckmann, Elger, & Alstrup, 1993). As a consequence of this transient potential difference, current flows from the nonexcited soma to the excited apical dendritic tree, and a negative polarity emerges at the surface (Speckmann et al., 1993).² In the opposite case, with excitation of the soma, the current flow will have inverse direction.

² Negative potentials at the surface can arise either due to (a) superficial EPSPs (i.e., excitation at apical dendrites) or (b) deep IPSPs (i.e., inhibition of the soma). Conversely, positive potentials at the surface can arise either due to (a) superficial IPSPs (i.e., inhibition at apical dendrites) or (b) deep EPSPs (i.e., excitation of the soma; Speckmann et al., 1993).

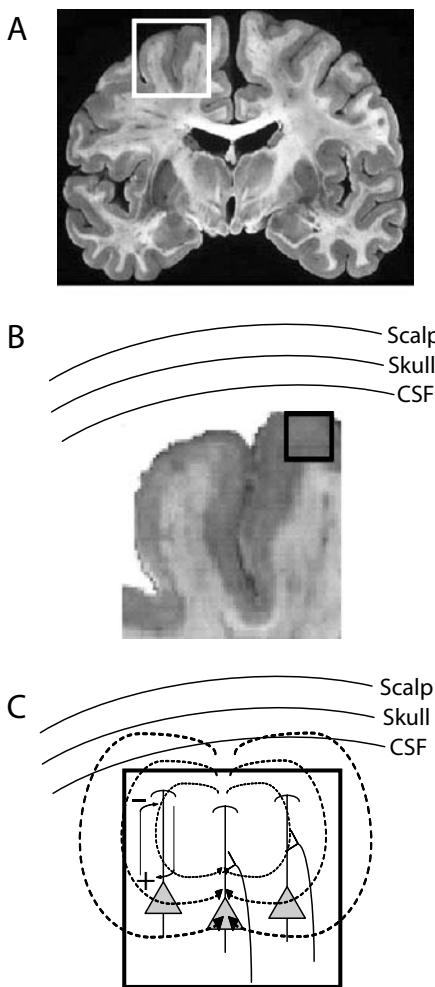

Figure 3.1. Neurophysiological basis of EEG generation. Scalp-recorded EEG oscillations generated by summation of excitatory and inhibitory post-synaptic potentials in cortical pyramidal neurons. (A) A coronal slice of the human brain is shown, with cortical gray matter highlighted in grey color. (B) An expanded view of cerebral gyri and sulci (see inset in A) is shown in relations to the scalp, skull, and cerebral spinal fluid (CSF). (C) A schematic illustration of cortical pyramidal cells within the cortical mantle (see inset in B) is shown. In this example, an excitatory post-synaptic potential (EPSP) is generated at the cell soma; local excitation (+ and -) leads to a tangential current flow (solid lines). The closed loops (dashed lines) represent the summation of extracellular currents produced by the postsynaptic potentials at cortical pyramidal cells, whose dendritic trunks are parallel to each other and perpendicular to the cortical surface. The deep EPSP shown in the example would produce a positive field potential at the cortical surface (Speckmann et al., 1993).

Scalp-recorded EEG oscillations are hypothesized to be generated by the summation of excitatory and inhibitory post-synaptic potentials in cortical pyramidal neurons (Speckmann et al., 1993; Figure 3.1). In the generation of an EEG oscillation, tens of thousands of synchronously activated pyramidal cortical neurons are assumed to be involved. The coherent orientation of their dendritic trunks (parallel to each other and perpendicular to the

cortical surface) allows summation and propagation to the scalp surface (Nunez & Silberstein, 2000). Accordingly, although subcortical contributions to scalp-recorded EEG have been reported (e.g., Llinas, Ribary, Jeanmonod, Kronberg, & Mitra, 1999), cortical macrocolumns are thought to be the main contributors of EEG signals (Fisch, 1999; Baillet et al., 2001).

2.2. EEG generation: II. The role of thalamo-cortical networks

Although mechanisms underlying EEG generation are not fully understood, interactions between thalamic and cortical networks are assumed to play a key role in various rhythmical EEG activities (Steriade, 1993). In animals, neurophysiological evidence has shown that several thalamic, thalamocortical, and cortical neurons display intrinsic oscillatory patterns, which in turn generate rhythmic EEG oscillations. The thalamus, in particular, has been described as a key player in the generation of alpha and beta oscillations. Accordingly, thalamic oscillations in the 7.5–12.5 Hz frequency range have been shown to activate the firing of cortical neurons (Steriade, 1993). The associated depolarization, which mainly occurs in the cortical layer IV, in turn creates a dipolar source with negativity in layer IV and positivity in superficial layers. Placing electrodes at the scalp allows measurement of small but reliable far-field potentials representing the summation of these potential fluctuations. In humans, thalamic contributions to alpha oscillations were investigated in a study integrating positron emission tomography (PET) and EEG recordings (Larson et al., 1998). Cortical alpha power was found to be inversely correlated to glucose metabolism in the thalamus, consistent with the assumption that thalamic activity in response to sensory or cortical input may lead to alpha suppression.

Corticocortical and thalamocortical interactions during information processing have also been postulated in the generation of oscillations at higher frequencies, including the beta band (13–30 Hz). Notably, the thalamus has been also implicated in the generation of delta waves (1–4 Hz), which might arise through interactions between deep cortical layers and the thalamus that are normally inhibited by afferents from the ascending reticular activating system. In addition, the septohippocampal system and various limbic regions (e.g., hippocampus, cingulate cortex) have been implicated in the generation of theta oscillations (Vinogradova, 1995; Bland & Oddie, 1998).

In sum, EEG oscillations appear to be dependent on interactions between the cortex and the thalamus, which both produce intrinsically rhythmical activities. Whereas the thalamus has been critically implicated in the pacing of such rhythmical activities, the cortex provides the coherent output in response to thalamic input and generates the vast majority of oscillations that can be recorded at the scalp (Fisch, 1999).

2.3. EEG generation: III. The role of local-scale and large-scale synchronization

As mentioned above, at any given moment in time, the signal recorded at the scalp is due to spatial summation of current density induced by synchronized post-synaptic potential occurring in large clusters of neurons. Considering that the diameter of EEG electrodes (~10 mm) is several orders of magnitude larger than single neurons (~20 μm) and that the area of an electrode covers approximately 250,000 neurons (Baillet et al., 2001), it is clear that many neurons must be activated synchronously in order to detect an EEG signal at the scalp.

Consistent with this notion, animal studies have described substantial synchronization among neighboring neurons ("local-scale synchronization"; e.g., Llinas, 1988), as well as between neuronal assemblies of distant brain regions ("large-scale synchronization"; e.g., Bressler & Kelso, 2001). Thus, synchronization of oscillations is a key mechanism for neuronal communication between spatially distributed brain networks (see Schnitzler & Gross, 2005 for a recent review). Emerging animal evidence indicates that oscillatory processes might (a) bias input selection, (b) temporally bind neurons into assemblies, and (c) foster synaptic plasticity (Buzsaki & Draguhn, 2004). Intriguingly, higher frequency oscillations (e.g., gamma) appear to originate from smaller neuronal assemblies, whereas low frequency oscillations (e.g., theta) span larger neuronal populations (Buzsaki & Draguhn, 2004). Large-scale neuronal synchronization plays an important role in various cognitive processes that rely on distributed neuronal networks (e.g., language processing; Weiss & Mueller, 2003), and can be studied through EEG coherence analysis, as will be discussed further in Section 5.3.

3. NORMATIVE EEG ACTIVITY

The millisecond temporal resolution of EEG allows scientists to investigate not only fluctuations of EEG activity (i.e., increases/decreases) as a function of task demand or subject samples but also to differentiate between functional inhibitory and excitatory activities. As a general rule, low frequencies (e.g., delta and theta) show large synchronized amplitudes, whereas high EEG frequencies (e.g., beta and gamma) show small amplitudes due to a high degree of desynchronization in the underlying neuronal activity. In adults, the amplitude of normative EEG oscillations lies between 10 and 100 μV (more commonly between 10 and 50 μV ; Niedermeyer, 1993). In the following section, a brief review of various EEG bands and their putative functional roles will be presented. For a review of the molecular and physiological basis underlying the generation of various EEG oscillations, the interested reader is referred to Steriade (1993) and Speckmann et al. (1993).

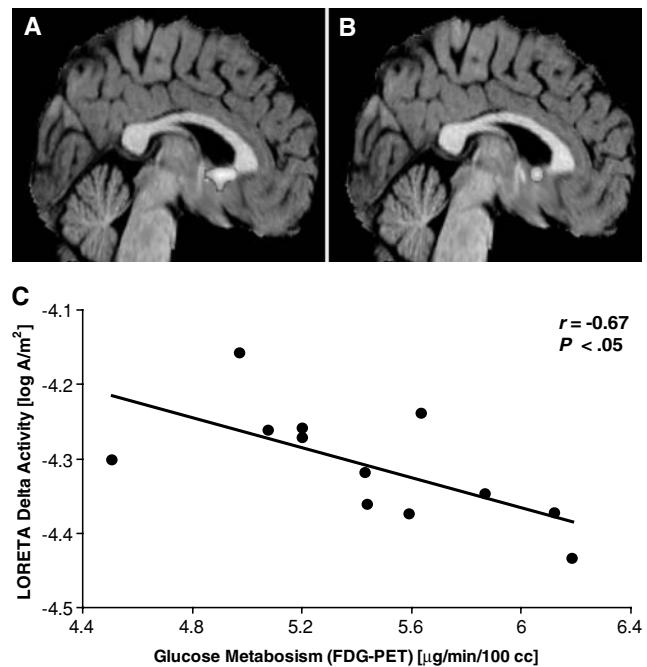

Figure 3.2. Reciprocal relation between delta activity and glucose metabolism. In a recent study integrating concurrently recorded electric (28-channel scalp EEG) and metabolic ($[^{18}\text{F}]$ -2-fluoro-2-deoxy-D-glucose positron emission tomography, FDG-PET) measures of brain activity, melancholic depression was characterized by (A) significantly increased delta current density (see yellow-red colors), as assessed with LORETA (see Section 8.2.3.); and (B) significantly decreased glucose metabolism (see blue colors). Statistical maps are thresholded at $P < .05$ (corrected) and displayed on a representative structural MRI. In psychiatrically healthy subjects, a significant negative correlation between delta current density and glucose metabolism in the subgenual prefrontal cortex emerged (C). Adapted from Pizzagalli et al. (2004) with permission. (See color plate.)

3.1. Delta band (1–4 Hz)

Delta oscillations reflect low-frequency activity (1–4 Hz) typically associated with sleep in healthy humans and neurological pathology. In adults, delta power has been shown to increase in proximity of brain lesions (Gilmore & Brenner, 1981) and tumors (Fernandez-Bouzas et al., 1999), during anesthesia (Reddy, Moorthy, Mattice, Dierdorf, & Deitch, Jr., 1992), and during sleep (Niedermeyer, 1993). Moreover, inverse relationships between delta activity and glucose metabolism have been reported in both pathological (e.g., dementia; Szelies, Mielke, Kessler, & Heiss, 1999) and normal (Pizzagalli et al., 2004) conditions. In our own study, an inverse relationship between delta current density (assessed via an EEG distributed source localization technique) and glucose metabolism (assessed via PET) was found within the subgenual prefrontal cortex (Figure 3.2). Delta is also the predominant activity in infants during the first two years of life. Ontologically, slow delta and theta activity diminish with increasing age, whereas the faster alpha and beta bands increase almost linearly across the life span (e.g., John et al., 1980).

Collectively, these findings suggest that delta activity is mainly an inhibitory rhythm.

3.2. Theta band (4–8 Hz)

Theta activity refers to EEG activity within the 4–8 Hz range, prominently seen during sleep. During wakefulness, two different types of theta activity have been described in adults (Schacter, 1977). The first shows a widespread scalp distribution and has been linked to decreased alertness (drowsiness) and impaired information processing. The second, the so-called frontal midline theta activity, is characterized by a frontal midline distribution and has been associated with focused attention, mental effort, and effective stimulus processing. Recent studies have implicated the anterior cingulate cortex (ACC) as a potential generator of frontal midline theta activity (e.g., Asada, Fukuda, Tsunoda, Yamaguchi, & Tonoike, 1999; Luu, Tucker, Derryberry, Reed, & Poulsen, 2003; Onton, Delorme, & Makeig, 2005). Consistent with these findings, in a recent study integrating electrical (EEG) and metabolic (PET) measurements of brain activity, we found that the ACC (Brodmann area 24/32) was the largest region with significant positive correlations between theta current density and glucose metabolism (Pizzagalli, Oakes, & Davidson, 2003).

Physiologically, the septo-hippocampal system has been strongly implicated in the generation of theta oscillations, although theta has also been recorded in numerous other limbic regions, including the ACC, entorhinal cortex, and the medial septum, among others (Vinogradova, 1995; Bland & Oddie, 1998). In rodents, generation of hippocampal theta activity is crucially dependent on afferents from the medial septum/vertical limb of the diagonal band of Broca complex (MS/vDBB), which is considered the pacemaker of hippocampal theta (Vertes & Kocsis, 1997). Additional evidence suggests that theta can be generated in the cingulate cortex independently of the hippocampal system (e.g., Borst, Leung, & MacFabe, 1987). In light of the observation that these oscillation facilitates transmission between different limbic structures, it has been speculated that theta activity may subserve a gating function on the information processing flow in limbic regions (Vinogradova, 1995).

3.3. Alpha band (8–13 Hz)

The alpha rhythm refers to EEG activity within the 8–13 Hz range. In healthy adults, alpha activity typically has an amplitude between 10 and 45 μ V, and can be easily recorded during states of relaxed wakefulness, although large individual differences in amplitudes are not uncommon (Niedermeyer, 1993). Topographically, alpha rhythms show their greatest amplitude over posterior regions, particularly posterior occipito-temporal and parietal regions, and can best be seen during resting periods in which the subjects has his/her eyes closed. In fact, alpha rhythm can

be greatly diminished or abolished by eye opening, sudden alerting, and mental concentration, a phenomenon known as alpha blockage or alpha desynchronization. The alpha rhythm can also be attenuated when alertness decreases to the level of drowsiness; this attenuation is, however, often accompanied by a decrease in frequency.

The physiological role of alpha rhythm remains largely unknown. Traditionally, the posterior distribution of these oscillations and the observation of alpha blockade with eye opening have been interpreted as suggesting that alpha may be associated with visual system functions emerging in the absence of visual input (Fisch, 1999). Indeed, some authors have expanded upon this notion by suggesting that alpha synchronization may represent an electrophysiological correlate of cortical “idling” or cognitive inactivity (e.g., Pfurtscheller, Stancak, Jr., & Neuper, 1996). In recent years, this conjecture has been heavily debated in the literature, particularly in studies investigating evoked EEG activity, in which alpha synchronization has been described during information processing (e.g., Cooper, Croft, Dominey, Burgess, & Gruzelier, 2003; Klimesch, 1999). Further complicating the physiological interpretation of alpha, emerging evidence indicates that different alpha sub-bands may be functionally dissociated, in particular with increasing task demands (Fink, Grabner, Neuper, & Neubauer, 2005). Specifically, in cognitive tasks, lower alpha (e.g., 8–10 Hz) desynchronization (suppression) has been associated with stimulus-unspecific and task-unspecific increases in attentional demands (e.g., Klimesch, 1999). Upper alpha (e.g., 10–12 Hz) desynchronization, on the other hand, appears to be task-specific, and it has been linked to processing of sensory-semantic information, increased semantic memory performance, and stimulus-specific expectancy (Klimesch, 1999).

3.4. Beta band (13–30 Hz)

Traditionally, lower-voltage oscillations within the 13–30 Hz frequency range have been referred to as beta. In adults, beta activity has amplitudes between 10–20 μ V, presents mainly a symmetrical fronto-central distribution, and typically replaces alpha rhythm during cognitive activity. Consistent with this view, beta rhythm has been shown to increase with attention (Murthy & Fetz, 1992) and vigilance (Bouyer, Montaron, Vahnee, Albert, & Rougeul, 1987), for example. Collectively, these findings suggest that beta increases generally reflect increased excitatory activity, particularly during diffuse arousal and focused attention (Steriade, 1993).

3.5. Gamma band (36–44 Hz)

Gamma oscillations have been associated with attention, arousal, object recognition, top-down modulation of sensory processes, and, in some cases, perceptual binding (i.e., the brain’s ability to integrate various aspects of a stimulus into a coherent whole; Engel, Fries, & Singer, 2001).

Various findings indicate that gamma activity is directly associated with brain activation. First, human intracortical EEG studies have reported increased gamma oscillations during various mental processes, including perception (Rodriguez, Lachaux, Martinerie, Renault, & Varela, 1999) and learning (Miltner, Braun, Arnold, Witte, & Taub, 1999). Second, dose-dependent decreases of gamma activity have been described during anesthesia (Uchida et al., 2000). Third, systematic decreases in gamma activity have been described throughout the sleep-wake cycle (highest during wakefulness, intermediate during REM sleep, and lowest during slow wave sleep; Gross & Gotman, 1999). A recent study from our laboratory using concurrent EEG and PET measurements provided further support for the notion that gamma is a direct indicator of activation because this band had the highest number of positive correlations between current density and glucose metabolism (Oakes et al., 2004).

Although the functional role of gamma oscillations needs to be more fully elucidated, these oscillations are assumed to reflect large-scale integration of and synchrony among widely distributed neurons, particularly in states of diffusely increased vigilance (e.g., Mann & Paulsen, 2005; Steriade, 1993). Physiologically, various mechanisms have been implicated in the generation of gamma oscillations, including: (1) intracortical circuitries, in particular those involving distant brain regions; (2) synaptic interactions among the cortex, thalamus, and limbic structures; and (3) brainstem-thalamic cholinergic activation (Steriade, 1993). Notably, recent animal and human findings have shown that gamma and theta oscillations can be functionally coupled both during activated (task-related) and resting (task-free) states (e.g., Fell et al., 2003; Mann et al., 2005; Schack, Vath, Petsche, Geissler, & Moller, 2002). In general, these studies have shown that gamma bursts occur within periods of the theta phase (Buzsaki, 1996 for review). Consistent with this notion, in a recent 128-channel source localization EEG study (Pizzagalli, Peccarlo, Davidson, & Cohen, 2006), we found significant positive correlations between resting theta and gamma current densities within various subdivisions of the ACC (correlation range: 0.51–0.59).

4. DATA ACQUISITION AND SIGNAL ANALYSIS

In the following sections, a selected discussion will be presented of issues associated with data acquisition and signal processing (for more in-depth reviews, see Davidson et al., 2000; Pivik et al., 1993; Gasser & Molinari, 1996; Nuwer et al., 1999; Thakor et al., 2004).

4.1. Electrodes

4.1.1. Electrode locations and high-density recordings

EEG signals always represent the potential difference between two electrodes, an active electrode and the so-called reference electrode. Accordingly, it is clear that the

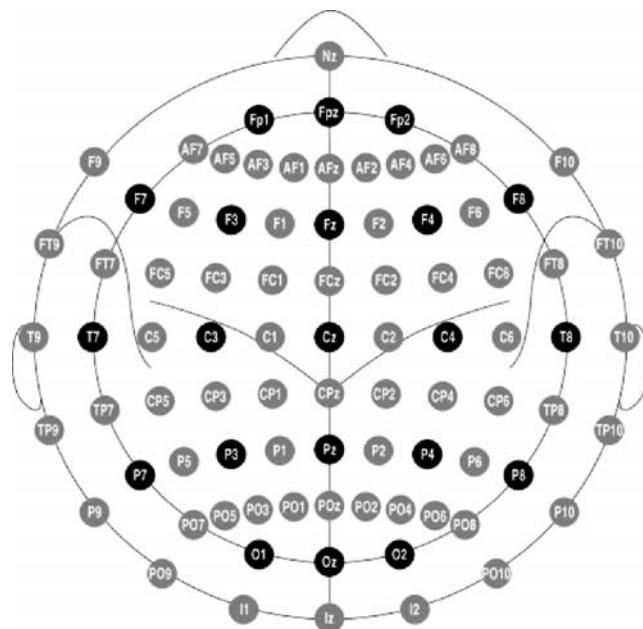

Figure 3.3. Electrode positions and labels in the International 10–20 System. Black circles denote electrode positions and labels from the 10–20 system; gray circles denote additional electrode positions and labels introduced with the 10–10 system. Reprinted from Clinical Neurophysiology, Vol. 112, Oostenveld, R. & Praamstra, P., The five percent electrode system for high-resolution EEG and ERP measurements, pp. 713–719, Copyright (2001), with permission from International Federation of Clinical Neurophysiology.

quality of EEG signals is dependent on the integrity of the electrode-electrolyte-skin interface (for a summary of clinical and experimental electrodes, see Fisch, 1999). Irrespective of their material, EEG electrodes should not attenuate signals between 0.5 and 70 Hz. To allow comparisons among studies it is important to adhere to standardized electrode locations. For many years, the accepted system for electrode placement has been the International 10–20 system proposed by Jasper (1958). The name refers to the fact that electrodes are placed at sites 10% and 20% from four fiducial points (nasion, inion, left, and right mastoids); this placement schema allows positioning of 19 electrodes homogenously across the scalp. In recent years, this system has been extended to the so-called 10–10 system (American Electroencephalographic Society, 1991) and the 5–5 system (Oostenveld & Praamstra, 2001), in which intermediate positions between those of the 10–20 system have been derived (Figure 3.3).

In recent years, high-resolution EEG systems with numbers of electrodes ranging from 64 up to as many as 256 have been introduced, with the goal of increasing the spatial sampling of the EEG (e.g., Gevins et al., 1994; Tucker, 1993). In one particular dense-array system (Tucker, 1993), scalp abrasion prior to the application of EEG electrodes is not necessary, reducing (a) the electrode application time (e.g., 15-min time for applying a 128-channel EEG net); (b) subject's discomfort; and (c) risk of infections. Instead, these systems are simply soaked in a saline

(electrolyte) solution and then applied directly to the head (but see Greischar et al., 2004 for potential issues associated with electrolyte spreading in high-density recordings). The use of high-input impedance ($200\text{ M}\Omega$) amplifiers allows the recording of reliable EEG traces with impedances one order of magnitude higher than the traditional $5\text{ K}\Omega$.

Studies using simulated as well as real EEG data have suggested that an electrode distance of 2–3 cm is required to prevent distortions of the scalp potential distribution, and thus allow resolution of spatially focal EEG patterns (e.g., Srinivasan et al., 1998). In addition, recent studies assessing the role of spatial density (i.e., number of electrodes) on *source reconstructions* have clearly shown an improved spatial resolution with high-density recordings. In a simulation study, Lantz, Grave, Spinelli, Seeck, & Michel (2003) reported that the source localization accuracy increased linearly from 25 to 100 electrodes but reached a plateau after 100 electrodes. In the same study, Lantz and coworkers also showed a marked improvement in localization precision of the epileptic sources when increasing electrodes from 31 to 63; again, at least in the case of spatially focal sources in epileptic patients, the improvements in localization accuracy were less dramatic when going from 63 to 123. Similar findings were reported by Luu et al. (2001), who investigated the role of electrode density in the ability to localize scalp abnormalities associated with acute cerebral ischemia. Using sensor downampling (128, 64, 32, and 19 electrodes), the authors found that only 64 and 128 electrode arrays were capable of resolving spatially localized EEG abnormalities. As in Lantz et al., minimal gain was achieved when moving from 64 to 128 electrodes. Note however that, because Lantz et al. used a source localization technique (EPIFOCUS; Grave de Peralta, Gonzalez, Lantz, Michel, & Landis, 2001) that assumes a single focal source, distributed source localization techniques (see Section 8.2) may benefit from the additional spatial sampling achieved with >100 electrodes. Consistent with this hypothesis, Michel et al. (2004) found that source imaging with 128-channel EEG epileptic spike data led to correct localization (to the order of the affected lobe) in 93.7% of the focal epileptogenic area, as independently assessed through presurgical assessments.

Regardless of the number of electrodes utilized, uniform and homogenous coverage of the scalp is of paramount importance for reliable measurements of the scalp potential field, a critical prerequisite for any source localization technique (Michel et al., 2004). Moreover, measurements of exact 3-D electrode position with a digitizer (if available) may provide important information to account for individual differences in electrode positioning (e.g., Towle et al., 1993). Recently, a solution based on photogrammetric measurements has been developed for quick and accurate measurement of electrode positions in high-density EEG system (Russell, Jeffrey, Poolman, Luu, & Tucker, 2005). In this approach, multiple cameras are used to record the location of individual sensors, allowing for the reconstruc-

tion of the 3-D sensor positions. In sum, both simulation and experimental studies suggest that at least 60 (preferably more) equally distributed electrodes are required for accurate spatial sampling of scalp activities.

4.1.2. Electrode interpolation

The importance of spatial sampling for source localization is associated with the issue of how best to deal with electrodes with corrupted EEG signals due to excessive artifacts or technical malfunction. As mentioned above, source localization strongly relies on the scalp potential distribution, which itself can be distorted by uneven spatial sampling. Consequently, simply omitting corrupted electrodes is not a feasible solution, and interpolation methods are needed. Broadly speaking, two interpolation methods have been utilized: linear (nearest neighbor) and spline interpolation methods (e.g., Perrin, Pernier, Bertrand, & Echallier, 1989). In the first method, corrupted activity is reconstructed through a weighted average using data from neighboring electrodes (the weights are proportional to the Euclidian distance between the electrodes). With the spline interpolation method, information from all sensors is used to represent the overall potential distribution on the entire scalp, and thus to reconstruct the activity at missing channels. Although mathematically simpler, linear interpolations have the disadvantage that (a) edge electrodes cannot be accurately estimated; (b) only a few electrodes are used; and (c) maxima and minima of activity are always located at electrode sites (Maurer & Dierks, 1991). Empirical evidence indicates that non-linear spline interpolation methods achieve greater accuracy (Soufflet et al., 1991).

4.1.3. Recording reference choice

As mentioned in Section 4.1.1, EEG waveforms represent the *differential* voltage between a given electrode and the recording reference. It is therefore clear that the choice of reference completely determines EEG waveforms (Lehmann, 1987; Dien, 1998), an important methodological consideration that all too often is still not recognized in the EEG literature. For example, recording with a vertex (Cz) reference would lead to small EEG deflections in the proximity of Cz due to potential synchronization of firing activities within closely spaced brain regions and volume propagation of the EEG signal. Similarly, recording with mastoid or linked ears montage would lead to rather small waveforms at electrodes positioned over temporal brain regions (Pivik et al., 1993).³

Ideally, the reference electrode should be electrically inactive, allowing the measurement of an absolute EEG value. Both cephalic and noncephalic references are never electrically inactive, and thus contribute to recorded EEG signals. Understanding this point is particularly important when deciding the location to the recording reference in

³ Note, however, that information contained in the reference (e.g., Cz) is not permanently lost, but can be recovered by recomputing the EEG data against a different reference electrode.

order to avoid situations in which the reference itself is contaminated by noncephalic activity (e.g., muscle or electrocardiogram artifacts). In these circumstances, because the potential difference is measured between the active and reference electrodes, substantial artifacts would be introduced in all EEG channels.

Due to the fundamental issue of reference-dependency of EEG waveforms, reference-free transformations have been proposed for an unbiased assessment of EEG measures. In particular, the use of an average reference (Lehmann, 1987), radial current flow (Hjorth, 1975), and current source density (Perrin, Bertrand, & Pernier, 1987) have attracted substantial interest. With the average reference approach, at each moment in time, EEG signals are re-derived against the average value across all electrodes. In the Hjorth method, also known as source derivation or Laplacian transformation, the average potential difference between each electrode and the nearest four electrodes is computed.⁴ By computing the density of local radial currents, this approach acts as a spatial high pass filter and emphasizes shallow cortical generators. Finally, current source density (also known as surface Laplacian) is computed as the second derivative of the voltage surface; by acting also as a spatial filter, surface Laplacians can be helpful in identifying focal patterns (Nunez & Pilgreen, 1991). Although these reference-free methods have been successfully used in the literature for an unbiased assessment of EEG signals, it is important to stress that they often require a relatively high number of electrodes (e.g., 32 electrodes or more), as well as homogenous electrode distribution across the scalp for reliable estimates (Pivik et al., 1993).

Although the choice of the reference electrode greatly influences *waveform* analyses, it is important to note that the reference choice is completely irrelevant for *any* source localization. In fact, the spatial configuration of the scalp potential distribution is independent of the reference electrode (the reference merely affects the zero line; Lehmann, 1987). As source localization relies on the spatial distribution of the scalp EEG and ERP, different reference montages (e.g., average reference, linked mastoids) lead to identical estimates of intracerebral sources.

4.2. Recording: Filters and sampling rate

The bandwidth of the EEG signal is 0.1–100 Hz in frequency, although most studies focus on frequencies below 30 Hz (or below 50 Hz if gamma activity is investigated). Although a comprehensive review of calibration, filtering, and digitization of EEG signals is beyond the scope of this chapter (see Davidson et al., 2000; Pivik

et al., 1993; Dumermuth & Molinari, 1987 for excellent reviews), some points should be emphasized here. First, the extent to which the digital signal under investigation accurately reflects the physiological (analog) signal completely depends on the sampling rate. As a general rule, the sampling rate should be at least twice the highest frequency present in the signal under investigation. This rule, also known as the *Nyquist Theorem*, prevents the introduction of spurious low-frequency components into the signal, a phenomenon called *aliasing* (Dumermuth & Molinari, 1987). Aliasing occurs when a signal is sampled at a rate that is too low, and introduces irreparable distortion to the digital waveform (Figure 3.4). Two methods can be used to avoid aliasing. First, frequencies higher than half the sampling rate should be removed from the EEG before digitization occurs (e.g., by using an analog or hardware filter). Second, high sampling rates (e.g., four-fold greater than the filter cutoff frequency) could be used. Because the EEG signals of interest are typically between 1 and <60 Hz, a sampling rate of 250 Hz with an analog 0.1–100 Hz filter are appropriate for most EEG studies. If contamination of low frequency artifacts is an issue, the high pass analog filter can be set as high as 1 Hz (Nuwer et al., 1999). Higher sampling rate is required to investigate early sensory ERP components or high-frequency EEG patterns.

4.3. Artifacts

When recorded, the raw EEG signal is virtually always contaminated by various sources of noise and artifacts. In general, biological and non-biological artifacts can be differentiated (see pp. 107–121 in Fisch, 1999 for illustrations of the most common artifacts). The former mainly derive from subjects' movements, muscle activities, blinks, eye movements, heartbeat, and sweating. As will be discussed later, concurrent recording of the electrocardiogram (ECG), electrooculogram (EOG), and electromyogram (EMG) can be very important for a proper detection and removal of these artifacts. Nonbiological artifacts primarily derive from interferences from power lines (50/60 Hz), additional electrical noise, poor subject grounding, and poor electrode contact. One common source of 50/60 Hz noise stems from fluorescent lights. Use of notch filters (50/60 Hz), proper subject grounding, and shielding of the recording system can greatly diminish the influence of nonbiological artifacts. Proper grounding, in particular, can substantially improve the quality of the EEG signals and avoid leakage of current from the EEG system to the subjects.⁵ Often, a midforehead electrode is used for this purpose.

Visual and, increasingly more often automatic, offline artifact detection is essential before any EEG analyses, and substantial expertise is required for a proper differentiation of normal and contaminated EEG activity. Drowsiness can introduce a substantial confound in baseline EEG

⁴ For instance, assume that a researcher wishes to compute the Laplacian transformation at electrode Cz, which has a potential value of 10 µV, and that the four neighboring electrodes Fz, C3, Pz, and C4 have potentials of 3, 5, 12 and 5 µV, respectively. The new source-derivation value for Cz would be 3.75, i.e., [(Cz-Fz) + (Cz-F3) + (Cz-Pz) + (Cz-C4)]/4.

⁵ Grounding can be achieved by connecting participants to the ground of the amplifier system.

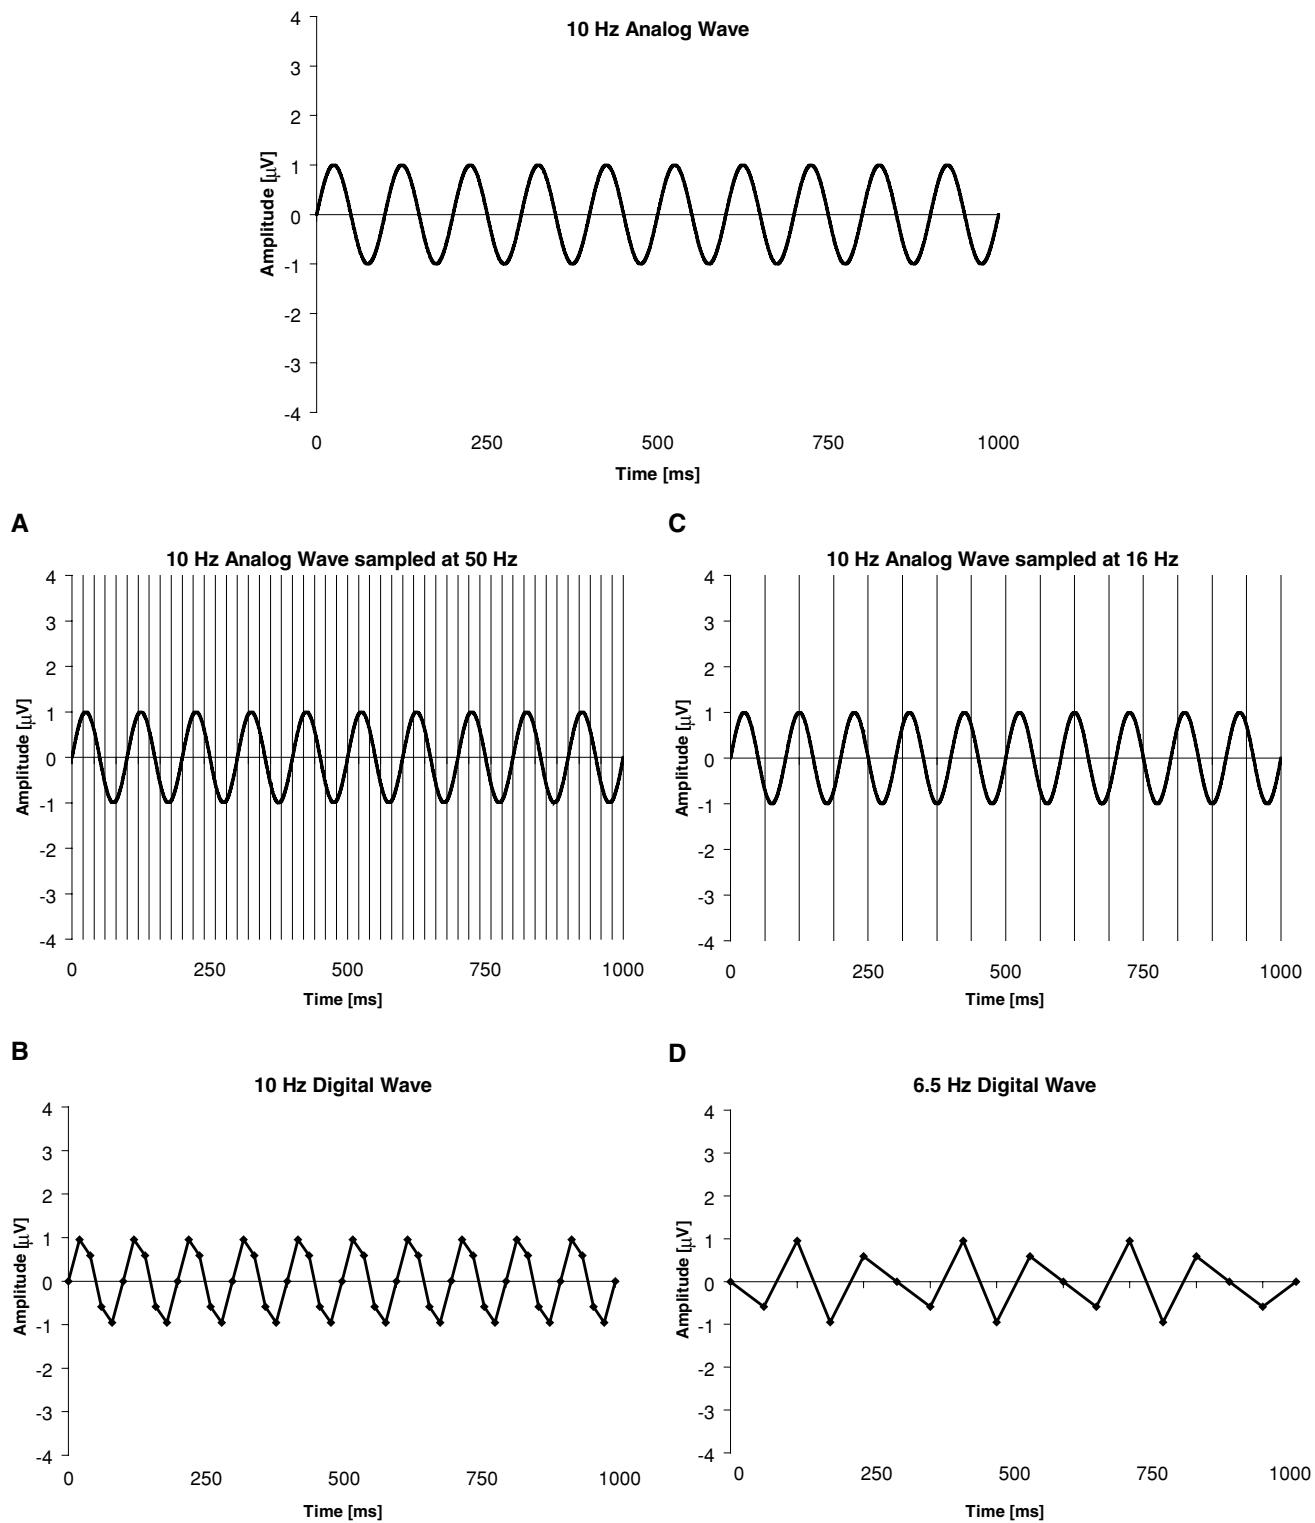

Figure 3.4. Example of aliasing due to insufficient sampling rate. A 10 Hz sine waveform is digitized at two different sampling rates. (A) The sampling rate (50 Hz) is greater than twice the waveform frequency, which results in (B) an appropriate digital representation of the analog signal. (C) The sampling rate (16 Hz) is less than twice the waveform frequency, yielding (D) a false (aliased) representation of the analog signal. Note how undersampling introduces an irreparable lower frequency component in the digital signal. Modified after Fisch (1999).

recording due to a global change in the functional brain state. Typically, EEG slowing over anterior regions, slowing and subsequent decrease of alpha activity, and slow eye movement (particularly horizontal), are associated with subjects' drowsiness. When this pattern is detected, it is recommended to exclude these periods of EEG (Pivik et al., 1993).

Removal of ECG and EOG artifacts is particularly important, because these artifacts overlap in frequency and amplitude with the EEG. In humans, normal ECG is within the 1–1.5 Hz range, suggesting that its second-order harmonics (2–3 Hz) is within the delta range (Thakor et al., 2004). Blinks and eye movements mostly generate activity within the delta and theta range (i.e., <7.5 Hz). Blinks, which typically last 200–400 ms and can generate artifacts with an amplitude up to 800 μ V, can however also affect the alpha band (and to a lesser extent the beta band), in particular at anterior sites (Hagemann & Naumann, 2001). For proper detection of ocular artifacts, it is essential to utilize additional channels to record vertical and horizontal eye movements. To record vertical eye movement, two electrodes are affixed below and above one eye; for horizontal movements, two electrodes are affixed at the extremities of an eye. Over the years, several methods have been described in the literature to detect and correct both sources of noise (see Croft, Chandler, Barry, Cooper, & Clarke, 2005 for a recent review and comparison of the most widely used EOG correction algorithms).

Artifacts originating from muscle activity can contaminate a broad range of EEG frequencies because the primary energy in EMG signals is between 10 and 200 Hz (Tassinary & Cacioppo, 2000). Due to this overlap with EEG frequencies, occurrence of these artifacts are particularly problematic for EEG analyses. Contamination from muscle activity can be troublesome for studies interested in gamma activity, which can be easily influenced by non-cephalic, myogenic sources. Considering the explosion in interest in the functional role of gamma activity in mental processes, it is clear that proper attention must be devoted to the issue of EMG contamination to the gamma band. Due to frequency overlap, removing muscle artifacts through filtering can greatly distort real EEG signals. Accordingly, several authors proposed the use of regression approaches for dealing with this issue (e.g., Allen, Coan, & Nazarian, 2004; Davidson et al., 2000). In this approach, activity in higher frequencies (e.g., 50–70 Hz) is typically taken as a marker of muscle artifact, and its variance is removed using regression analyses or entered as covariate in analyses of variance (ANOVA).

In recent years, the method of independent component analysis (ICA) has been increasingly used for removal of ECG and other artifacts (see Makeig, Bell, Jung, & Sejnowski, 1996 for a tutorial). In view of the fact that artifacts typically do not occur time-locked to a given event or evoked response, ICA is ideally suited to remove such interfering signals. Consistent with this notion, ICA works best when applied to unaveraged (raw) EEG data. In the

case of ECG, contaminated EEG is entered into the ICA, which separates the EEG and EOG components. In a subsequent step, the ECG component is set to zero in the coefficient matrix leading to a removal of ECG artifacts. ICA approaches have been also used to remove EOG artifacts (Thakor et al., 2004).

5. QUANTITATIVE SCALP ANALYSES

The introduction of computers has enabled the development of several methods to investigate EEG signals with respect to various parameters, including waveform frequencies, amplitudes, phase, and coherence. Quantitative EEG (qEEG) analyses can be divided into linear and nonlinear approaches. Among the most widely used linear methods to quantify spontaneous or task-related EEG activity are spectral and coherence analyses, which typically assume that the EEG signals are stationary processes.⁶ Nonlinear approaches, which often incorporate higher order statistics, information theory, or chaos theory, started to emerge in the 1990s, and have demonstrated their usefulness particularly when applied to transient and irregular EEG patterns (see Thakor et al., 2004 for a review).

5.1. Spectral analyses

Spectral analyses are based on the notion that any oscillatory activity can be characterized by the sum of different sinusoidal waves with distinct frequencies and amplitude (see Figure 3.5 for a simulation). The goal of spectral analyses, which are often performed using the Fast Fourier Transform (FFT), is to estimate the contribution of various frequencies on the measured EEG signal. Commonly, spectral estimates are computed for discrete frequencies (e.g., 8.5–10 Hz for lower alpha). For a given frequency or discrete EEG band, the root-mean-square average amplitude or the power (the square of the amplitude) is used to quantify its contribution to the measured EEG signal. Mathematically, the Fourier coefficients indicate the strength of the signal at a given frequency.

In a typical EEG study, all available artifact-free EEG segments are entered in spectral analyses. When selecting the length of the artifact-free EEG segments, it is important to understand that this variable determines the maximal frequency resolution available for the analyses. Thus, selection of 2-sec segments will provide a 0.5 Hz resolution (i.e., the inverse of 2 sec), allowing to resolve, for example, 10 and 10.5 Hz frequencies. Note, however, that spectral analyses assume that the EEG is a stationary signal. Accordingly, segments entered in FFT analyses cannot be too long because of potential violation of the stationarity assumption (Gasser & Molinari, 1996). When relatively short segments are considered (e.g., <3.5 sec), the

⁶ In simple terms, stationarity implies that the statistical properties of an EEG signal (e.g., mean, variance) do not vary over time.

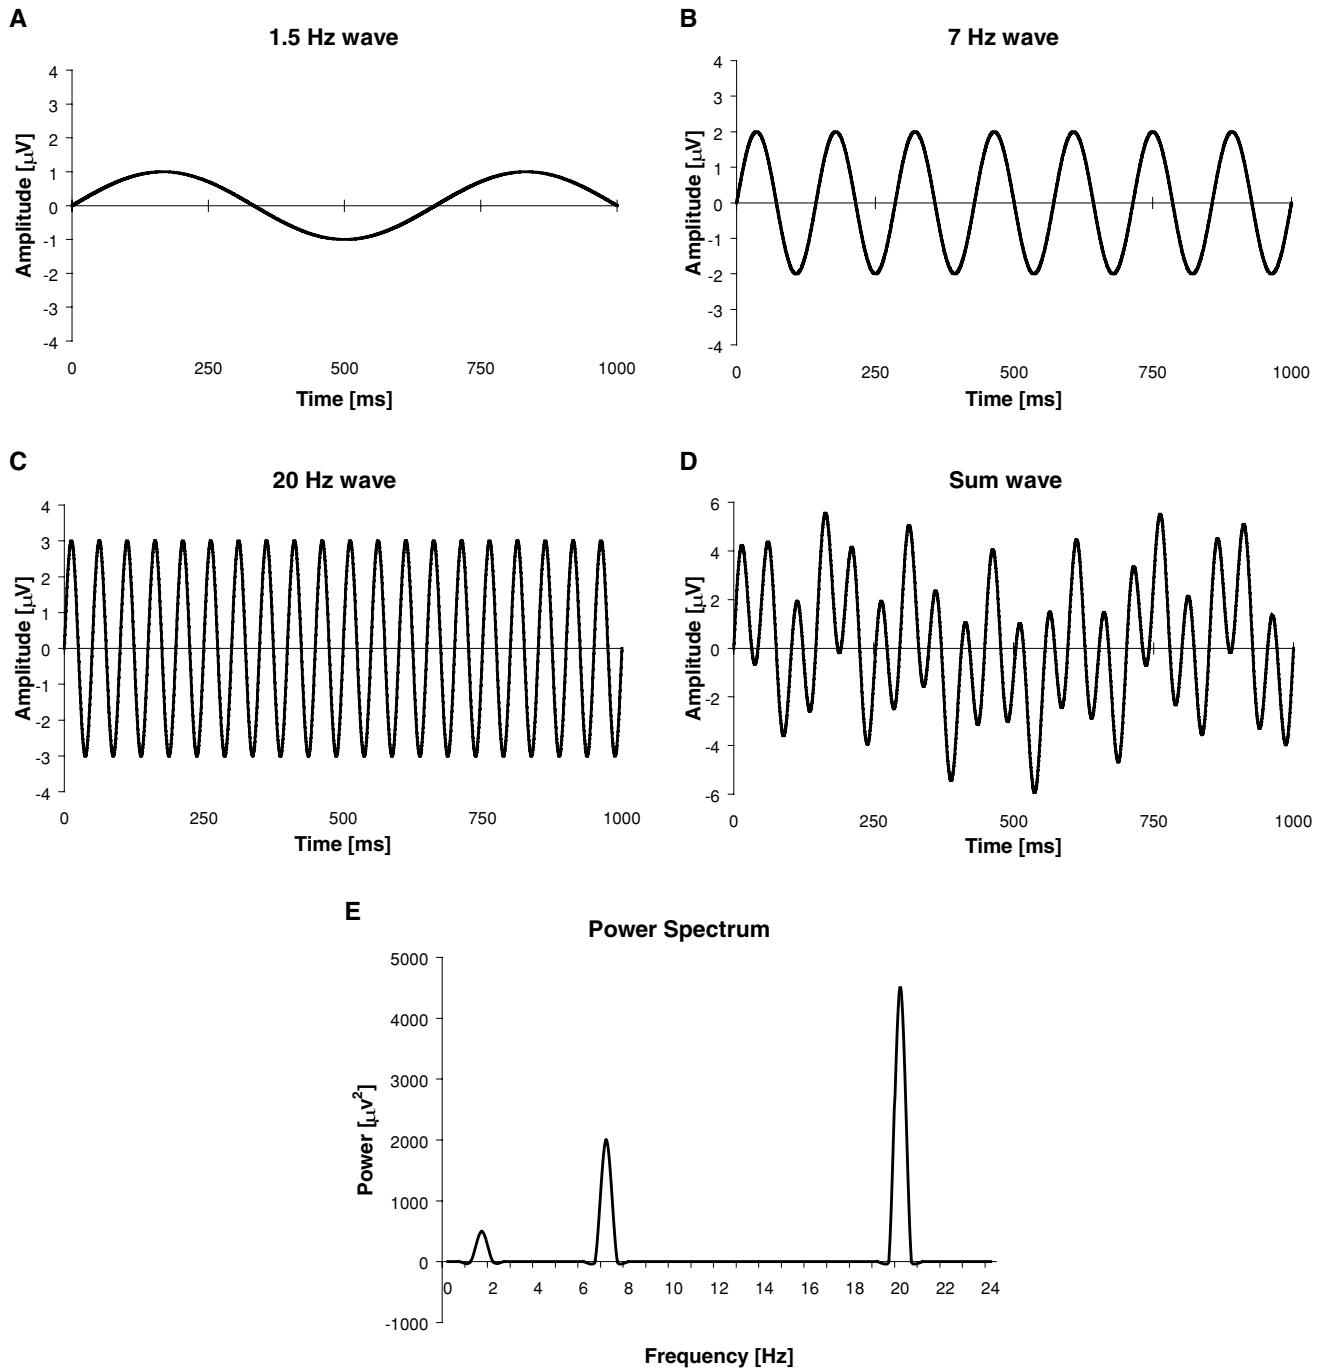

Figure 3.5. Simulation of power spectrum computation through Fast Fourier Transformation (FFT). In (A), (B), and (C), simple sine waves oscillating at 1.5, 7, and 20 Hz are shown. In (D), the sum of these three sine waves is shown. In (E), the results of an FFT analysis of the complex waveform displayed in (D) are shown. Not surprisingly, the spectrum identifies frequency peaks at 1.5, 7, and 20 Hz.

stationarity assumption is typically met in spontaneous EEG recording.

To allow reliable estimation of spectral features and to reduce the impact of second-to-second variability in EEG signals, at least 60 sec of artifact-free data should be used for spectral analyses (Nuwer et al., 1999; Pivik et al., 1993). Further, to avoid introduction (“leakage”) of spurious fre-

quencies arising from abrupt changes in EEG signals at the beginning and the end of the EEG segments, a so-called taper transformation should be used. For this purpose, the Hanning (cosine) window has been commonly utilized. This window tapers the beginning and end of the EEG segment to zero, whereas the middle of the segment retains 100% of its amplitude (see Dumermuth & Molinari, 1987

for a review of various windowing approaches). Because the use of windowing reduces the amount of data that can be analyzed within a segment, overlapping segments (e.g., 50%) are often used to restore the amount of data for spectral analyses.

Although we refer to prior reviews for a comprehensive discussion of spectral analyses (e.g., Gasser & Molinari, 1996; Davidson et al., 2000), several important methodological points should be emphasized here. First, an underappreciated issue is that the frequency range for a given oscillatory activity (e.g., alpha activity) can show substantial individual differences. Klimesch (1999) has long advocated the use of individually defined frequency ranges and has shown in several experimental situations that this choice can have substantial effects on the findings. Second, measures of *absolute* or *relative* power can be derived from spectral analyses. Whereas absolute power reflects the amount of a given frequency within the EEG, relative power is calculated as the amount of EEG activity in a given frequency band divided by the total power. In general, absolute power should be preferred because it can be more easily interpreted. Third, when dealing with power data, transformations (e.g., log) are often used before statistical analyses to approximate a Gaussian distribution (Davidson et al., 2000). Finally, ratios or difference scores are often computed between different electrodes in an attempt to draw inferences about differential hemispheric activation. Conceptual and methodological considerations concerning these asymmetry metrics are discussed next (for reviews, see Allen et al., 2004; Coan and Allen, 2004; and Davidson et al., 2000).

5.1.1. Asymmetry metrics

In many experimental situations, psychophysologists are interested in investigating whether the two brain hemispheres are differentially involved in specific cognitive and affective processes, personality traits, or various forms of psychopathology. Although many metrics have been used to investigate hemispheric differences (Pivik et al., 1993), the alpha power asymmetry index has been among the most commonly used. This index is derived from subtracting the natural logarithm of the left hemisphere power value from the natural logarithm of the right hemisphere power value ($\ln R - \ln L$). Because alpha power is considered to be inversely related to brain activation, positive numbers on this index indicate relatively greater right activity, whereas negative numbers denote relatively higher right activity.

The investigation of frontal EEG asymmetry has received particular attention, and over 80 studies have examined its role in emotion, motivation, and psychopathology (for a recent review, see Coan & Allen, 2004). In general, the picture emerging from this literature is that frontal EEG asymmetry is associated with (a) state-dependent emotional reactivity; (b) individual differences in emotional reactivity; and (c) individual differ-

ences in risk for a variety of emotion-related disorders (e.g., depression, anxiety). Conceptually, it has been proposed that left prefrontal regions might be implicated in a system that facilitates appetitive behavior and certain forms of affect that are approach-related. Conversely, right prefrontal regions have been implicated in withdrawal-related, negative affect (Davidson, 2004).

From a methodological perspective, the use of asymmetry metrics has several advantages. First, they allow researchers to control for individual differences in skull thickness, a variable that can artificially cause individual differences in scalp power values. Second, asymmetry metrics can increase statistical power by reducing individual differences in overall activity, and limit the number of statistical tests performed. Third, the internal reliability of the alpha power frontal asymmetry index is high, ranging from 0.76 to 0.93 across studies, and the test-retest reliability is acceptable (e.g., 0.69–0.84 across three weeks) (Allen et al., 2004). When asymmetry scores are reported, however, follow-up analyses assessing the unique contribution of each hemisphere to the asymmetry index should be presented. For example, a finding of relatively increased right frontal activity in a given patient population, although an important first step, should be subjected to further analyses to ascertain whether this pattern is due to (1) an increase of right frontal activity; (2) a decrease of left frontal activity; or (3) a combination of the above. From a statistical perspective, a laterality effect can only be claimed if the *Group × Hemisphere* or *Condition × Hemisphere* interaction is significant (Allen et al., 2004; Davidson et al., 2000).

5.2. Time-frequency analyses

From the last section it is clear that spectral analyses can provide important information about the frequency compositions of EEG oscillations. Spectral analyses cannot, however, provide any information about *when in time* such frequency shifts occur. Because the EEG is a dynamic, time-varying, and often non-stationary phenomenon, approaches allowing the investigation of transient changes in the frequency domain appear particularly important. To achieve this goal, various time-frequency analysis methods have been developed, including (a) short-time Fourier Transform (STFT), for computation of an FFT-based time-dependent spectrum (so-called spectrogram); and (b) wavelet analyses, which allow a more adaptive time-frequency approach affording flexible resolution. Wavelet analyses, in particular, have gained popularity in recent years due to their ability to accurately resolve EEG waveforms into specific time and frequency components (see Samar, Bopardikar, Rao, & Swartz, 1999 for a nontechnical tutorial). In this approach, EEG signals are viewed as shifted and scaled versions of a particular mathematical function (the wavelet), rather than a composition of sine waves with varying frequencies as in the FFT.

5.3. Coherence analyses

As summarized in Section 2.3., neurophysiological studies have demonstrated the presence of both local-scale synchronizations (i.e., synchronization among neighboring neurons) as well as large-scale synchronizations (i.e., synchronization among distant regions; e.g., Bressler & Kelso, 2001; Llinas, 1988). In EEG studies, the investigation of large-scale neuronal synchronization appears particularly important in experimental situations hypothesized to recruit distributed neuronal network. In order to quantitatively measure the dynamic functional interactions among EEG signals recorded at different scalp locations, *coherence measures* can be computed (Nunez et al., 1997).

Coherence is a frequency-dependent measure, mathematically obtained by dividing the cross-spectrum between two time series by the root of the two spectra (this computation is similar to a correlation; Schack et al., 2002). Cross-power spectrum is obtained by multiplying the Fourier transform of one signal with the complex conjugate of another signal, thus allowing the quantification of relationships between different EEG signals. Accordingly, coherence can range from 0, indexing the absence of any synchrony, to 1, indicating maximal synchrony between the frequency components of two signals, irrespective of their amplitudes.

Intriguingly, increased synchronization among distant regions has been observed within low-frequency oscillations (e.g., theta), whereas increased local synchronization has been observed for high-frequency oscillations (e.g., gamma; Buzsaki & Draguhn, 2004; von Stein & Sarnthein, 2000). In general, brain regions that are co-activated during a given cognitive process are assumed to show increased coherence (“neuronal synchronization”) within specific EEG frequency bands, depending on the nature and difficulty of the task (Weiss & Mueller, 2003). For some authors, such coherence measurements have been interpreted as reflecting cortical interactions or connectivity (e.g., Thatcher, Krause, & Hrybyk, 1986). Consistent with this speculation, increased coherence has been generally observed with increased task complexity and efficient information processing, whereas pathological conditions characterized by dysfunctional networks (e.g., dementia, dyslexia) are characterized by decreased coherence (Leonciani & Comi, 1999; Weiss & Mueller, 2003).

Finally, it is important to note that, although coherence analyses assess the degree of synchronization between different brain regions, they cannot inform us about the *causality* of these interactions or the *direction* and *speed* of the information transferred. Only in recent years, advanced methods for assessing these important aspects of brain function have been described, including the Directed Transfer Function (DTF), the Directed Mutual Information (DMI), and the partial directed coherence (PDC) techniques (Thakor et al., 2004 for a review). In a recent

study, Astolfi et al. (2005) presented a promising approach to estimate connectivity by applying structural equation modeling and DTF to cortical signals derived from high-resolution EEG recordings.

5.4. Quantitative EEG (qEEG)

In qEEG studies, also known as “neurometrics” (John et al., 1980), various variables derived from spectral and coherence analyses of multi-channel EEG recordings (e.g., absolute power, relative power, interhemispheric and intrahemispheric coherence, asymmetry scores) are entered into large normative, age-dependent databases in conjunction with demographic and clinical information. Age-regression qEEG equations and Z-scores are then utilized to (1) identify patterns of abnormal EEG patterns associated within specific neurological or psychiatric disorders; and (2) provide supportive evidence for differential diagnoses and treatment decisions (for a recent review, see Hughes & John, 1999). Recent studies have confirmed the ability of qEEG approaches of detecting abnormal EEG patterns in pathological conditions but also some of their limitations, which might in part derive, however, from the fact that clinical conditions are far from being homogeneous entities. Thus, whereas abnormal qEEG patterns were found in 83% of 340 psychiatric patients but only in 12% of 67 controls, no EEG abnormality was specific to a given clinical entity, and patients with the same diagnosis often showed different EEG abnormalities (Coutin-Churchman et al., 2003).

5.5. EEG mapping and space-oriented EEG analyses

The advent of multi-channel EEG systems has fostered the development of EEG mapping techniques (Lehmann, 1987; Duffy, Burchfiel, & Lombroso, 1979 for seminal reviews). Conceptually, at a given moment in time, this method considers values at each electrode and through interpolation display the field distribution of brain electric activity. Unlike traditional EEG waveform approaches, EEG mapping considers data in the spatial domain first, and then in the temporal domain, providing a display of the constantly changing spatial distribution of brain activity (see Maurer & Dierks, 1991 for a tutorial). For topographic mapping, at minimum the complete 10–20 system should be used (i.e., >19 electrodes; Nuwer et al., 1999). One of the main advantages of space-oriented EEG analysis is that, at any given time point, activity from all electrodes is considered simultaneously. A second main advantage is that, unlike waveform analyses, space-oriented analysis is independent from the reference electrodes. In fact, the spatial configuration or landscape of a map does not change when a different reference is used. In a manner analogous to a geographical map, the topographical features, such as the location of maximum or minimum potential or the

potential gradients, are not affected by the chosen reference that defines the zero line.

Critically, when examining the unfolding of momentary potential distributions over time, one observes that these maps tend to remain relatively constant for some periods of time, and are then abruptly interrupted by the emergence of new landscapes (Lehmann, 1971). Lehmann (1990) called these temporal segments of quasi-stable map landscapes “microstates” and considered them the building blocks of human information processing. Note that different configurations of scalp potentials are assumed to index different functional brain states because (a) different scalp potential distribution must have been generated by different neural sources (Fender, 1987); and (b) different neural sources likely subserve different functions.

Consistent with this assumption that microstates index different functional brain states, studies have shown that different mental processes (Lehmann, Henggeler, Koukkou, & Michel, 1993) or arousal states (Cantero, Atienza, Salas, & Gomez, 1999) are associated with different microstate classes. Further converging evidence comes from the notable observations that different age groups can be characterized by distinctive patterns of changes in microstate durations and preponderance (Koenig et al., 2002). Such age-dependent microstate changes mirror comparable transitional stages classically described by developmental psychologists. Likewise, psychopathological conditions characterized by dysfunctional mental states, such as schizophrenia (e.g., Lehmann et al., 2005) or dementia (e.g., Strik et al., 1997), showed shortened durations for specific microstates. Intriguingly, in a recent study, Lehmann et al. (2005) reported that acute, medication-naïve, first-episode schizophrenic subjects had different “microstate syntax” (i.e., different microstate concatenations and transitions) as well as truncated duration for some microstates, raising the interesting possibility that this disease may be characterized by different concatenations of mental operations and precocious termination of information processing for certain types of mental operations. For methodological details about microstate analyses of EEG data, see Koenig et al. (2002) and Lehmann et al. (2005).

Although EEG mapping represents a powerful and unambiguous approach for scalp EEG data, it is important to stress that this technique does not provide any additional information about the generating sources underlying scalp measurements (Pivik et al., 1993). In Section 8, source localization techniques required for localization of intracerebral sources will be reviewed.

6. SURFACE-SOURCE IMAGING APPROACHES

6.1. Scalp Laplacian mapping

As mentioned in the Introduction, the spatial resolution of scalp EEG is limited by the blurring effects of the head

volume conductor. In fact, the head acts as a low-pass spatial filter, transmitting to the scalp broad, as opposed to focal, spatial patterns of activity (Srinivasan et al., 1998). Scalp Laplacian mapping can be used to restore high-frequency spatial information of brain electric activity that has been distorted by the low-conductivity skull (Hjorth, 1975; Nunez et al., 1997; Perrin et al., 1987). The surface Laplacian approach does not solve the inverse problem (i.e., it is not a 3-D source localization technique); rather it allows source mapping directly over the scalp surface. As reviewed by He (1999), surface Laplacian is thought to represent an approximation of the local current density flowing perpendicularly to the skull into the scalp (for this reason, it has been also called *current source density* or *scalp current density*). A further advantage of surface Laplacian methods is that they are reference-independent.

The scalp Laplacian was first introduced for EEG data by Hjorth (1975), who proposed a difference estimation scheme to calculate local Laplacian by using the potentials at surrounding electrodes (see Footnote 4). Although computationally easy to implement, this so-called local approach was found to have some limitations, including inaccurate estimation for large interelectrode distances and for border electrodes (He, 1999). To overcome these drawbacks, Perrin et al. (1987) introduced a global approach based on the mathematical modeling of the global scalp surface and a curvilinear coordinate system. In their implementation, Perrin and coworkers assumed that the scalp surface can be approximated by a sphere. Later, Babiloni et al. (1996) presented a solution called “realistic Laplacian estimator” that can be applied to any arbitrarily shaped scalp.

6.2. Cortical imaging

To increase the spatial resolution of the EEG, the cortical imaging approach can also be used to deconvolve the low-pass spatial filtering effects of head volume conduction (Gevins et al., 1994). In this approach, biophysical models of the passive conducting features of the head are used to deconvolve a scalp potential distribution into estimation of potentials or current dipole distribution at the superficial cortical surface (for a review, see He, 1999). Gevins and coworkers (1994), for example, presented a deblurring technique based on a realistic biophysical model of the passive conducting properties of the head to estimate the potential distribution at the cortical surface. To this end, a finite element model (see Section 7.1) based on MRI-reconstructed scalp, skull, and cortical surfaces was used. Conceptually, the rationale for this approach stems from the empirical observation that cortical pyramidal cells oriented perpendicularly to the cortical surface mainly contribute to the recorded scalp EEG signal (Speckmann et al., 1993). Note that neither the scalp Laplacian nor the cortical imaging approach are source localization techniques

and thus are unable to reconstruct sources in 3-D space. This important topic will be discussed next.

7. THE NEUROELECTROMAGNETIC FORWARD AND INVERSE PROBLEM

The “forward problem” refers to the process of estimating scalp potentials from intracranial current sources (Koles, 1998). If the configurations of intracranial sources and the conductivity proprieties of the tissues are known, then the scalp potential distribution can be calculated using basic physical principles. Therefore, the forward problem can be unambiguously solved. In contrast, the “inverse problem,” the estimation of sources underlying scalp-recorded EEG data, is ill-posed. Although recording of the human EEG was first reported by Berger in 1929, it soon became evident that scalp-recorded electromagnetic measurements do not contain sufficient information about the 3-D distribution of the electric neuronal activity. As early as the mid-nineteenth century, Helmholtz (1853) had already described the nonuniqueness of this type of electromagnetic inverse problem: the current distribution inside a conducting volume cannot be uniquely determined by the field and potential information outside it. Thus, scalp-recorded EEG/MEG measurements can be explained by an infinite number of different generating distributions, even with an infinite numbers of recording electrodes (Fender, 1987). To understand this concept, consider that the inverse problem can be mathematically represented as:

$$D = GX + n \quad (3.1)$$

where D is a vector representing the scalp-recorded potentials, X is an unknown vector representing the generating sources (the current density vector), n is noise, and G is the transfer matrix, which mathematically implements both the electromagnetic (e.g., conductivity values for the brain, skull, and scalp) and geometrical (e.g., shape) features of the solution space considered in the inverse solution (“the head volume conductor model”). The inverse problem refers to finding X given known D . Specifically, the main goal is to minimize the following function:

$$O(X) = \|D - GX\|^2 \rightarrow \min \quad (3.2)$$

In general terms, it is not possible to determine which solution among the infinite possibilities corresponds to the actual solution; consequently, the quest for developing an electromagnetic tomography appears, at first, hopeless. Fortunately, the EEG and MEG follow certain electrophysiological and neuroanatomical constraints, which when combined with the laws of electrodynamics, provide an approximate solution of the inverse problem (Baillet et al., 2001; Michel et al., 2004; Pascual-Marqui, Esslen, Kochi, & Lehmann, 2002). When considering Equation 1, it becomes immediately evident that the localization accuracy of *any* source localization technique is critically dependent on: (1) the head model used to compute the inverse solu-

tion; and (2) the inverse solution itself (Michel et al., 2004). In the following section, these two important aspects will be reviewed, followed by a description of various solutions to the inverse problem currently used in the EEG literature.

7.1. Head volume conductor model

The head volume conductor model plays a critical role in source localization because it determines the way intracerebral sources give rise to the scalp-recorded signal. As indicated above, the head model mathematically implements both the electromagnetic and geometrical properties of the solution space. Over the years, three head models have been used: (1) three-spherical head model (e.g., Ary, Klein, & Fender, 1981); (2) a boundary element model (BEM; e.g., Hamalainen & Sarvas, 1989); and (3) a finite element model (FEM; e.g., Miller & Henriquez, 1990). In terms of complexity and computational burden, the spherical model represents the simplest, the BEM the intermediate, and the FEM the most complex model. BEM and FEM models are typically developed from high-resolution structural MRI scan of individual subjects and can better account for individual anatomical differences, providing therefore more realistic head models.

The three-spherical head model, which has been most frequently used, approximates the head as a set of nested concentric and homogenous spheres, in which the skull, scalp, and brain are modeled as different layers with different conductivity. Typically, standard conductivity values, which have been measured in separate studies from excised tissue, are used for the different compartments, but in recent years attempts to assess conductivities through diffusion tensor MR imaging have begun to emerge (e.g., Tuch, Wedeen, Dale, George, & Belliveau, 1999). In general, spherical models can provide appropriate localization in superior regions of the brain, where the head shape approximates a sphere.

The BEM, in contrast, approximates different compartments of volume conductor models (e.g., skin, skull, cerebral spinal fluid) through closed triangle meshes with different conductivity values and dimension and thus attempts to take into account realistic geometry. Although the BEM clearly represents an improvement and more realistic model than the three-spherical head model, this model assumes homogeneity and isotropy within the head and brain. To cope with this potential issue, FEM models have been developed.

The FEM, unlike other methods, can account for the actual head shape and tissue discontinuities, and accommodate anisotropic tissue⁷ in the conductivity model of the head volume, allowing detailed 3-D information on tissue conductivity for each region. This approach models current flow in an inhomogeneous volume by representing the conductor as a complex assemblage of many equally

⁷ Anisotropy refers to the property of having different values when measured in different directions.

sized cubes or tetrahedrons. The use of tetrahedrons can accommodate elements that vary in size, thus allow modeling of the head geometry and anisotropy precisely. For several authors, the high computational efficiency of the BEM makes this model a valuable compromise between the oversimplifying sphere head volume model and the computationally intensive FEM model (He, 1999).

8. SOURCE LOCALIZATION TECHNIQUES

Estimating the sources of scalp-recorded electromagnetic activity has attracted considerable interest, and various solutions have been described in the literature. In general these solutions can be divided into two broad categories, *equivalent dipole approaches* and *linear distributed approaches*. The first approach typically assumes that EEG/MEG signals are generated by a relatively small number of discrete and focal sources, which can be modeled as single, fixed, or moving dipoles (e.g., Scherg & Ebersole, 1994). Through an iterative process, locations, orientations, and strength of these equivalent current dipole (ECD) are selected to minimize the difference between the predicted and the actual EEG measurements. The solution derived through this approach strongly relies on the numbers of dipoles; unfortunately, in many experimental situations, the numbers of dipoles cannot be determined a priori (e.g., Phillips, Rugg, & Friston, 2002a).

Distributed approaches, in contrast, consider all possible source locations simultaneously. In addition to the advantage conferred when no a priori assumptions about the numbers of sources are required, distributed approaches typically allow researchers to limit the solution space by means of anatomical and functional constraints. As will be discussed in the [next section](#), anatomical constraints assume that some specific compartments (e.g., gray matter) or regions of the brain (e.g., cortical structures) have a higher likelihood of generating scalp-recorded EEG signals than others, and are thus essential for narrowing the search for a “unique” solution. In the following sections, a non-technical survey of various source localization techniques will be presented (for more technical reviews, see Baillet et al., 2001; Hamalainen & Ilmoniemi, 1994; Grave de Peralta & Gonzalez Andino, 2000; Phillips et al., 2002a; Phillips et al., 2002b; Pascual-Marqui et al., 2002; Trujillo-Barreto et al., 2004).

8.1. Equivalent dipole approaches (Dipole Source Modeling)

The equivalent current dipole (ECD) model is the most basic source localization technique and assumes that scalp EEG potentials are generated by one or few focal sources (for review, see Fuchs, Ford, Sands, & Lew, 2004). A dipole does not reflect the presence of a unique and discrete source but it is rather a mathematically convenient representation (i.e., the center of gravity) of synchronized activation of a large number of pyramidal cells likely extending

larger patches of gray matter (Baillet et al., 2001). In fact, a dipole is assumed to represent a patch of cortical gray matter layer containing approximately 100,000 pyramidal cells oriented in parallel to each other and activated simultaneously (Fuchs et al., 2004). Heuristically, the position of a dipole can provide clues about the extent and configuration of the activated cortical area (Lopes da Silva, 2004): superficial dipoles typically reflect localized cortical activity, whereas deeper dipoles reflect the activity of an extended cortical area.

In this approach, focal sources are modeled by an ECD through six parameters: three location parameters (X, Y, Z), two orientation parameters, and one strength (amplitude) parameter. Depending on the experimental procedures and/or a priori hypotheses, moving, fixed, or rotating dipoles can be used. Using an iterative procedure and nonlinear multidimensional minimization procedures, the inverse problem is solved by attempting to identify dipole parameters that best explain the observed scalp potential measurements (Fuchs et al., 2004). In its simplest terms, initial dipole parameters are selected, the forward solution is computed, and a least-squares comparison between estimated and actual measurements is calculated. This process is continued until the difference between estimated and actual measurements is minimized. Without a priori assumption, one of the main concerns with this approach is that it can get trapped in local minima (Michel et al., 2004). Additionally, depending on the spatial configuration of the underlying sources, a dipole can sometimes be found at physiologically implausible locations, such as within white matter or even outside of the brain.

Over the years, various dipole source models have been developed, including the moving dipole model, rotating dipole model, regional dipole model, fixed (coherent) dipole model, and fixed (multiple signal classification or MUSIC) model (see Fuchs et al., 2004 for a review). Another interesting approach, called EPIFOCUS, has been recently proposed by Grave de Peralta et al. (2001). EPIFOCUS assumes a single focal source, but unlike single dipole modeling, does not assume that this source is spatially restricted to a single point. The *moving dipole model* assumes only one dipole at the time and allows all parameters to vary. The *rotating dipole model* constrains location to a single point but allows orientations and strength to vary. The *fixed dipole model*, in contrast, holds position and orientation constant within a given interval and it estimates the dipole strength for each time point. These subtle differences in these models, which are the ones most frequently used, underscore the need to incorporate prior neuroanatomical and neurophysiological knowledge to guide the selection of the physiologically most plausible model, making source reconstruction a hypothesis-driven process. In general, some caution should be exerted when interpreting dipole modeling solutions because users’ interventions and decisions about the number of underlying sources are required in dipole fitting. To cope with this issue, Mosher, Lewis,

and Leahy (1992) developed a mathematical approach aimed to estimate the likely number of underlying sources. This method, called multiple signal classification (MUSIC), attempts to decompose the signal to identify underlying components in the time series data (see Mosher & Leahy, 1998 for further improvements).

In recent years, substantial progress has been made to extend the original dipole fitting approach implemented using simplified spherical head models to more realistic geometry head model constructed from single subject's MRI images, in particular using boundary element methods (BEM) or finite element methods (FEM). Not surprisingly, simulation and experimental studies have shown that a more accurate localization can be achieved by using realistic head models (e.g., Fuchs, Wagner, & Kastner, 2001). In a recent study (Cuffin, Schomer, Ives, & Blume, 2001), the best average localization that could be achieved with spherical head model was 10 mm. In addition to improved localization capability, co-registration with MRI images can be used to visualize the dipole location coordinates relative to brain anatomy, facilitating comparisons with other functional imaging modalities. Studies combining electrophysiological and hemodynamic measures have further extended dipole source localization approaches by using PET- or fMRI-identified activation loci to seed the iterative optimization procedure, providing clues about the putative location of sources (e.g., Heinze et al., 1994). As will be discussed in Section 9, the relationship between electrophysiological changes measured by EEG/MEG and hemodynamic changes measured by PET/fMRI is not fully understood (Nunez & Silberstein, 2000), posing some challenges in situations in which fMRI activations are used to choose the *number* and *location* of potential sources. A more promising (and potentially less biased) approach involves independent EEG/MEG source modeling, which is then weighted based on hemodynamic findings to select the most likely solution (e.g., Liu, Belliveau, & Dale, 1998).

In summary, although dipole source modeling has been successfully used to localize spatially restricted and focal sources (e.g., early sensory evoked potentials), its main limitation is that the *exact* number of dipoles often cannot be determined a priori. Further, because intracranial recordings have provided very little support for the notion that only a few sites in the brain are active in generating ERP or spontaneous EEG recording (e.g., Towle et al., 1998), dipole fitting results should be interpreted with caution.

8.1.1. Dipole source modeling for EEG data:

FFT-dipole-approximation

As reviewed in Section 5, qEEG approaches have been extensively used in both clinical and experimental settings to investigate the spectral aspects of scalp-recorded EEG signals. For many clinical and experimental researchers, the next step following spectral analysis might be to localize the sources underlying different EEG frequency bands.

Unfortunately, topographic maps of power distributions derived from traditional scalp spectral analyses cannot be used for source localization because (1) these maps represent squared potential values, in which polarity information is lost; and (b) power maps are reference-dependent (Lehmann, 1987). In 1989, Lehmann and Michel published a method, called FFT-Dipole-Approximation, which allows computation of intracerebral, three-dimensional location of single dipole source model in the frequency domain. Conceptually, this approach reduces multi-channel EEG data by focusing on the principal features of the spatial organization of brain activity. In assuming a single, common phase angle for all generator processes, the FFT-Dipole-Approximation approach models multichannel brain electric field data in the frequency domain by a potential distribution map, which contains polarity information and consequently can be used for conventional source modeling.

Analytically, standard frequency analyses via FFT are computed first. Then, for each artifact-free EEG segment, the Fourier coefficients for each electrode are plotted in a sine-cosine diagram, and subsequently projected onto the straight line given by the first principal component of the entries. Note that only assessing the first principal component of standard FFT result implies a single phase-angle modeling (i.e., all phase angles between recording electrodes are either 0° or 180°), which typically explains more than 93% of the variance of the original baseline EEG data (Michel, Lehmann, Henggeler, & Brandeis, 1992). For any user-specified EEG frequency band, the single phase-angle assumption allows the computation of a mean potential distribution map (the FFT Approximation Map), which can then be subjected to standard 3-D equivalent dipole source modeling (Lehmann & Michel, 1989). In a final step, the model source's location coordinates on the anterior-posterior, left-right, and inferior-superior axes and its strength for conventional EEG frequency bands, can be compared between experimental conditions or groups.

The FFT-Dipole-Approximation method has several strengths. First, unlike scalp localization of EEG spectral value, this approach is completely independent from the chosen reference electrode location, and thus does not require any assumptions about an inactive site (Michel et al., 1992). Second, no assumption is needed about the orientation of the generating sources, thus allowing an unbiased approximation of the 3-D spatial organization of brain activity. Physiologically, locations of the model sources describe the center of gravity of all neural elements that are active in the brain during a given recording. Accordingly, different locations of centers of gravity unambiguously imply different geometry (i.e., locations and/or orientations) of the underlying neuronal sources between experimental conditions or groups. The FFT-Dipole-Approximation approach has been successfully used to compute intracerebral sources of various

EEG frequency bands during experimental situations or conditions assumed to involve widely distributed brain systems, including sleep (Tsuno et al., 2002), pathological conditions (e.g., Alzheimer's disease; Huang et al., 2000), and epilepsy (Worrell et al., 2000), among other examples. In situations, in which the assumption of a single oscillating dipole generator is unwarranted or unlikely, results are expected to be less reliable.

8.2. Linear distributed source localization techniques

Considering the intrinsic limitation of dipole modeling, and in particular the fact that it is often difficult to determine *a priori* the number of underlying sources, it is not surprising that attempts to develop distributed source modeling approaches have received considerable attention. In simple terms, these approaches are based on the estimation of brain electric activity at each point within a 3-D solution space. Each point, in turn, can be considered a dipole. Unlike equivalent dipole models, these "dipoles" have fixed positions (e.g., Pascual-Marqui et al., 1999) and sometimes fixed orientations (e.g., Phillips et al., 2002a; Phillips et al., 2002b), which are determined by anatomical and physiological constraints implemented within the localization algorithms. As these methods are used to estimate the strengths (and in some cases, the orientation) of the source, the equations describing distributed solutions are linear.

Because the number of measurements (electrodes) is typically <100, and the number of unknowns (electrical activity at each point in the solution space) is often on the order of 10,000, it is clear that the inverse problem is greatly underdetermined (Baillet et al., 2001; Michel et al., 2004). Mathematically, so-called regularization methods are needed to limit the range of allowable solutions and identify the "optimal" or "most likely" solution. Regularization methods can be understood as mathematical representations of the physiological/structural assumptions implemented in a given method. In the literature, various regularization methods have been utilized. Some of the most widely used include minimum norm solution (Hamalainen & Ilmoniemi, 1994), maximal smoothness (Pascual-Marqui et al., 1994), structural/functional priors (Phillips et al., 2002a; Phillips et al., 2002b), and fMRI-weighted solution space (Dale et al., 2000). Although some of these methods have received important empirical validation indicating that it is possible to solve the inverse problem, the severe underdetermined nature of the inverse problem leads to the consequence that the solutions have low spatial resolution – their solutions are often blurred. In the following section, a review of distributed source localization techniques is presented. The LORETA algorithm has been used extensively by researchers in the field and by our group (e.g., Pizzagalli et al., 2001; Pizzagalli et al., 2002; Pizzagalli et al., 2003; Pizzagalli et al., 2004;

Pizzagalli et al., 2006). Therefore, a more extended discussion of emerging cross-modal validation as well as limitations of LORETA will be presented in Sections 8.2.3.1 and 8.2.3.3, respectively.

8.2.1. Minimum norm solutions

The MN solution (Hamalainen & Ilmoniemi, 1994) was one of the first linear inverse solutions. In the MN approach, the head model is first mapped onto a 3-D grid, and three mutually perpendicular dipole current sources are placed at each grid point (Koles, 1998). The goal of the MN approach is to estimate the distribution and strengths of these tens of thousands of dipoles. Among the infinite possible, the MN approach selects the one that contains the least energy, that is, minimal overall current density within the brain. Mathematically, the MN solution estimates the 3-D source distribution with the smallest L2-norm solution⁸ that fit the actual data.

MN does not incorporate any prior information. In particular, unlike other methods (e.g., Pascual-Marqui et al., 1994; Phillips et al., 2002a; Phillips et al., 2002b), MN solutions do not impose any spatial correlation among sources. However, there is no strong physiological evidence that the solution with the smallest L2-norm is also the most plausible one. In fact, simulation studies have shown that the MN solution typically favors weak and localized activation patterns, and can misplace deep sources onto the outermost cortex (Pascual-Marqui, 1999). Accordingly, MN does not completely fulfill the promise of a 3-D source localization technique. LORETA, as we will see, was the first approach that successfully extended the good localization properties of the 2-D MN solution to 3-D solution space.

8.2.2. Weighted minimum norm solutions

To compensate for the depth dependency of MN solution, in particular the tendency to favor superficial sources, various weighting factors have been suggested. Two solutions are mentioned here. The first, known as the *weighted MN solution*, uses a lead field normalization for compensating for the lower representation of deeper sources (e.g., Jeffs, Leahy, & Singh, 1987). The second, called FOCUSS (Focal Underdetermined System Solution; Gorodnitsky, George, & Rao, 1995), is a nonparametric algorithm for solving the inverse solution, in which the weights are iteratively modified according to the solution estimated in a previous step. Specifically, at each step, the weights of grid points with the lowest current density are reduced, and this process is repeated until the current density at most of the grid points is zero (Koles, 1998). Although these weighted MN approaches gave some promising results for reducing the low spatial resolution (blurring) of all MN solutions and for reducing the depth-dependency of sources

⁸ In the L2-norm approach, the squared deviation of the data from a given model is minimized using a least-squares method.

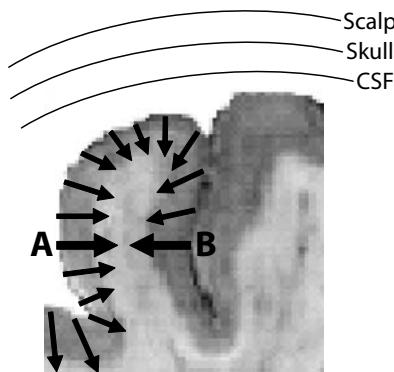

Figure 3.6. Graphical representation of the LORETA assumptions. The core assumptions of the LORETA algorithm are that (A) neighboring neurons are synchronously activated and display only gradually changing orientations; and (B) the scalp-recorded EEG originates mostly from cortical gray matter. These two assumptions are graphically displayed in the figure. Note that, in this fictive example, activity generated by the dipolar sources A and B would not be detected by scalp EEG; in fact, due to the gyral and sulcal configurations, activity from these opposing dipoles would cancel out.

(Michel et al., 2004), it is important to point out that weighting is selected based on mathematical operations rather than physiological assumptions.

8.2.3. Low-resolution Electromagnetic Tomography (LORETA)

Low-resolution Electromagnetic Tomography (LORETA) (Pascual-Marqui et al., 1994), a form of Laplacian-weighted MN solution, solves the inverse problem by assuming that: (1) neighboring neurons are synchronously activated and display only gradually changing orientations; and (2) the scalp-recorded signal originates mostly from cortical gray matter (Figure 3.6). The first assumption, which is generally consistent with neurophysiological studies in animals (e.g., Haalman & Vaadia, 1997), is mathematically implemented by computing the “smoothest” of all possible activity distributions. Note that the smoothest solution is assumed to be the most plausible one *giving rise to the scalp-recorded EEG signal*. The second assumption constrains the solution space to cortical gray matter (and hippocampi), as defined by a standard brain template. Mathematically, LORETA selects the solution with the smoothest spatial distribution by minimizing the Laplacian (i.e., the second spatial derivatives) of the current sources.

In recent implementations (Pascual-Marqui et al., 1999), LORETA uses a three-shell spherical head model registered to the Talairach brain atlas (available as digitized MRI from the Brain Imaging Centre, Montreal Neurological Institute (MNI); Evans et al., 1993) and EEG electrode coordinates derived from cross-registrations between spherical and realistic head geometry (Towle et al., 1993). The solution space, that is, the 3-D space where the inverse problem is solved, is restricted to corti-

cal gray matter and hippocampi, as defined by a digitized probability atlas provided by the MNI.⁹ Under these constraints, the solution space includes 2394 voxels at 7 mm spatial resolution.

For analyses in the frequency domain, LORETA computes current density as the linear, weighted sum of the scalp electrical potentials, and then squares this value for each voxel to yield power of current density in units proportional to amperes per square meter (A/m^2).

In 2002, Pascual-Marqui introduced a variant of the LORETA algorithm, in which localization inferences are based on standardized current density (standardized LORETA, or sLORETA). Conceptually, sLORETA was inspired by work by Dale et al. (2000). Using a two-step process, Dale et al. first estimated current density using the MN solution; subsequently, current density was standardized using its expected standard deviation, which was assumed to fully originate from measurement noise. Although sLORETA uses a slightly different implementation that considers simultaneously two sources of variations (variations of the actual sources and variations due to noisy measurements), its localization inference is also based on standardized values of current density estimates. As a result, unlike LORETA, sLORETA does not introduce Laplacian-based spatial smoothness to solve the inverse problem and does not compute current density but rather statistical scores. In initial simulations, sLORETA was reported to have zero-localization error (Pascual-Marqui, 2002). Independent simulations using (a) a dipolar source, or (b) two spatially well-separated dipolar sources with similar depth replicated that sLORETA had higher localization accuracy than LORETA or MN solutions (Wagner, Fuchs, & Kastner, 2004). However, in the presence of a strong (or superficial) source, a second weak (or deeper) source remained undetectable by all methods, including sLORETA (Wagner et al., 2004). Thus, sLORETA successfully resolved two simultaneously active sources only when their fields were distinct enough and of similar strength.

8.2.3.1. Cross-modal validation of LORETA. In initial studies, the physiological validity of LORETA was indirectly evaluated by comparing LORETA solutions with functional imaging findings derived from similar experimental manipulations. For example, physiologically meaningful findings were observed during basic visual, auditory, and motor tasks (e.g., Mulert et al., 2001; Thut et al., 1999), epileptic discharges (e.g., Lantz et al., 1997), and cognitive

⁹ Accordingly, LORETA coordinates are in MNI space. Note, however, that the LORETA software uses the Structure-Probability Maps atlas (Lancaster et al., 1997) to label gyri and Brodmann area(s). Because the MNI (used by LORETA) and the Talairach (used by the Structure-Probability Maps atlas) templates do not precisely match, MNI coordinates are temporarily converted to Talairach coordinates (Brett et al., 2002) before the Structure-Probability Maps atlas is utilized. In our publications (e.g., Pizzagalli et al., 2001, 2004) as well as those relying on the LORETA-KEY software, reported coordinates remain in MNI space.

tasks tapping specific brain regions (e.g., Pizzagalli et al., 2002).

In more recent years, important cross-modal validation has come from studies directly combining LORETA with functional fMRI (Mulert et al., 2004; Vitacco, Brandeis, Pascual-Marqui, & Martin, 2002), structural MRI (Worrell et al., 2000), PET (Pizzagalli et al., 2004; but see Gamma et al., 2004), and intracranial recordings (Seck et al., 1998). In Pizzagalli et al. (2001), theta current density in the rostral anterior cingulate cortex (ACC) was associated with treatment response in major depression; the ACC region implicated in this 28-channel EEG study overlapped with the one implicated in similar studies using PET and fMRI (see Pizzagalli et al., 2006 for a meta-analysis). In Pizzagalli et al. (2004), subjects with the melancholic subtype of depression were characterized by decreased activity within the subgenual PFC, which was manifested as increased inhibitory EEG delta activity and decreased PET glucose metabolism (Figure 3.2A–B). Delta current density and glucose metabolism were significantly and inversely correlated ($r = -0.66$; Figure 3.2C). In two recent EEG/fMRI studies, LORETA localizations were, on average 16 mm (Mulert et al., 2004) and 14.5 mm (Vitacco et al., 2002) from fMRI activation loci, a discrepancy that is in the range of the spatial resolution of LORETA (1–2 cm). Despite some controversy in the field about the localization capability of LORETA (Grave de Peralta & Andino, 2000) and recent null findings (Gamma et al., 2004), substantial consistency between LORETA findings and other traditional neuroimaging techniques has been reported.

8.2.3.2. Incremental validity of LORETA. In addition to improving the spatial resolution of EEG data, initial evidence suggests that EEG source localization techniques may allow researchers to uncover information not available in traditional scalp spectral analyses. Two examples from our laboratory are pertinent to this point. In a first study, traditional scalp power and LORETA analyses were applied on the same resting EEG data to investigate putative abnormalities in major depression (Pizzagalli et al., 2002). In the LORETA data, depression severity was significantly correlated ($r = 0.60$, $p < 0.015$) with an “intracerebral” frontal asymmetry index that included the inferior and superior frontal gyri, indicating that relatively higher right prefrontal activity was associated with higher depression severity. When identical analyses were performed on the scalp frontal asymmetry index ($\ln F4 - \ln F3$), the correlation was not significant.

In a more recent study, we investigated whether resting EEG alpha activity predicted response bias in a separate verbal memory task played under different incentive (monetary) conditions (Pizzagalli, Sherwood, Henriques, & Davidson, 2005). Extending prior scalp frontal EEG asymmetry studies (e.g., Sutton and Davidson, 2000), we found that higher LORETA alpha2 (10.5–12 Hz) current

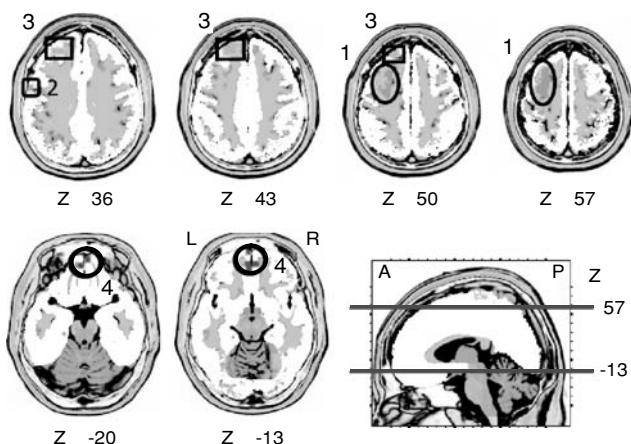

Figure 3.7. Example of LORETA findings highlighting relations between resting intracerebral EEG sources and approach-related behavior. Whole-brain analyses showing voxel-by-voxel correlations between resting alpha2 (10.5–12 Hz) current density and response bias toward reward-related cues for 18 healthy subjects. Six axial brain slices (head seen from above, nose up, L = left, R = right; A = anterior, P = posterior) are shown. Alpha2 current density within both dorsolateral prefrontal regions (clusters #1–3; see green colors) and ventromedial prefrontal regions (cluster #4; see blue colors) was negatively correlated with reward bias, indicating that higher resting activity within these regions was associated with stronger reward bias. Adapted from Pizzagalli et al. (2005). (See color plate.)

density within left dorsolateral regions (Brodmann areas 6, 8, 9, 10, 46) was associated with stronger bias to respond to reward-related cues (Figure 3.7; see clusters #1–3). Notably, left dorsolateral prefrontal resting activity accounted for 54.8% of the variance in reward bias. Whereas this finding fits the hypothesis that frontal EEG asymmetry in favor of the left hemisphere might reflect the propensity to respond with approach-related tendencies (Davidson, 2004), a second important finding emerged: alpha2 current density within ventromedial prefrontal regions (Brodmann areas 10, 11) was also associated with reward bias (Figure 3.7; see cluster #4). This latter finding, which is consistent with functional neuroimaging and animal findings implicating the ventromedial prefrontal cortex in reward monitoring and evaluation of reinforcers, could obviously not have been achieved with scalp EEG data. More generally, findings from this study highlight that source localization techniques can be used to predict complex behavior.

8.2.3.3. Current limitations and future directions of LORETA. Although the LORETA algorithm has received important cross-modal validation, it is important to highlight three factors that, in most of the studies to date, likely affected the spatial resolution of this method.¹⁰ First, the vast majority of LORETA studies have used a three-shell

¹⁰ These methodological limitations are not restricted to the LORETA algorithm but would equally apply to any distributed source localization technique.

spherical head model, which represents only a rather crude approximation of the biophysical problem. As recently demonstrated by Ding, Lai, and He (2005), a more complex head model that better represents the geometry of gray and white matter regions (e.g., FEM) can substantially improve the spatial resolution of LORETA. Second, most of the studies have used a general (average) brain template (Evans et al., 1993). Clearly, use of individual anatomical MRI scans is expected to improve the precision of the solution space. Third, although LORETA studies typically used EEG electrode coordinates derived from cross-registrations between spherical and realistic head geometry (e.g., Towle et al., 1993) and registered to a MRI template, digitization of electrode positions for individual subjects is expected to further improve the spatial resolution of LORETA.

In addition to these issues, which could be addressed in the future, some more conceptual limitations should be mentioned. First, due to the smoothness assumption used to solve the inverse problem, LORETA is incapable of resolving activity from closely spaced sources; in such cases, LORETA will find a smeared, single source located between the original two sources. In fact, in experimental situations in which the generating source is known to be well-represented by a single dipole (e.g., early sensory ERPs), dipole fitting procedures might be preferred, as LORETA will tend to blur the solution (e.g., Fuchs, Wagner, Kohler, & Wischmann, 1999; Moffitt & Grill, 2004). Moreover, despite the fact that LORETA showed the smallest overall localization error in the simulations by Fuchs et al. (1999), these authors found that LORETA tended to overestimate the depth of sources at eccentricities above 70%, likely due to the fact that the 3-D smoothness constraint is difficult to fulfill at the boundary of the solution space. Second, some authors have argued that the electrophysiological and neuroanatomical constraints used by LORETA are somewhat arbitrary. In particular, concerns have been raised about whether the assumption of maximal synchronization between neighboring neuronal populations can be appropriately extended to adjacent voxels (Kincses, Braun, Kaiser, & Elbert, 1999). Third, although sources in LORETA are appropriately constrained to gray matter, their orientation is left undetermined. Phillips et al. (2002a,b) have recently shown that EEG distributed source localization approaches can make better use of anatomical constraints. For example, in their approach, dipole orientation was fixed perpendicular to the interface between gray and white matter, as derived from high-resolution MRI. Fourth, at least in current implementations, LORETA does not accommodate other functional priors (e.g., weighting factors based on independently assessed fMRI activations), which have been recently used to limit the spatial dispersion of distributed source localization techniques (e.g., Phillips et al., 2002a; Phillips et al., 2002b; Dale et al., 2000). Success in addressing these issues is expected to further improve the LORETA localization accuracy.

8.2.4. Variable resolution electromagnetic tomography (VARETA)

Frequency-domain VARETA is a discrete, spline-distributed solution¹¹ that has been used to estimate sources of EEG frequency bands (Valdes-Sosa, Martí, García, & Casanova, 1996; Bosch-Bayard et al., 2001). Conceptually, it belongs to the family of weighted MN solutions.

As mentioned above, LORETA imposes maximal spatial smoothness; as a consequence, LORETA is able to recover smoothly distributed sources with low localization error, but focal sources are blurred. VARETA, on the other hand, utilizes different amounts of spatial smoothness for different types of generators. This is achieved by a data-driven procedure that estimates the spatial covariance matrix through the scalp cross-spectra, which ultimately selects the amount of spatial smoothness required at each voxel in the brain (Valdes-Sosa et al., 1996). Mathematically, this is done by allowing the regularization parameter to vary according to the location in the solution space. According to the developers, a further key difference between LORETA and their algorithm is that VARETA is able to estimate discrete and distributed sources with equal accuracy (Fernandez-Bouzas et al., 1999). Nonetheless, initial empirical findings seem to contain substantial degree of blurring (e.g., Fernandez et al., 2000; Bosch-Bayard et al., 2001).

In VARETA, current sources are also restricted to gray matter, as defined by a probabilistic brain atlas. Currently, a limited number of studies have used VARETA, although encouraging results have been reported for localizing EEG current density during normative mental processes (e.g., Fernandez et al., 2000) as well as in pathological conditions (e.g., Fernandez-Bouzas et al., 1999). Additional testing from independent laboratories will be important to assess the validity of this promising approach.

8.2.5. Local Auto-Regressive Average (LAURA)

In 2001, Grave de Peralta and colleagues (Grave de Peralta et al., 2001) proposed a distributed linear inverse solution that constrains the minimum norm solution based on biophysical laws. To solve the inverse problem, this technique selects the source configuration that better mirrors the biophysical behavior of electric vector fields. Mathematically, this approach uses a Local Auto-Regressive Average (LAURA) model with coefficients that depend on the distances between solution points in order to mirror the electromagnetic laws that (a) the strength of the source declines with the inverse of the squared distance of the potential field; and (b) the estimated activity at one point depends on the activity at neighboring points. As with other distributed inverse solutions, this method makes no assumptions about the number or location of active sources. Simulation studies show that LAURA is able to resolve multiple simultaneously active sources (Grave de

¹¹ Spline estimates can be understood as the spatially smoothest solutions accounting for the observed data.

Peralta et al., 2001), and promising applications have recently appeared (e.g., Murray et al., 2004).

8.2.6. Bayesian solutions

In recent years, Bayesian approaches have attracted increased attention because they allow incorporation of a priori information into source estimation by means of probability distributions (Phillips et al., 2002a; Phillips et al., 2002b; Trujillo-Barreto et al., 2004). For example, Phillips et al. (2002a,b) described an EEG source localization approach based on the weighted MN solution that incorporates physiological and anatomical constraints derived from other imaging modalities. Their approach rests on three anatomical/physiological assumptions, which are used to reduce the solution space a priori. They assume that sources are: (1) located in gray matter; (2) oriented perpendicularly to the cortical mantle; and (3) locally coherent (i.e., their activity changes smoothly along the cortical mantle). The first assumption can be implemented by constraining the solution space to gray matter, as determined by each subject's structural MRI (e.g., Phillips et al., 2002a). This step can be achieved by segmenting an MRI image into gray matter, white matter, and cerebrospinal fluid and creating a mask containing a gray matter coefficient value ranging from 0 (null probability that a given voxel is in gray matter) to 1 (100% probability). Anatomical information gathered in this first step can also be used to constrain the orientation of a local dipole to fulfill the requirements of the second assumption. Although a description of the mathematical corollaries of these assumptions is beyond the scope of this chapter, it is clear that by determining a priori the orientation of dipoles based on well-grounded anatomical and physiological bases, the inverse problem is reduced from a vectorial problem (orientation and strength are unknown) to a scalar problem (only strength is unknown). The third assumption of locally coherent and synchronized electrical activity can be met by imposing spatial smoothness (Pascual-Marqui et al., 1994), which is mathematically implemented by minimizing differences among neighboring voxels.

In addition to these assumptions, which are essentially identical to the ones implemented by LORETA, Phillips et al. (2002b)'s method allows the use of basis functions to further reduce the solution space in the temporal and spatial domains; in the spatial domain, weighting factors can be introduced a priori based on independent information derived from fMRI, for example. Simulations showed that (1) in the absence of noise and localization priors, the best localization was achieved with a relatively large smoothness constraint; and (2) location priors greatly improved the localization accuracy, even in the presence of noise and with reduced smoothing.

In a recent extension of the Bayesian approach, Trujillo-Barreto et al. (2004) proposed a technique that calculates a "final" solution through averaging of various models, each with different anatomical constraints, which are weighted

based on their probability of contributing to the generation of EEG signals. In initial evaluations with simulated and real EEG data, this approach has shown promising findings (Trujillo-Barreto et al., 2004).

8.2.7. Simulation studies comparing different distributed inverse solutions

As evident from the previous section, the past decade has witnessed substantial progress in developing distributed source localization techniques that do not assume a priori the number and location of underlying sources. Although these approaches have similarities and an identical goal (i.e., to solve the underdetermined and ill-posed inverse problem), they often differ in the nature and extent of the anatomical, physiological, and/or statistical assumptions they implement. Ultimately, no matter how sophisticated their mathematical and biophysical implementations are, the validity and reliability of *any* of these methods should be exclusively evaluated by their ability to provide physiologically meaningful solutions, in particular in relations to other neuroimaging techniques (e.g., fMRI, PET; but see Section 9 for a discussion of challenges relating electro-physiological and hemodynamic measures).

For most of these techniques, however, their reliability and validity have been evaluated by means of artificial data. In these simulation studies, four basic steps are used (Michel et al., 2004): (1) dipole(s) is/are placed at each grid of the solution space; (2) the forward solution is computed to determine the associated scalp potential distribution; (3) sources underlying the scalp potential distribution are estimated using various source localization techniques; and (4) a localization error is computed by comparing the initial and estimated source location. Over the years, several simulations have been published, and a brief summary is reported in the following section.

Pascual-Marqui (1999) compared LORETA, MN, weighted MN, and other linear, distributed inverse solutions. He reported that only LORETA was capable of correct localization with, on average, localization error of 1 voxel resolution, whereas the other methods showed large localization errors, in particular with deep sources. Although LORETA showed the best 3-D localization accuracy, it is important to stress that LORETA tended to underestimate deep sources and that correct localization was achieved with some degree of blurring. Higher localization accuracy for LORETA compared to standard MN solutions has also been reported by Fuchs et al. (1999) and Babiloni et al. (2004a). Fuchs et al.'s (1999) simulations showed, however, that the MN tended to emphasize superficial sources, whereas LORETA tended to suppress them, yielding instead overly deep, blurred solutions for the same sources. In a later simulation, Pascual-Marqui et al. (2002) compared the localization error and spatial dispersion (i.e., resolution) of sLORETA, MN (Hamalainen & Ilmoniemi, 1994), and a new tomographic method described by Dale et al. (2000). Findings showed that sLORETA had smaller localization error and

higher spatial resolution, irrespective of the presence or absence of noise and source orientation. Indeed, sLORETA was the only algorithm achieving zero-error localization. Moreover, the spatial blurring of sLORETA was smaller than the one achieved by the method employed by Dale et al. (2000). Recently, Yao and Dewald (2005) compared the performance of moving dipoles, MN solution, and LORETA using simulated EEG data and real ERP data. Compared to the other methods, LORETA had the smallest localization error, as well as the smallest percentage of undetected sources and falsely-detected sources in simulated EEG data. Not unexpectedly, LORETA (as well as the other methods) was unable to separate two discrete sources spaced only by 5 mm. Whereas these simulation studies used the three-spherical head model to solve the inverse solution, Ding et al. (2005) recently evaluated the localization accuracy of LORETA using a realistic geometry head model (BEM). As expected, the LORETA localization error was lower when using the BEM compared to the spherical head model (approximately 10 mm vs. 20–30 mm).

Other simulations, however, have challenged the localization accuracy of LORETA. Gráve de Peralta et al. (2001), for example, compared MN, weighted MN, LORETA, and LAURA, and found the best localization accuracy for LAURA, followed by LORETA and the weighted MN solution, which showed similar performances. Similarly, Trujillo-Barreto et al. (2004) compared LORETA with an extension of the Bayesian model incorporating probabilistic maps derived from segmentation of standard brain template within 71 separate brain regions, and found that the latter method gave higher localization accuracy and less spatial distortion (i.e., higher spatial resolution), particularly when subcortical regions were implicated. Better localization accuracy of a Bayesian model incorporating structural and physiological priors compared to LORETA was also reported by Phillips et al. (2002a,b). Indeed, in their simulations, Phillips et al. (2002a,b) showed that the inclusion of a priori location information improved the performance of the distributed minimum norm approach, whereas LORETA tended to over-smooth the solution. In the absence of prior information about location, Phillips's method and LORETA achieved similar localization capabilities.

As correctly pointed out by Michel et al. (2004), these simulation studies are intrinsically limited by the fact that the dipole localization error used to evaluate the “goodness” of any distributed inverse solution is the “most unnatural test for them.” In fact, as mentioned above, distributed source localization techniques have been developed to resolve multiple and spatially distributed sources, and thus these simulations cannot predict “how a distributed inverse solution deals with the reciprocal influences of simultaneously active sources (Michel et al., 2004; p. 2205).” Accordingly, real EEG data collected during functionally and anatomically well-characterized experimental tasks (e.g., finger tapping, checkerboard stimula-

tion, N-back working memory task) may provide a better test of various source localization algorithms. Additionally, physiological validation through other neuroimaging techniques would provide converging evidence. As reviewed in Section 4.3.1., encouraging cross-modal validity has started to emerge for the LORETA algorithm, particularly in studies comparing LORETA with functional fMRI (Mulert et al., 2004; Vitacco et al., 2002), structural MRI (Worrell et al., 2000), PET (Pizzagalli et al., 2004), and intracranial recordings (Seeck et al., 1998). Similar cross-modal validity will be necessary for evaluating the localization accuracy of other distributed source localization techniques.

8.2.8. The issue of multiple testing

As with hemodynamic neuroimaging studies, which typically involve statistical comparisons at thousands or tens of thousands of locations in the brain, distributed EEG source localization techniques also face the issue of how best to determine a statistical threshold that will protect against Type I errors due to multiple comparisons. In our own work with LORETA (e.g., Pizzagalli et al., 2001), we have implemented a randomization procedure based on the t_{\max} approach to estimate the false-positive rate under the Null Hypothesis of no voxel-wise differences between two given groups or conditions. This approach, which was inspired by statistical solutions developed for neuroimaging data (Arndt et al., 1996; Holmes et al., 1996), relies on permutation procedures. When comparing an experimental and a control group, for example, two randomly selected groups each containing half of the subjects under investigation can be tested at each of the 2394 voxels. At every iteration, the largest absolute t value (from a two-tailed test) can then be stored in a histogram. After 5000 iterations, the t value cutting off the most extreme 5% of the distribution can be identified and used to threshold the data, i.e., to accept or reject the Null Hypothesis.

8.2.9. Summary

The main goal of any EEG source imaging technique is to draw reliable conclusions about sources underlying scalp-recorded signals, that is, to solve the inverse problem. Importantly, the choice of the inverse method also depends on the experimental situation. Dipole fitting methods can provide accurate localization in situations of highly focal activations, for example during somatosensory stimulation or epileptic discharges (Michel et al., 2004; Fuchs et al., 2004). In more complex cognitive or pathological conditions that likely recruit widespread neuronal networks, distributed imaging techniques are expected to perform better.

As appropriately emphasized by Michel et al. (2004), it should be beyond the scope of any review to declare a specific source localization algorithm as “the best”. Two main reasons justify this position. First, as discussed above, simulation studies based on focal sources may not be

the most appropriate test of the localization accuracy of distributed source localization techniques, which may perform substantially better when real EEG data generated by widely distributed neuronal networks are considered. Second, inconsistencies and even contradictions between simulation studies stemming from different laboratories raise some concerns about (1) the mathematical implementations of “competing” localization algorithm (e.g., Pascual-Marqui et al., 2002 for a discussion of this important point); and (2) the selection of test sources that might favor a given algorithm over the others. Clearly, in order to progress in this important field, independent validation studies devoid of experimenter bias or preferences are needed.

9. DIFFICULTIES INTEGRATING ELECTROMAGNETIC AND HEMODYNAMIC VARIABLES

Approaches integrating EEG and PET/fMRI are based on the assumption that brain regions that are electrically more active over time will also show increases in metabolic or hemodynamic activities. Although this assumption is plausible (Logothetis, Pauls, Augath, Trinath, & Oeltermann, 2001), several factors contribute to a difficult comparison between electrophysiological and hemodynamic techniques, making a complete integration conceptually challenging (Nunez & Silberstein, 2000). First, due to the fundamentally different physiological basis of electromagnetic and hemodynamic measures, situations can arise in which the activation period of neurons is too brief to produce a detectable hemodynamic change, whereas it could be easily detected by EEG. Second, scalp EEG signals are highly dependent on synchronization/desynchronization mechanisms, and their relation to glucose or oxygen utilization is unclear (Nunez & Silberstein, 2000). For example, increased neuronal firing and reduced synchrony would produce a small scalp EEG (e.g., alpha blockade after eye opening), a process that would require, however, substantial metabolic supply. Similarly, based on the observation that both excitatory and inhibitory processes require glucose utilization (Ackermann, Finch, Babb, & Engel, 1984), loss of inhibitory synaptic action in pathological conditions (e.g., interictal periods in epileptic patients) would produce large EEG signals but decreased PET metabolic signal. Third, whereas hemodynamic measures are not affected by the spatial arrangement of the activated neurons, scalp EEG cannot detect activity from neuronal assemblies arranged in closed electrical fields (Nunez & Silberstein, 2000). This may explain why in the EEG literature it has been generally very difficult to reliably measure sources originating from the hippocampus, which represents a closed field due to its structural features. Along similar lines, spatial configurations of sources involving opposing dipoles located in sulci would generate activity that cannot be detected by scalp EEG, as the opposing dipoles would cancel each other (see dipolar sources A and B in Figure 3.6).

Consistent with these fundamental limitations, empirical evidence indicates that integration of electromagnetic and hemodynamic measures works extremely well in situations in which the fMRI and EEG/MEG activations correspond (Dale et al., 2000). However, in cases of imperfect or lacking correspondence between the fMRI and MEG/EEG activations, erroneous findings are likely to emerge (Baillet et al., 2001).

10. CONCLUSIONS

The past 20 years have witnessed unprecedented progress in our ability to study human brain function noninvasively. The high temporal resolution of electromagnetic measurements (EEG/MEG) continues to offer a unique window into the dynamics of brain function. In particular, EEG/MEG measures are exquisitely sensitive to spontaneous and induced changes of the functional brain state allowing investigation of brain mechanisms associated with covert internal states, which may not necessarily be accessible to introspection or behavioral observation.

The field of EEG research has perhaps witnessed its largest advances in the critical area of source imaging. A variety of innovative and sophisticated solutions for estimating intracerebral sources are continuing to emerge. In particular, approaches that make no a priori assumptions about the number of underlying sources and incorporate physiologically and anatomically sound priors to mathematically constrain the inverse solution have shown promising results. These improvements have opened exciting new avenues for functional brain imaging with both high temporal and spatial resolution. This is especially relevant for the wide range of experimental situations in which distributed neural networks are implicated.

In conclusion, advances in spatial sampling through high-density recordings, development of more realistic head models through high-resolution MRI, substantial progress in source localization techniques, and integration of different functional neuroimaging techniques have all contributed to improving our ability to investigate spatiotemporal dynamics of brain mechanisms underlying normal and pathological mental processes and states. In fact, the picture emerging from these methodological and conceptual improvements is that the spatial resolution of the EEG may approach that of other neuroimaging approaches, particularly when spatially smoothed fMRI or PET data are considered (e.g., Michel et al., 2004; Babiloni et al., 2004b). In the years to come, critical contributions to our understanding of the human mind can be expected from the EEG field.

ACKNOWLEDGMENTS

Preparation of this chapter was supported by NIMH Research Grant R01MH68376. The author is grateful to Richard Davidson, Alex Shackman, Lawrence Greischar,

Kyle Ratner, and John Potts for their comments on an earlier draft, and to James O'Shea for creating Figures 3.4 and 3.5.

Event-Related Brain Potentials: Methods, Theory, and Applications

MONICA FABIANI, GABRIELE GRATTON, AND KARA D. FEDERMEIER

1. INTRODUCTION AND HISTORICAL CONTEXT

Ever since Berger (1929) demonstrated that it is possible to record the electrical activity of the brain by placing electrodes on the surface of the scalp, there has been considerable interest in the relationship between these recordings of neurophysiological activity and psychological processes. Although Berger and his followers focused their attention on spontaneous rhythmic oscillations in voltage (i.e., on the electroencephalogram or EEG) more recent research has concentrated on those aspects of the electrical potential that are specifically time-locked to events (i.e., on event-related brain potentials or ERPs). ERPs reflect brain activity from synchronously active populations of neurons that occurs in preparation for or in response to discrete events, be they internal or external to the subject. Conceptually, ERPs are regarded as neural manifestations of specific psychological functions.

The history of ERP research is closely linked with the development of technologies that allow for the extraction of event-related brain activity from the background EEG oscillations, which are usually much larger in amplitude and therefore tend to obscure it (for an extended review see Donchin, 1979). The first of these techniques was based on the photographic superimposition of several time-locked EEG traces (Dawson, 1947; Ciganek, 1964). This method, however, was very cumbersome, and it was soon replaced by the development of several analog signal averagers (see Donchin, 1979). However, it was not until the 1960s and the advent of digital computers (and, thus, of digital signal averaging) that ERP research really took flight.

The last several decades have seen a number of paradigmatic shifts in the focus of this research. In the 1970s and early 1980s, the analysis and interpretation of ERPs was informed by the computer analogy of the human information processing system: ERP components (i.e., peaks and troughs in the waveforms that tend to covary in response to experimental manipulations) could be viewed as subroutines within this system, each indexing some aspect of cognitive processing (Donchin, 1979; 1981). Within this framework, the focus was mostly on the relationship

between specific cognitive processes and ERP activity, without much reference to the possible underlying brain sources of the potentials. Beginning in the 1990s, however, the rapid expansion of non-invasive brain imaging methods (e.g., Toga & Mazziotta, 1996) and recent technological advances that allow for the simultaneous recordings from dense electrode arrays (e.g., Tucker, 1993) have brought forth two further changes (which will be discussed more extensively in Section 2.4): (a) several algorithms have been developed to derive the putative brain sources of scalp-recorded electrical activity; and, (b) several attempts have been made at integrating the recording of ERPs with other brain imaging methods, such as Positron Emission Tomography (PET), functional Magnetic Resonance Imaging (fMRI), magneto-encephalography (MEG) and optical imaging (event-related optical signal, or EROS, and near-infrared spectroscopy, or NIRS). At present, ERPs are one of the most established methods in cognitive neuroscience – and one of the few that provide a direct measure of neural activity – and are considered the “gold standard” for temporal resolution¹ among noninvasive imaging methods.

In Section 2 of this chapter, we will review: (a) the procedures for ERP derivation; (b) what is known about the underlying sources of ERPs and their relationship to physiological function; and (c) the concept of a component and some aspects of component quantification. Later in this chapter, we will focus on the relationship between ERPs and psychological function.

2. THE PHYSICAL CONTEXT

2.1. Deriving event-related potentials

The procedures used to derive ERPs begin with the same amplifiers and filters used to obtain EEG (see Figure 4.1). Electrodes are attached to the scalp at various locations

¹ Temporal resolution can be defined as the ability to determine the order of occurrence of two events that are close to each other in time.

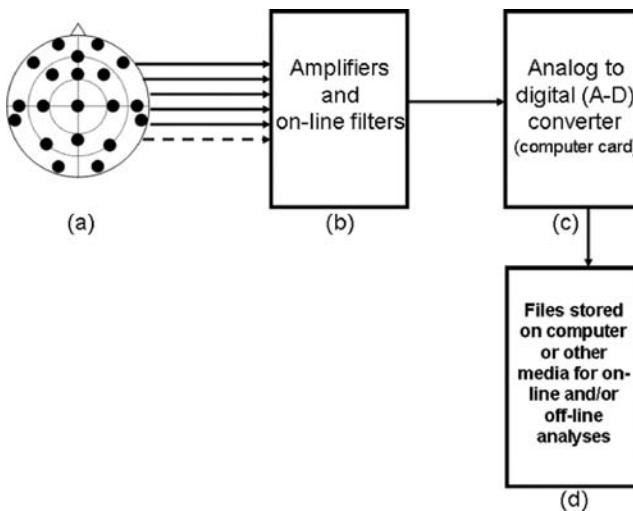

Figure 4.1. Schematic representation of the operations involved in the recording of ERPs. From left to right: (a) Top view of the head, indicating the placements of several electrodes from which EEG is recorded; (b) the EEG signal is then transferred to an amplifying and on-line filtering system; (c) the analog signal is then converted into a digital signal by sampling the potential at a high frequency (usually at least 100 Hz) by an Analog-to-Digital converter (usually a dedicated computer card); (d) the digitally transformed signal is stored on a computer or other media for on-line or off-line analyses, which often include artifact removal and averaging as well a number of other steps.

(at least two leads are needed for measuring a voltage difference) and connected to amplifiers. The recording locations are most often chosen according to the International 10–20 system (Jasper, 1958) or expanded versions of this system (e.g., Nuwer, 1987), to facilitate between-laboratory and between-experiment comparisons. However, given the ever-growing availability of computing power, more and more labs are also using custom-designed dense arrays, often geodesic, to allow for better interpolation and ultimately better characterization of the scalp distributions of the potentials and source modeling. The outputs of the amplifiers are converted to numbers by a device for measuring electrical potentials, an analog-digital converter. The potentials are sampled at a frequency ranging from 100 to 10,000 Hz (cycles per second), depending on the temporal properties of the brain activities of interest, and are then stored in files for subsequent analysis.

The ERP is small (a few microvolts) in comparison to the EEG (about 50 microvolts). Thus, analysis generally begins with procedures to increase the discrimination of the *signal* (the ERP) from the *noise* (background EEG). The most common of these procedures involves *averaging* samples of the EEG that are time-locked to repeated occurrences of a particular event or type of event. The number of samples used in the average is related to the signal-to-noise ratio (see Section 2.6.2). However, in all cases, the samples are selected so that they bear a consistent temporal relationship to the event. Because aspects of the EEG that are not time-locked to the event are assumed to vary randomly from sample to sample, the averaging procedure should

result in a reduction of these noise potentials, rendering the signal, event-related potentials visible.² The resulting voltage × time function (see Figure 4.2) contains a number of positive and negative peaks that can then be subjected to a variety of measurement operations (see Section 2.6 and chapters by Jennings et al. and Gratton, *this volume*).

Because ERPs are always measured as differences in potential between two recording locations, they will also vary as a function of the electrode site at which they are recorded, as well as the reference electrode used. Spatial (topographic) distribution is regarded as an important discriminative characteristic of the ERP (Donchin, 1978; Sutton & Ruchkin, 1984). Therefore, positive and negative peaks in the ERP are generally described in terms of their characteristic scalp distribution, as well as their polarity, and latency.

The labels given to the peaks of an ERP waveform often include descriptors of polarity and latency. According to this logic, P300 refers to a positive deflection with a modal peak latency of 300 ms. A similar labeling system involves a descriptor of polarity (P or N) followed by a number designating the ordinal latency of the component. Within this system, P3 refers to the third positive peak in the waveform. Other descriptors that can be used in labeling peaks make reference to the scalp locations at which the potential is maximal (e.g., frontal P300), or to the psychological or experimental conditions that control the potential (e.g., novelty P3, readiness potential or RP, mismatch negativity, or MMN).

2.2. The exogenous versus endogenous distinction

From a psychological point of view, it has often been convenient to distinguish between different types of ERPs. Traditionally, investigators have identified those ERPs whose characteristics are largely controlled by the physical properties of an external eliciting event. Such evoked potentials are considered to be obligatory (in the sense that if the eliciting stimulus is perceived they will be always be elicited) and are referred to as “sensory” or “exogenous.” Examples of these evoked activities are the brainstem potentials. The counterparts of these exogenous activities are ERPs whose characteristics are largely determined by the nature of the interaction between the person and the event. For example, some ERPs vary as a function of the information processing activities required of the subject; others can be elicited in the *absence* of an external eliciting event. These potentials are referred to as “endogenous.” Examples of exogenous activities are the P300 and the error-related negativity (ERN; for a discussion of the distinction between exogenous and endogenous potentials, see Donchin, Ritter, and McCallum, 1978).

² Note that this assumption may not always be valid, as, for example, in the case of variability in the latency and other characteristics of the ERP from sample to sample (see Section 2.6.2). Furthermore, the ERP derived by averaging may include potentials that do not originate in the brain but are time-locked to the event (see Section 2.6.1).

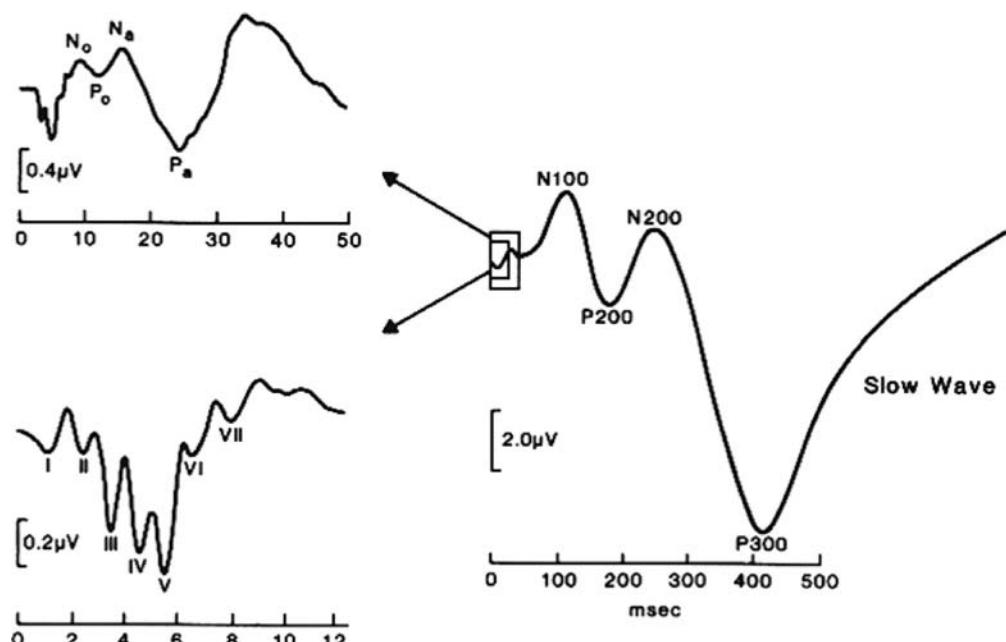

Figure 4.2. A schematic representation of ERP components elicited by auditory, infrequent target stimuli. The three panels represent three different voltage \times time functions: the left bottom panel shows the very early sensory components (with a latency of less than 10 ms); the left top panel shows the middle latency sensory components (with a latency between 10 and 50 ms); and the right panel shows late components (latency exceeding 50 ms). Note the different voltage and time scales used in the three panels, as well as the different nomenclatures used to label the peaks (components). (Adapted with permission of the author from Donchin, 1979, with kind permission of Springer Science and Business media.)

Although the exogenous/endogenous distinction provides a useful method for classifying many ERP components, there are potentials that possess characteristics that are intermediate between these two groups, and are therefore called “mesogenous.” The N100 (see Section 4.3.1) is such an example, as it is sensitive to both the physical properties of the stimulus and the nature of the interaction between the subject and the event (e.g., whether the event is to be attended).

2.3. From the brain to the scalp: the generation and physiological basis of ERPs

In this section, we review evidence that relates the scalp-recorded electrical activity to its underlying anatomical and physiological basis (see also Allison, Wood, & McCarthy, 1986; Nunez, 1981). It is generally assumed that ERPs are distant manifestations of the activity of populations of neurons within the brain. This activity can be recorded on the surface of the scalp because the tissue that lies between the source and the scalp acts as a volume-conductor. Because the electrical activity associated with any particular neuron is small, at the scalp it is only possible to record the integrated activity of a large number of neurons. Two requirements must be met for this integration to occur: (a) the neurons must be active synchronously, and (b) the electric fields generated by each particular neuron must be oriented in such a way that their

effects at the scalp cumulate. As a consequence, only a subset of the entire brain electrical activity can be recorded from scalp electrodes.

Two considerations further restrict the likely sources of the scalp-recorded ERP. First, because the ERP represents the synchronous activity of a large number of neurons, it is probably not due to the summation of pre-synaptic potentials (action potentials or spikes), because these potentials have a very high frequency and short duration. In contrast, post-synaptic potentials, having a relatively slower time course, are more likely to be synchronous, and therefore to summate to produce scalp potentials. Thus, it is commonly believed that most scalp-recorded ERPs are the outcomes of summation of post-synaptic potentials of a large number of neurons that are activated (or inhibited) synchronously (see Allison et al., 1986).

A second consideration concerns the orientation of neuronal fields. Because the electric fields associated with the activity of each individual neuron involved must be oriented in such a way as to cumulate at the scalp, only neural structures with a specific spatial organization may generate scalp ERPs. Lorente de Nò (1947) specified the spatial organizations that are required for the distant recording of the electrical activity of a neural structure. He distinguished between two types of configurations: “open fields” and “closed fields.” A structure having an open-field organization is characterized by neurons that are ordered so that their dendritic trees are all oriented on one side of the

structure, whereas their axons all depart from the other side. In this case, the electric fields generated by the activity of each neuron will all be oriented in the same direction and summate. Only structures with some degree of open-field organization generate potentials that can be recorded at the scalp. Open fields are obtained whenever neurons are organized in layers, as in most of the cortex, parts of the thalamus, the cerebellum, and other structures.

A structure with a closed-field organization is characterized by neurons that are concentrically or randomly organized. In both cases, the electric fields generated by each neuron will be oriented in very different, sometimes opposite, directions, and therefore will cancel each other out. Examples of closed-field organization are given by some midbrain nuclei.

From this analysis it is clear that ERPs represent just a sample of the brain electrical activity associated with a given event. Thus, it is entirely possible that a sizeable portion of the information processing transactions that occur after (or before) the anchor event is "silent" as far as ERPs are concerned. For this reason, some caution should be used in the interpretation of ERP data. For instance, if an experimental manipulation has no effect on the ERP, we cannot conclude that it does not influence brain processes. By the same token, if two experimental manipulations have the same effect on the ERP, it cannot be concluded that they necessarily influence completely identical processes.

2.4. From the scalp to the brain: inferring the sources of ERPs

So far we have examined how particular properties of neuronal phenomena may determine whether they will be recorded at the scalp. We have approached the problem of ERP generation in the "forward" direction – from properties of the generators to predictable scalp observations. In most cases, however, we have only limited information about the neural structure(s) responsible for a specific aspect of the ERP. The typical ERP database consists of observations of voltage differences between scalp electrodes or between scalp electrodes and a reference electrode. To determine which neural structures are responsible for the scalp potentials (i.e., to identify the neural generators of ERPs) we must solve the "inverse problem" – that is, we have to infer the *unique* combination of neural generators whose activity results in the potential observed at the scalp.

In solving this problem, we are confronted with an indefinite number of unknown parameters. In fact, an indefinite number of neural generators may be active simultaneously, and each of them may vary in amplitude, orientation of the electric field, and location inside the head. Because a limited number of observations (the voltage values recorded at different scalp electrodes) is used to estimate an indefinite number of parameters, it is clear that the inverse problem does not have a unique solution (i.e., an infinite number

of different combinations of neuronal generators may produce the same scalp distribution). A further complication is that the head is not a homogeneous medium. Therefore the propagation of an electric field generated by the activity of a given structure is difficult to compute. A particularly important distortion of the electric fields is caused by the skull – a very low conductance medium that reduces and smears electric fields. For all these reasons, we cannot unequivocally determine which structures are responsible for the ERP observed at any point in time, when the only information available is given by the potentials recorded at scalp electrodes.

Notwithstanding these problems, investigators have tried to identify the neural sources of scalp-recorded ERPs using a variety of approaches, involving both noninvasive and invasive techniques. Noninvasive techniques include: (a) scalp recordings from dense electrode arrays combined with interpolated mapping and source analysis algorithms (which involve complex mathematical procedures and are based on a number of assumptions); and (b) combining ERP recordings with other imaging methods that possess higher spatial resolution (e.g., PET, fMRI, MEG, EROS), to help restrict the number of solutions to the inverse problem. Invasive techniques include: (a) recordings from indwelling macro-electrodes (in humans or animals); and (b) lesion data (also in humans or animals).

2.4.1. Dense electrode arrays and source modeling

During the last several years, a number of companies have marketed data acquisition systems for electrophysiology designed to record from a large array of channels (up to 256; e.g., Tucker, 1993). These systems allow investigators to derive detailed maps of brain electrical activity, which can, in principle, reveal differences that are of interest for the study of various experimental conditions and/or subject populations, and may not be visible with sparser electrode montages. Because the skull operates as a low-pass spatial filter, however, one important question concerns the effective optimal spatial sampling for ERP recording. For instance, Srinivasan, Nunez, Tucker, Silberstein, and Cadusch (1996; see also Tucker, 1993) have shown that 256 locations may accurately reproduce the most significant local variations in scalp electrical activity.

The increase in the number of recording locations has facilitated the study of the distribution of ERP activity across the scalp, and, in particular, the construction of accurate maps of surface activity, which are usually based on interpolation procedures (e.g., Perrin, Pernier, Bertrand, Giard, & Echallier, 1987). Another advantage of dense-array recording is the possibility of generating models of the 3-D locations of the brain generators involved in producing the surface ERP activity (i.e., equivalent dipole analysis). Computational approaches to dipole analysis involve generating several alternative hypotheses about the neural structures that may be active at a particular point in time, and that may be responsible for an observed scalp ERP. The distribution of potentials across the scalp that

would be generated by each of these structures can then be computed using a forward approach. Finally, the structure whose activity best accounts for the observed scalp distribution can be identified (e.g., Scherg & Von Cramon, 1986; Scherg, Vajsar, & Picton, 1989; see also Gratton, *this volume*).

The use of large electrode arrays, however, introduces two disadvantages: (a) the probability of channels showing artifacts increases, and (b) the presence of a larger number of channels may reduce the power of the analysis, unless data reduction methods such as Principal Component Analysis, PCA, or Independent Component Analysis, ICA, are used. These issues are discussed more in detail in Gratton (*this volume*). Thus, the selection of the number of electrode locations to use in a particular study requires an analysis of the related costs and benefits, which may vary from one experiment to another.

2.4.2. Combining ERPs and other imaging methods to infer the sources of ERP activity

The computational approaches highlighted in the *previous section* make a number of assumptions that cannot always be verified, and require the availability of specific neurophysiological knowledge about candidate underlying structures. In some cases, this knowledge can be based on data obtained with other imaging methods, such as the use of magnetic field recordings (MEG). Magnetic fields generated by brain activity are extremely small in relation to magnetic fields generated by environmental and other bodily sources. Therefore, their measurement is both difficult and expensive. The advantage of measuring magnetic fields is that they are practically insensitive to variations of the conductive media (such as those due to the presence of the skull). It is therefore easier to compute the source of a particular magnetic field than it is to compute the source of the corresponding electric field. An in-depth discussion of the characteristics and problems of MEG is beyond the scope of this chapter and can be found elsewhere (Beatty, Barth, Richer, & Johnson, 1986; Hari, Levanen, & Raij, 2000). We will only note here that using MEG to determine the source of neural components still requires assumptions about the number of neural structures active at a particular moment in time.

In other cases, knowledge about candidate ERP sources can be based on the integration of data from a variety of different imaging methods applied to the same subjects in the same experimental conditions. In this way, one can exploit the differential spatial and temporal resolutions of the different methods (see also Gratton, *this volume*). For example, several investigators have used data obtained in fMRI studies to “seed” the source modeling of ERP data obtained in the same subjects and paradigm (e.g., Bledowski et al., 2004; Opitz, Mecklinger, Von Cramon, & Kruggel, 1999).

2.4.3. Invasive methods for ERP source localization

Invasive techniques can also be used to identify the sources of ERP components. One such technique involves implant-

ing electrodes within the brain of humans or animals. Research on humans has been made possible by the need for recording EEG activity in deep regions of the brain for medical diagnostic purposes (Halgren et al., 1980; Wood et al., 1984; Puce, Allison, & McCarthy, 1999). However, even recording from indwelling electrodes is not completely free from volume conduction issues, which need to be addressed using recordings from very closely spaced electrodes. A clue to the local origin of potentials is given by the presence of polarity inversions at such closely spaced recording locations.

A further problem with human research using indwelling electrodes is that the electrodes are located according to clinical, rather than scientific, criteria, and therefore may fail to map the regions involved in the generation of scalp ERPs. This issue may be partially addressed by research on animals (e.g., Buchwald & Squires, 1983; Csepe, Karmos, & Molnar, 1987; Starr & Farley, 1983; Javitt, Schroeder, Steinschneider, Arezzo, & Vaughan, 1992). However, a problem with animal research is that it is sometimes difficult to determine whether the ERP observed in animals corresponds to that observed in humans, because of fundamental differences in the anatomy and physiology of animal and human brains. Finally, a general problem with depth recording is that it is difficult to know the extent to which the scalp recorded ERP is due to the activity of the structures that have been identified by the indwelling electrodes. This problem can be addressed, at least in part, by lesion studies with animals and humans, showing that lesions in the structure identified as the candidate generator result in the elimination of the scalp potential. Examples of animal lesion studies have been reported by Paller, Zola-Morgan, Squire, and Hillyard (1988) and by Javitt et al. (1992) and examples of studies of lesioned human patients by Alho, Woods, Algazi, Knight, and Näätänen (1994), Knight (e.g., 1984, 1997; see also Knight, Hillyard, Woods, & Neville, 1981; Yamaguchi & Knight, 1992), and Johnson (1988; 1989; 1993).

In summary, although solving the inverse problem does present difficulties, several techniques have been developed for identifying the source of ERP components. Whereas no single method may be able to give definitive answers in all cases, the convergence of several techniques could provide useful information about the neural structures whose activity is manifested at the scalp by the ERP.

2.5. The concept of a component and its alternatives

As noted above, the ERP can be described as a *voltage by time by location* function. We assume that the various voltage fluctuations represented by this function reflect the summed activity of neuronal populations. This neurophysiological activity, in turn, is assumed to correspond to some psychological process or processes. One concept that has evolved in the area of ERP research is that of a “component,” which is commonly taken to reflect the

tendency of segments of the ERP waveforms to covary in response to specific experimental manipulations. According to this logic, the total ERP is assumed to be an aggregate of a number of ERP components. Components can be defined in three different (but not mutually exclusive) ways (Fabiani, Gratton, Karis, & Donchin, 1987; Näätänen & Picton, 1987). First, components can be defined in terms of the positive and negative peaks (maxima and minima) that are observed in the ERP waveform. Second, components can be defined as aspects of the ERP waveform that are *functionally* associated, that is, which covary across subjects, conditions, and/or locations on the scalp in response to experimental manipulations. Third, components can be defined in terms of those neural structures that generate them. These definitions may converge in some circumstances. However, as Näätänen and Picton (1987) have indicated, a peak in the ERP waveform (for example, the N1) may represent the summation of several functionally and structurally distinct components. It can also be assumed that the same brain structure may contribute to more than one component and that different brain structures may produce activity that is functionally equivalent (e.g., homologous structures in the left and right hemispheres, such as the primary sensory and motor cortices). Thus, the adoption of one or other of these definitions will have important consequences for the interpretation of the component structure of the ERP waveform. A corollary of this discussion is that different measurement procedures will be required depending on which component definition is adopted. These procedures will be reviewed in subsequent sections after a brief discussion of general measurement issues.

Recently, other approaches to the interpretation of the ERP have been developed in which the classic concept of a component is not required. For instance, investigators have used subtraction methods to isolate effects that may subsume several different components, as classically defined. These include, among others, the “repetition effect” (i.e., the differential response observed for items that have been previously seen with respect to new items, see Section 4.4.1.4) and the “attention effect” (i.e., the differential response to items that are attended with respect those that are not, see Section 4.3.1). Note that, by using this approach, the focus is shifted from an interest in describing the functional significance of the ERP component per se (see Section 3.2) to an interest in what the observed ERP can tell us about the way stimuli are processed.

2.6. Quantification of ERP components

In this section, we describe some general measurement issues pertaining the ERP, as well as procedures that have been used to quantify ERP activity. As mentioned earlier, the precise choice of measurement operations will depend, at least in part, on the way in which ERP activity is interpreted. For further information about ERP measurement

issues, see Gratton ([this volume](#)). In general, ERP measures are quite reliable and adequate to monitor individual differences. For instance, Fabiani et al. (1987) showed that estimates of P300 amplitude can give test-retest reliability of the order of 0.8, comparable to that of many psychological tests.

2.6.1. Artifacts

The potential recorded at the scalp can be influenced by sources of electrical activity that do not arise from the brain, and that therefore are considered spurious or artifactual. Examples of these sources of artifacts include the movement of eyeballs and eyelids, tension of the muscles in the head and neck, and the electrical activity generated by the heart. These artifacts can be dealt with in the following ways. First (and most important), one can set up the recording situation so that artifacts are minimized. This can be accomplished by suitable choice of recording environment, electrode locations, and experimental task. Second, one can simply discard trials that contain artifacts, or, especially in the case of high-density recordings, discard individual artifact-contaminated sites and interpolate. Unfortunately, this procedure may lead to a bias in the selection of the observations and/or subjects. Third, one can use filters (see below) to attenuate artifactual activity. This procedure is most useful when the frequency of the artifactual activity is outside the frequency range of the ERP signals of interest. For example, the frequency of electromyographic activity is higher than that of most endogenous ERP components, and can therefore be attenuated by filtering. Fourth, one can attempt to measure the extent of the artifact and then remove it from the data. This procedure has been used most frequently in the case of ocular artifacts, and a number of correction algorithms have been developed (for reviews see Brunia et al., 1989; Gratton, 1998). The use of correction procedures is particularly useful whenever the number of trials that can be collected is limited, and/or the participants have difficulty in controlling their eye movements (e.g., children or patient populations).

2.6.2. Signal-to-noise ratio

Several procedures have been advocated to increase the signal-to-noise ratio, including filtering, averaging, pattern recognition and use of wavelet analyses (see Coles, Gratton, Kramer, & Miller, 1986; Samar, Bopardikar, Rao, & Swartz, 1999; and Gratton, [this volume](#)). Filtering involves the attenuation of noise, whose frequency is different from that of the signal. For example, most endogenous components have frequencies of between 0.5 and 20 Hz. Thus, at the time of recording, or later at the time of analysis, analog or digital filters can be used to attenuate activity outside this frequency range. Great care should be taken in the selection of filters. The amplitude and latency of an ERP component (as well as the general ERP waveform) can be distorted if the bandpass of the filter excludes frequencies

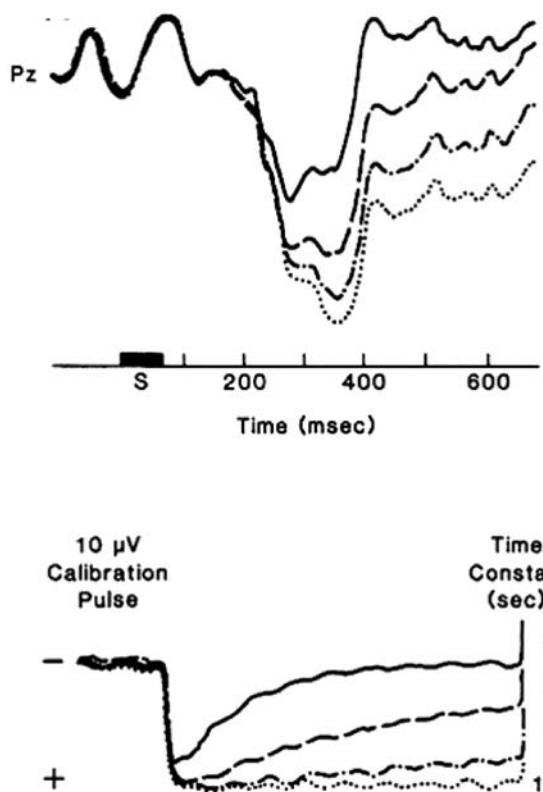

Figure 4.3. ERPs elicited by counted, rare tones (upper panel). The data recorded with four different high-pass filter settings ("time constant") are superimposed. Stimulus occurrence is indicated by an S on the time scale. Calibration pulses (lower panel) are plotted on the same voltage \times time scale as the ERPs. Note the reduction in amplitude and deformation of the ERP waveform produced by progressively shorter time constants, which reduce low frequency activity. (Copyright 1979, Blackwell Publishers. Reprinted with permission of the author and publisher, from Duncan-Johnson & Donchin, 1979.)

of interest (Duncan-Johnson & Donchin, 1979; see Figure 4.3).

Averaging involves the summation of a series of EEG epochs (or trials), each of which is time-locked to the event of interest. These EEG epochs are assumed to be the product of two sources: (a) the ERP, and (b) other voltage fluctuations that are not time-locked to the event. Because, by definition, these other fluctuations are assumed to be random with respect to the event, they should average to zero, leaving the time-locked ERP both visible and measurable. If it is the case that (a) the ERP signals are constant over trials, (b) the noise is random across trials, and (c) the ERP signals are independent of the background noise, then the signal-to-noise ratio will be increased by the square root of the number of trials included in the average.

One of the problems with the averaging procedure is that the three assumptions described in the previous paragraph may not always be satisfied in a typical experiment. In particular, if the latency of the ERP varies from trial to trial (latency jitter) the average ERP waveform will not be representative of the actual ERP of any individual trial. A related issue is that investigators may be interested in

measures of the ERP on individual trials. Thus, a major thrust in ERP methodology has been to derive procedures for single-trial analysis.

Pattern recognition techniques allow the investigator to identify segments of the EEG epoch that contain specific features (e.g., a particular peak pattern, characteristic of a given ERP component). Examples of traditional pattern recognition techniques are cross-correlation, Woody filter (Woody, 1967), and step-wise discriminant analysis (Donchin & Herning, 1975; Horst & Donchin, 1980; Squires & Donchin, 1976). Recently, a number of new pattern recognition procedures have also been applied to ERP analysis, including spatial principal component analysis (spatial PCA; Spencer, Dien, & Donchin, 1999; 2001), independent component analysis (ICA; e.g., Makeig et al., 1997), and wavelets analysis (e.g., Samar et al., 1999). For a more general discussion of pattern recognition techniques, see Glaser and Ruchkin (1976), Fabiani et al. (1987), and Gratton (*this volume*).

2.6.3. Peak measurement

As indicated above, ERP components can be defined in terms of peaks having characteristic polarities and latency ranges. Thus, a measurement operation that corresponds to this definition involves the assessment of the amplitude of the peak in microvolts, and/or the assessment of its latency in ms (see Figure 4.4). Amplitude is usually measured with reference to either the pre-event voltage level or

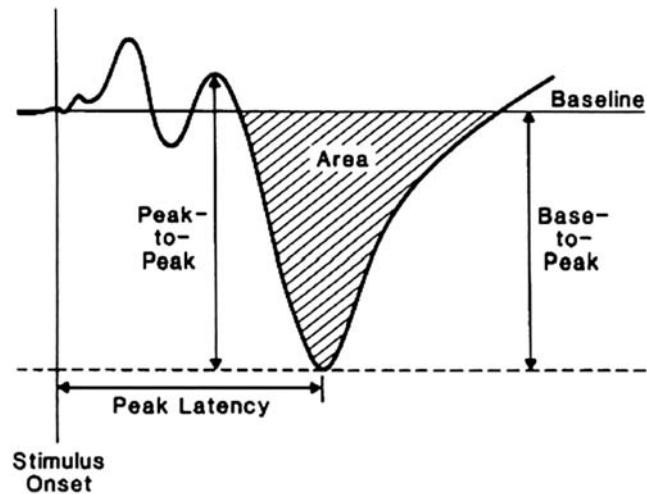

Figure 4.4. Schematic representation of an ERP waveform, indicating different procedures for component quantification. Three types of peak measures are indicated. The peak latency is obtained by measuring the interval (in ms) between the external triggering event and a positive or negative peak in the waveform. The base-to-peak amplitude measure is obtained by computing the voltage difference (in microvolts) between the voltage at the peak point and a baseline level (usually the average pre-stimulus level). The peak-to-peak amplitude measure is obtained by computing the voltage difference (in microvolts) between the voltage at the peak point and the voltage at a previous peak of opposite polarity. The area measure is obtained by integrating the voltage between two timepoints.

baseline (base-to-peak amplitude) or to some other peak in the ERP waveform (peak-to-peak amplitude). Latency is measured with reference to the onset of the event. In some cases, for example when the component under analysis does not have a definite peak, it is customary to measure the integrated activity (area measure) or the average activity (mean-amplitude measure) across a particular latency range. In these cases, the latency of onset or maximum of the effect may also be obtained.

2.6.4. Covariation measures

Components can also be defined in terms of segments of the ERP waveform that covary across subjects, conditions, and scalp locations in response to experimental manipulations. As a consequence, procedures are needed to identify and measure these segments. These procedures often entail measuring the extent to which a particular pattern of variation is represented in a waveform. This can be determined by measuring the covariation (or, sometimes, the correlation) of the waveform (or a segment of it) with an idealized wave, representing the component of interest. The “ideal” wave can be identified using statistical methods, such as PCA (Donchin & Heffley, 1978), discriminant analysis (Donchin & Herning, 1975), ICA (e.g., Makeig et al., 1997), and wavelets analysis (e.g., Samar et al., 1999). Alternatively, the ideal wave can be selected using arbitrary models, such as a sinusoidal function (e.g., Fabiani et al., 1987; Gratton, Kramer, Coles, & Donchin, 1989). Although these types of analyses may be advantageous in the presence of noise, or when there is substantial component overlap, Fabiani et al. (1987) and Gratton et al. (1989) showed that component recognition using peak procedures may actually be both reliable and valid, provided that data are adequately filtered. Note that similar cross-correlation procedures are used in the analysis of event-related fMRI data (e.g., Dale & Buckner, 1997).

2.6.5. Source activity measures

A third way of defining components is in terms of their underlying sources. According to this definition, we should quantify the activity of these sources to provide latency and amplitude measures of the different components. As we noted earlier (Section 2.4), the relationship between scalp-recorded electrical activity and source activity is difficult to describe and requires a number of assumptions. Recently, important strides have been made in this area, with the development of algorithms for dipole (e.g., BESA, Scherg & Von Cramon, 1986; Scherg et al., 1989) and distributed (e.g., EMSE, Greenblatt, et al., 1997; LORETA, Baillet, & Garnero, 1997; Pascual-Marqui, Michel, & Lehmann, 1994; and minimum norm, Liu, Dale, & Belliveau, 2002) source analyses.

Both of these approaches are based on modeling efforts. Spatio-temporal dipole models fit a small number of individual point-dipoles to data varying over space and time. The location and orientation of the dipoles may be fixed, whereas amplitude and polarity are left free to vary over

time. In this way it is possible to represent variations in surface activity in terms of variations of the activity of a few underlying brain structures.

In contrast to dipole models, distributed source models assume that extended segments of the cortex (or even the entire cortex) can be active simultaneously. To express local variations (and, therefore, explain variations in surface distribution) these algorithms allow the relative contribution of individual areas of the cortex to vary over time. These models, although perhaps more realistic, are usually largely under-determined from a statistical point of view (i.e., they include more free parameters than data points). Therefore, external criteria are necessary to constrain the number of possible solutions (e.g., minimum norm, correlation between adjacent data points).

Note that both dipole and distributed modeling efforts can be guided and constrained by anatomical and functional data obtained with other methods, such as MRI, fMRI, and PET (e.g., Bledowski et al., 2004; Opitz, Mecklinger, Von Cramon, & Kruggel, 1999; Liu, Dale, & Belliveau, 2002). These approaches can provide very useful results. However, some caveats should be taken into account when mapping brain signals with very different neurophysiological underpinnings onto each other. In fact, dissociations between hemodynamic and neuronal signals have been observed and may speak to the different nature of the signals (Logothetis et al., 2001; Huettel et al., 2004).

2.6.6. Problems in component measurement

In this section we discuss two specific problems that arise during component measurement. The first problem concerns the commensurability of the measurements of different waveforms. Is a particular component, recorded under a particular set of circumstances, the same as that recorded in another situation? This is especially a problem when we define components as a peak observed at a given latency. For example, if the latency of the peak differs between two experimental conditions, we might be led to conclude that different components are present in the two sets of data. How can we determine whether the same component varies in latency between the two conditions, or, rather, whether two different components are present in the two different conditions? A solution to this problem could be derived from a careful examination of the pattern of results obtained, and from a comparison of these results with what we already know about different ERP components. Of course, this means that we are including a large number of empirical and theoretical arguments in the definition of each ERP component, which, in turn, may differ from one component to another, and from time to time. As a consequence, the definition of a component may include not only polarity and latency, but also distribution across the scalp and sensitivity to experimental manipulations (see, for example, Fabiani et al., 1997). Thus, it is clear that a correct interpretation of the component structure of an ERP waveform requires some background information about the components themselves (see Section 2.5). In

turn, this indicates that the concept of component is likely to evolve over time (as more knowledge is accumulated) and that revisions of traditional component classifications may some time be necessary.

A second problem in component measurement is that of component overlap. Usually, ERP components do not appear in isolation, but several of them may be active at the same moment in time. This reflects the parallel nature of brain processes. When this occurs, it is difficult to attribute a particular portion of scalp activity to a particular component. Peak and area measures are particularly susceptible to this problem. PCA has been proposed as a tool to separate the contribution of overlapping components (Donchin & Heffley, 1978), but even PCA can, in some cases, misallocate variance across different components (see Wood & McCarthy, 1984). As a result, we may attribute a difference obtained between two particular experimental conditions to the wrong component.

Several procedures have been proposed to solve the problem of component overlap, but none of them seems to have universal validity. In some cases, it can be assumed that only one component varies between two experimental conditions. In this case, the variation of this component can be isolated by subtracting two sets of waveforms and performing the measurement on the resulting "difference waveform." Unfortunately, we cannot always assume that the effect of an experimental variable is so selective. Furthermore, the subtraction procedure implies that only amplitude, and not latency, varies across experimental conditions. Thus, serious interpretation errors may occur when subtracted waveforms are used and latency varies across conditions.

Other approaches are based on using scalp distribution data to decompose overlapping components (Vector Filter, Gratton, Coles, & Donchin, 1989; Gratton et al., 1989; spatial PCA, Spencer et al., 1999; 2001; ICA, Makeig et al., 1997). These procedures involve setting up spatial filters describing the scalp distributions of the components contributing to the data. Note that distributional filters perform the same kind of operations in the spatial domain that frequency filters perform in the frequency domain. Although frequency filters apply different weights to activity in different frequency bands, distributional filters apply different weights to activity from different spatial locations.

3. THE INFERRENTIAL CONTEXT

In this section, we review the procedures through which we make inferences about psychological and physiological processes and states from the measurement of ERPs. Previous work by Cacioppo and Tassinary (1990) describes different types of relationships between psychological and physiological variables, which limit the extent to which inferences can be drawn from psychophysiological data, as well as their generalizability. More recent papers (Kutas & Federmeier, 1998; Miller, 1996; Sarter, Berntson, &

Cacioppo, 1996) also discuss existing limitations in making inferences about brain function on the basis of brain imaging data. The general framework described in these papers is assumed in the approach presented here, which is more limited in scope, and is intended as a description of the experimental logic that is often employed in ERP research.

3.1. Experimental logic

If the ERP waveform is interpreted as an aggregate of several components, some theory about the functional significance of each component is useful to the understanding of the meaning of changes that this component will exhibit as a function of specific subject, stimulus, and task contexts. We should emphasize that by "functional significance" we do not necessarily mean a specification of the neurophysiological significance of the component, but rather a specification of the information processing transactions that are manifested by it. In this sense, then, neurophysiological knowledge may be useful, but not necessarily critical, to the psychophysiological enterprise. Of course, neurophysiological knowledge is very important if we wish to use ERPs as a tool to make statements about brain function.

In the case of all ERP components (or effects), the initial phase in the process of establishing functional significance begins with its discovery. A theory about the functional significance of that component/effect is then developed. This is a complex process that involves: (a) studies of the component's "antecedents," where antecedent conditions refer to those experimental manipulations that will produce consistent variations (in amplitude, latency, and in some cases, scalp distribution) in an ERP component or observed effect; (b) establishing the consequences of variation in the latency or amplitude of the component, which can be used to test statements relating to functional significance; and (c) speculations about the psychological and/or neurophysiological function it manifests (e.g., Donchin, 1981).

For cases in which converging evidence about the brain origins of the ERP component or effect of interest are available, these speculations can be corroborated and extended by means of this additional information. One such example is work done by McCarthy and colleagues, who have collected extensive fMRI and intracranial recording data in traditional ERP paradigms (e.g., McCarthy, Nobre, Bentin, & Spencer, 1995; Puce et al., 1999; Huettel & McCarthy, 2004; see also Kiehl et al., 2005; Laurens, Kiehl, & Littel, 2005). Other examples are provided by the simultaneous recording of ERP and fast optical (EROS) data (e.g., DeSoto et al., 2001; Fabiani et al., 2003; 2006; Gratton, Goodman-Wood, & Fabiani, 2001).

In Section 4.4.1, we review examples of this inferential logic as it applies to studies of the P300 component. In the remainder of this section, we will consider the ways in which ERP measures are used to make inferences about psychological processes, and, in some cases, about brain

activity. We will review a series of inferential steps that depend to a greater and greater extent on assumptions about the functional significance of the ERP. For the purposes of elucidating the inferential process, we will consider an experiment in which subjects are run in two different conditions.

3.2. Using ERP measures: Psychophysiological inference

3.2.1. Inference 1: Conditions are different

At the most fundamental level, we can ask whether or not the two conditions are associated with different ERP responses. Note that this inference, as well as the next (Section 3.2.2), do not depend on the classification of the ERP into components, but, rather, are based on the evaluation of the waveforms obtained in different conditions. The analytic procedure necessary to answer this question would involve a univariate or multivariate analysis of variance, with *condition* and *measure* (e.g., peak or datapoint within a specified time window) as factors. If such an analysis yields a significant effect of condition or a condition by measure interaction, we can infer that the conditions are different. If we assume that the ERP is an index of brain activity and/or that it reflects some psychological process, then we can infer that the brain activity and associated psychological process are different in the two conditions.

3.2.2. Inference 2: Conditions differ at a particular time

The second level of inference concerns the time at which the two conditions differ. This inference could be made on the basis of post-hoc tests of the significant *condition* by *time* interaction. It would take the form of “processing of stimuli in condition A is different than processing of stimuli in condition B by at least X ms.” This kind of inference is frequently made in studies of selective attention, where an important theoretical issue concerns the relative time at which an attended event receives preferential processing. As with the most primitive form of inference, we need only assume that the ERP is a reflection of some non-specified aspect of psychological processing. Note that this same evidence can also be used to infer the time at which some (non-specified) brain structure(s) shows differential processing for two events.

3.2.3. Inference 3: Conditions differ with respect to the latency of some process

For this level of inference, additional assumptions and measurement operations must be made. Here, ERPs are used to study the duration of processes preceding the occurrence of a particular physiological event (such as a component’s peak). This requires that we can identify a particular physiological event (or component) across conditions, and that this event varies in latency. Further, we usually assume that the ERP component can only occur after a particular psychological process is carried out. Note

that for this inferential level, we must: (a) adopt a procedure to identify the component in question (e.g., by using its polarity, distribution, response properties, etc.); (b) measure its latency; and (c) use an analytic procedure (analysis of variance, *t*-test, etc.) to evaluate the difference between the conditions with respect to the component latency. As a result of this procedure, we make the inference that the conditions differ with respect to the timing of process X.

3.2.4. Inference 4: Conditions differ with respect to the degree to which some process occurs

The notion of component also allows us to use ERPs to infer that a particular process occurs to a greater extent under one condition than under another. In this case, we must assume that a particular ERP component is a manifestation of process X. We must further assume that changes in the magnitude of the component correspond directly to changes in the degree to which the process is invoked. Then, we must devise a suitable measurement procedure to identify and assess the magnitude of the component. Finally, we can proceed with the usual inferential test and determine whether or not the conditions differ with respect to the *degree* of process X. Of course, if precise knowledge were available about the underlying brain sources of a particular ERP activity, statements that are made about the ERP could also apply to the brain structures in question.

4. PSYCHOLOGICAL CONTEXT: SELECTIVE REVIEW OF ERP FINDINGS

In this section, we review a number of findings in the ERP literature. We begin with a discussion of ERPs that are related to the preparation, execution, and evaluation of motor responses. This is followed by a brief overview of sensory and cognitive ERP components that occur after a marker event, with particular emphasis on ERP effects related to attention, memory, and language.

4.1. Response-related potentials

In this section we review research on ERP activity that is typically observed in relationship to movement preparation and generation (readiness potential, or RP, lateralized readiness potential, or LRP, and contingent negative variation, or CNV), or as a reaction to errors (error-related negativity, or ERN).

4.1.1. Movement-related potentials

One class of event-preceding potentials includes those that are apparently related to the preparation for movement. These potentials were first described by Kornhuber and Deecke (1965) who found that a negative potential develops slowly, beginning some 800 ms before the initiation of a voluntary movement (see Figure 4.5). These “Readiness Potentials” (or “Bereitschaftspotentials”) were

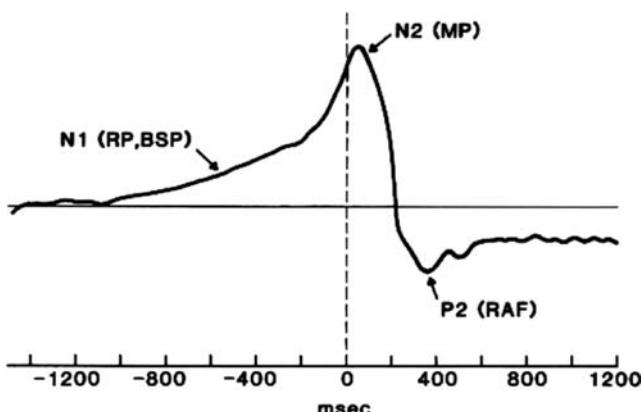

Figure 4.5. Typical movement-related potential (recorded from a central electrode – Cz) preceding a voluntary hand movement. Note that the potential begins about 1 sec before the movement (indicated by the dashed vertical line). The potential can be subdivided into different components as follows: N1 (RP – Readiness Potential, BSP – Bereitschaftspotential); N2 (MP – Motor Potential); and the P2 (RAF – Reafferent Potential). (Copyright 1980, Elsevier Science Publishers. Adapted with permission of the author and publisher from Kutas & Donchin, 1980.)

distinguished from those that followed the movement, the “Reafferent Potentials.” In a condition in which a similar, but passive movement was involved, only post-movement potentials were observed. Both readiness and reafferent potentials tend to be maximal at electrodes located over motor areas of the cortex. Furthermore, some components of the potentials are larger at electrode locations *contralateral* to the responding limb (at least for hand and finger movements), as would be expected based on the organization of motor cortex. Indeed, this kind of lateralization has become an important criterion for movement-related potentials.

The investigation of movement-related potentials has developed along several different paths, including (a) the discovery and classification of different components of the movement-related potential (for reviews, see Brumia, Haagh, & Scheirs, 1985, and Deecke et al., 1984), (b) analysis of their neural origin using the scalp topography of ERPs (e.g., Vaughan, Costa, & Ritter, 1972) or magnetic field recordings (e.g., Okada, Williamson, & Kaufman, 1982; Deecke, Weinberg, & Brickett, 1982), (c) analysis of the functional significance of different components (see Brumia et al., 1985, and Deecke et al., 1984, for reviews), and (d) recording of movement-related potentials in special populations (e.g., in mentally retarded children, Karrer & Ivins, 1976, and in Parkinson’s patients, Deecke, Englitz, Kornhuber, & Schmidt, 1977). In general, these studies confirm that the potential described by Kornhuber and Deecke is generated, at least in part, by neuronal activity in motor areas of the cortex and is a reflection of processes related to the preparation and execution of movements.

4.1.1.1. The lateralized readiness potential (LRP). In the last two decades, movement-related potentials have been

applied to the investigation of human information processing. Studies reviewed in the previous section (Kornhuber & Deecke, 1965) indicated that the readiness potential occurs prior to voluntary movements of the hand and is maximal at central sites, contralateral to the responding hand. In addition, lateralized readiness potentials can also be observed in the foreperiods of warned reaction time tasks, when subjects know in advance which hand to use in response to the imperative stimulus (Kutas & Donchin, 1977).

Based on this evidence, researchers working independently at the Universities of Groningen (De Jong et al., 1988) and Illinois (Coles & Gratton, 1986) concluded that one could exploit the lateralization of the readiness potential in choice reaction time tasks to infer whether and when subjects had preferentially prepared a response (see Gratton et al., 1989; De Jong, Wierda, Mulder, & Mulder, 1988; Gehring, Gratton, Coles, & Donchin, 1992; Gratton, Coles, Sirevaag, Eriksen, & Donchin, 1988; Kutas & Donchin, 1980).

The derivation of the LRP (Coles, 1989) is based on the following steps, which are designed to insure that any observed lateralization can be specifically attributed to motor-related asymmetries rather than to other kinds of asymmetrical brain activity: (a) potentials recorded from electrodes placed over the left and right motor cortices are subtracted. This subtraction is performed separately for the conditions where left-hand movements represent the correct response and those where right-hand movements are correct. In each case, the potential ipsilateral to the side of the correct response is subtracted from the potential contralateral to the side of the correct response, thus eliminating symmetrical activity; (b) the asymmetry values for left- and right-hand movements are then averaged to yield a measure of the average lateralized activity as subjects prepare to move. This average eliminates lateralized activity not related to movement, and yields the LRP.

Measures of the LRP have been used to make three different kinds inferences: (a) To infer whether a response has been preferentially activated or prepared (note that no LRP will be observed if both responses are equally activated); (b) To infer the degree to which a response has been preferentially activated. This inference presupposes that the level of asymmetry as reflected by the LRP is related to the level of differential response activation. In fact, Gratton et al. (1988) showed that the amplitude of the LRP at the time of an overt response was fixed: that is, there appeared to be a threshold level of the LRP which, when crossed, was associated with an overt response (for a similar observation in an animal model see Hanes & Schall, 1996); (c) To infer when a response is preferentially activated. This inference has, perhaps, proved to be the most troublesome, because of the problems associated with the measurement of the onset of the LRP (Smulders, Kenemans, & Kok, 1996).

To use the LRP in the context of research in experimental/cognitive psychology, it is necessary to arrange the experimental design such that the question of interest can

be phrased in terms of a question about the *relative activation* of the two responses – responses with the left or right hands. To illustrate the LRP approach, we give two examples of work using the LRP.

The first experiment addressed a question about the nature of information transmission: *Can partial information about a stimulus be transmitted to the response system before the stimulus is completely processed* (e.g., Miller, 1988; Sanders, 1990)? The rationale is as follows. For a stimulus that contains two attributes, compare (a) conditions under which both attributes are mapped to the same (correct) response versus (b) conditions where the attributes are mapped to different (correct and incorrect) responses. If you observe incorrect response activation in the conflict condition, then partial information about the attribute must have been transmitted and processed at some level. Evidence in favor of partial transmission was reported by Gratton et al. (1988; see also Smid et al., 1990, 1991) using a noise compatibility paradigm (Eriksen & Eriksen, 1974). They found that the incorrect response is activated on the conflict trials even though the correct response is executed.

Similar findings were obtained in a Go/No-Go paradigm by Miller and Hackley (1992; see also Osman et al., 1992; Shin, Fabiani, & Gratton, 2004; Heil, Hennighausen, & Ozcan, 1999; van Turrenout, Hagoort, & Brown, 1996). In this case the trick is to map one stimulus attribute to response hand and the other attribute to response decision. If a response is activated when no response is required, then partial information about the attribute associated with response hand must have been transmitted.

In the experiment by Miller and Hackley, the stimuli were letters that had two attributes: size and identity, with size being deliberately made more difficult to determine than identity. Letter size was mapped to the Go/No-Go decision, whereas letter identity was mapped to response hand. Miller and Hackley found that, on Go trials, there was the expected development of an LRP associated with the subject's response on these trials. For No-Go trials, there was also a (smaller) LRP even though the subject showed no sign of any response-related muscular activity. These data indicate that, on No-Go trials, a response was activated, even though that response was never executed. Partial information about letter identity was being transmitted to the response system.

These two examples are illustrative of the kinds of inferences that can be made using the LRP. The LRP has also helped identify the processing locus of particular experimental effects (i.e., whether a given process or effect occurs before or after response activation) and how these effects may vary depending on individual differences (e.g., Low, Miller, & Vierck, 2002). Furthermore, measures of the LRP have provided insights about at which level(s) in the information processing system inhibitory mechanisms can still act to interrupt a response (e.g. De Jong et al., 1990). For further information about these and other issues, the interested reader should consult the following review articles and chapters: Coles, Gratton, and Donchin (1988);

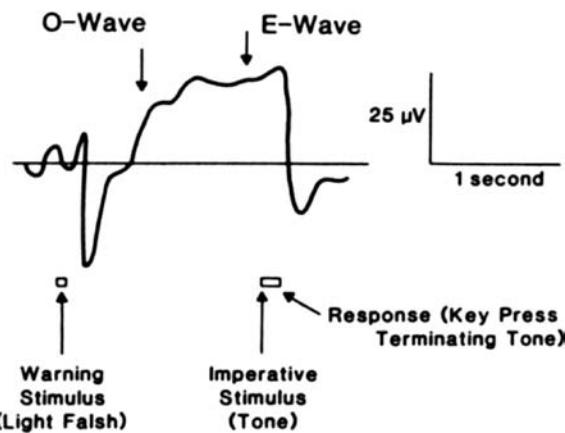

Figure 4.6. Schematic representation of a typical contingent negative variation (CNV) recorded from Cz. The CNV is the negative portion of the wave between the presentation of the warning and imperative stimuli. The early portion of the CNV is labelled “O-wave” (or Orienting wave), whereas the late portion is labelled “E-wave” (or Expectancy wave). (Copyright 1983, Elsevier Science Publishers. Adapted with permission of the author and publisher from Rohrbaugh & Gaillard, 1983.)

Coles, De Jong, Gehring, and Gratton (1991); Coles, Smith, Scheffers, and Otten, 1995; Band & Van Boxtel, 1999).

4.1.1.2. The contingent-negative variation (CNV). The CNV was first described by Walter, Cooper, Aldridge, McCallum, and Winter (1964) as a slow negative wave that occurs during the foreperiod of a reaction time task (see Figure 4.6). A paradigm typically used to study the CNV is the “S1-S2” paradigm, which consists of a warning stimulus (S1) followed, after an interval, by a stimulus requiring a response (imperative stimulus, S2). The CNV tends to be largest over central (vertex) and frontal areas. Researchers investigating its functional significance have manipulated several aspects of the S1-S2 paradigm, including subject's task, discriminability of the imperative stimulus, foreperiod duration, stimulus probability, presence of distractors, and so on. The component has been variously described as related to expectancy, mental priming, association, and attention (for reviews, see Donchin, Ritter, & McCallum, 1978; Rohrbaugh & Gaillard, 1983).

A controversy in research in this area concerns whether the CNV consists of one, or several, functionally distinct, components. A further, but related, question is whether the late portion of the CNV (just prior to the imperative stimulus) reflects more than the process of motor preparation as the subject anticipates making a response to the imperative stimulus. This controversy was raised by Loveless and his co-workers (e.g., Loveless & Sanford, 1974; see also, Connor & Lang, 1969), who argued that the CNV consists of two components, an early orienting wave (the O-wave) and a later expectancy wave (the E-wave). Subsequent research by these investigators led them to argue that the E-wave is a readiness potential and reflects nothing more than motor preparation. Research by Rohrbaugh et al. (1976) and by Gaillard (1978; see also Rohrbaugh & Gaillard, 1983) also supports this interpretation. However, the question

of the functional significance of the latter component (the E-wave) remains controversial. Some investigators have claimed that because a late E-wave is evident even in situations in which no overt motor response is required, the E-wave has a significance over and above that of motor preparation. However, it is clear that even though the overt motor response requirement may be removed from these situations, attention to a stimulus necessarily involves some motor activity associated with adjustment of the sensory apparatus. Perhaps the most persuasive arguments for a non-motor role for the late CNV come from a study of Damen and Brunia (1987). These authors found evidence for a motor-independent wave that precedes the delivery of feedback information in a time-estimation task (see also van Boxtel & Brunia, 1994).

4.1.2. The error-related negativity (ERN)

As its name implies, the error-related negativity (ERN) is a negative component of the ERP that occurs when subjects make errors in sensorimotor and similar kinds of tasks. The component was first observed by Falkenstein and colleagues (Falkenstein et al., 1990) but it has been observed in several other laboratories (e.g., Dehaene, Posner, & Tucker, 1994; Gehring et al., 1993).

In the prototypical experiment, subjects perform a choice reaction time task in which they must respond to two different auditory (or visual) stimuli with their left or right hands. When they respond incorrectly, for example by using their left hand to respond to a stimulus requiring a right hand response, a negative potential is observed at the scalp. The ERN peaks at around 150 ms after response onset (defined on the basis of EMG activity) and is maximal at fronto-central scalp sites. Interestingly, the negativity evident in the waveform for the incorrect trials begins to diverge from the waveform associated with correct trials at around the time of the response.

Several different studies have evaluated the functional significance of this component. For example, Gehring et al. (1993; see also Falkenstein et al., 1995) found that the amplitude of the ERN depends on the degree to which experimental instructions stress accuracy over speed. It is larger when accuracy is stressed. Bernstein et al. (1995) found that ERN amplitude also varies with the degree of error (defined on the basis of movement parameters). It is larger when the incorrect response deviates from the correct response in terms of two rather than one parameter. Finally, whereas errors in these tasks are sometimes followed immediately by correct responses, error correction does not appear to be a necessary condition for the appearance of an ERN. In fact, an ERN is observed when subjects respond (incorrectly) to NoGo stimuli, a situation where the errors cannot be corrected by a second motor response (Scheffers et al., 1996).

The ERN is related to a variety of behaviors that, together, can be regarded as remedial actions that are taken to compensate for the fact that an error is being made or has been made. These actions include attempts to inhibit the error, correct the error, or slow down so that the system

does not make errors in the future (Gehring et al., 1993; Scheffers et al., 1996).

Evidence for the generality of the process manifested by the ERN has been provided by Miltner, Braun, and Coles (1987). In their experiment, subjects were required to perform a time-interval production task. Shortly after subjects made a response indicating the end of a (perceived) 1-second interval, a feedback stimulus provided information about whether the preceding interval was correct or incorrect. For incorrect feedback stimuli, an ERN-like negative potential was observed. These results suggest that the same error-processing can be engaged by feedback stimuli as by incorrect actions themselves.

Finally, there is evidence to suggest that the ERN is generated by frontal brain structures involving either the supplementary motor area or the anterior cingulate cortex. Equivalent dipole analyses for the ERN observed in choice reaction time tasks (Dehaene et al., 1994; Holroyd, Dien, & Coles, 1998) and for the ERN-like negativity observed to feedback stimuli (Miltner et al., 1997) implicate activity in these neural structures as being responsible for the ERN signal recorded at the scalp.

Involvement of these structures is consistent with the picture that has begun to emerge from the functional studies of the ERN. That picture includes error-monitoring and remedial action processes as essential aspects of the human cognitive system. Whenever humans perform tasks, they must not only set up their cognitive systems to execute the tasks, they must also set up a system to assure that performance on the tasks conforms to task goals. The ERN may be a manifestation of the activity of this system, although it is presently unclear whether it is more closely related to the error-detection process itself or some consequence of error-detection involving an aspect of remedial action (see Coles, Scheffers, & Holroyd, 1998; Falkenstein et al., 1995; Gehring et al., 1995; and Holroyd & Coles, 2002).

Alternative views of the ERN have been proposed by Cohen, Carter, and colleagues (e.g., Botvinik, Cohen, & Carter, 2004) and Luu, Collins, & Tucker (2000). Cohen, Carter, and colleagues propose that the ERN is a manifestation of conflict monitoring – a process they envision as being a part of a general attention system. In support of this idea they point out that activity similar to the ERN can be observed on correct trials in situations of high conflict (correct related negativity, or CRN). Holroyd and Coles (2002) however, argue that these finding may be accounted by a broader definition of error, which takes into account sub-threshold activation of incorrect responses that are more likely to occur on conflict than on no-conflict trials. Interestingly, Bartholow et al. (2005) recently showed that CRN activity can be observed even in no-conflict trials, whenever subjects are led to expect a high-conflict trial and therefore use a conservative response strategy. This suggests that the ERN may be the reflection of a monitoring process that compares the current stimulus with the processing mode currently in use. If the processing mode is likely to lead to an error – or indeed to a high level of

response conflict – a remedial action may need to be taken. Luu et al. (2000) take a very different view of the ERN: they interpret it as part of a set of emotional responses related to the detection of errors or conflict. It is difficult to compare this view with the error detection or conflict monitoring views because it represents a very different level of description.

4.2. Sensory components

The presentation of stimuli in the visual, auditory, or somatosensory modality elicits a series of voltage oscillations that can be recorded from scalp electrodes. In practice, sensory potentials can be elicited either by a train of relatively high-frequency stimuli or by transient stimuli. In the former case, the ERP responses to different stimuli overlap in time. The waveforms driven by the periodic stimulation have quite fixed periodic characteristics, and are therefore referred to as “steady-state” responses (see Regan, 1972). In the case of transient stimuli, the responses from different stimuli are separated in time.

Both steady-state and transient potentials appear to be obligatory responses of the nervous system to external stimulation. In fact, the earliest aspects of all sensory potentials (within, say, 100 ms) are invariably elicited whenever the sensory system of interest is intact. In this sense, they are described as “exogenous” potentials. They are thought to represent the activity of the sensory pathways that transmit the signal generated at peripheral receptors to central processing systems. Therefore, these components are modality-specific, that is, they differ both in waveshape and scalp distribution as a function of the sensory modality in which the eliciting stimulus is presented. As would be expected of manifestations of basic sensory processes, sensory components are influenced primarily by stimulus parameters such as intensity, frequency, and so on. For a review of these components, see Hillyard, Picton, and Regan (1978).

For clinical purposes, sensory evoked potentials are used in the diagnosis of neurological diseases (i.e., demyelinating diseases, cerebral tumors and infarctions, etc.). Of particular diagnostic importance are the auditory brainstem potentials (diseases involving the posterior fossa), and the steady-state visual potential (multiple sclerosis). Auditory potentials can also be used to diagnose hearing defects in uncooperative subjects (such as newborn infants). Because most sensory potentials appear to be insensitive to psychological factors, they have not been used extensively in the study of psychological processes.

4.3. The early negativities

Several negative components have been described in the period between 100 and 300 ms after the presentation of an external stimulus. In this section, we will examine two families of negative components that have been associated with selective attention, elementary feature anal-

ysis, and auditory sensory memory. Their scalp distribution and morphology vary as a function of the modality of the eliciting stimulus. For these reasons these potentials may be considered “mesogenous” as they lie at the interface between purely exogenous and purely endogenous components.

4.3.1. ERPs and the locus of selective attention

Selective attention refers to the ability of the human information processing system to selectively analyze some stimuli and ignore others. The locus of selective attention within the information processing flow has long been an issue of contention in psychology (e.g., Johnstone & Dark, 1986). Two metaphors have been associated with selective attention, that of filtering (see Broadbent, 1957) and that of resources (see Kahnemann, 1973, Norman & Bobrow, 1975). Filtering theories have focused on the issue of whether filtering occurs at an early, perceptual level (early selection theories, Broadbent, 1957) or at later stages of processing (late selection theories, Deutsch & Deutsch, 1963). According to the resource metaphor, selective attention is a mechanism by which the system allocates more resources to process information coming through a particular attended channel than through other unattended channels. Thus, the primary questions are how many processing activities can be performed simultaneously, and what factors limit the availability of processing resources. These latter questions have mostly been addressed in the context of research on the P300, and will be briefly reviewed in Section 4.4.1. Psychophysicists in general and ERP researchers in particular have rephrased the question of the locus of selective attention to ask where in the sequence of electrophysiological responses that follow sensory stimulation the effects of attention begin to emerge. The “attention effect” is usually defined as an enhanced response to a stimulus when the subject’s attention is directed to some of the stimulus features, as compared with the subject’s response when his/her attention is directed elsewhere. For example, the first indications that ERPs could be used to investigate attentional processes came from studies in which the ERP response to attended stimuli was compared with that to unattended stimuli (e.g., Eason et al., 1964; Hillyard, Hink, Schwent, & Picton, 1973). These kinds of studies suggested that attended stimuli are associated with a more negative ERP between 100 and 200 ms. Subsequent research has been concerned with three issues: (a) the use of ERPs to test theories of selective attention; (b) the nature of the attentional effect on ERPs; and, (c) the neurophysiological basis of selective attention effects.

In a typical paradigm (Hillyard et al., 1973), four types of stimuli are presented. The stimuli (e.g., tones) differ along two dimensions (e.g., location and pitch), each having two levels (left vs. right ear and standard vs. deviant pitch). The subject is instructed to attend to stimuli at a particular location and to detect target tones of a deviant pitch (e.g., left ear tones of high pitch). To investigate attention effects,

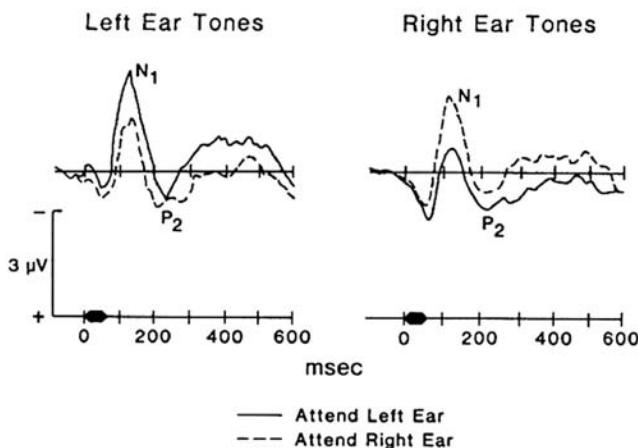

Figure 4.7. The effect of attention on early components of the auditory event-related potential recorded at the vertex electrode (Cz). The left panel shows ERPs for tones presented in the left ear. Note that the difference between the ERPs to attended tones (solid line) versus those for unattended tones (dashed line) consists of a sustained negative potential. A similar difference can be seen for tones presented to the right ear (see right panel). (Copyright 1981, Elsevier Science Publishers. Adapted with permission of the author and publisher from Knight et al., 1981.)

ERPs to standard tones occurring in the attended channel (location) are compared to those to standard tones in the unattended channel.

Using this paradigm, Hillyard and his colleagues have observed a larger negativity with a peak latency of about 100–150 ms for stimuli presented in the attended channel (see Figure 4.7, which shows data from a similar experiment by Knight, Hillyard, Woods, & Neville, 1981). The moment in time at which the waveforms for attended and unattended stimuli diverge is considered the time at which filtering starts playing a role.

Subsequent studies have shown that, by and large, ERP peaks are influenced by attention manipulations in one of three ways (see Hackley, 1993):

(a) They may be unaffected by the attention manipulation. In this case the ERP activity is considered an automatic response to the stimulation. An ERP response with these properties is often referred to as an “exogenous” component. An example of this type of component is the visual C1 component, believed to arise from primary visual cortical areas (e.g., Di Russo, Martinez, Sereno, Pitzalis, & Hillyard, 2002).

(b) They may be affected by the attention manipulation but occur even when attention is directed somewhere else. In this case the ERP activity can be treated as a “semi-automatic” response, in that it may occur even without attention, but it is larger (or smaller) when attention is deployed to the stimulus. An ERP response with these properties is often labeled a “mesogenous” component. The visual and auditory N100 (or N1) are examples of this type of component (Näätänen & Picton, 1987; Woods, 1995).

(c) They may require attention to occur. In this case, the ERP activity is optional, in that it only occurs when the subject is actively engaged in processing the information provided by the stimulus. An ERP response with these properties is often labeled “endogenous.” Perhaps one of the best known of this type of component is the P300, to be discussed in Section 4.4.1.

With respect to the locus of selective attention, the issue then arises of which are the earliest ERP responses (after stimulation) to be influenced by manipulations of attention. A theory advanced by Hernandez-Peon, Scherrer, and Jouvet (1956), called the “peripheral gating hypothesis,” proposes that attention influences responses at a very early level within the sensory pathway. In favor of this theory are anatomical observations of centrifugal fibers from the central nervous system directed toward sensory organs (such as the cochlea and the retina). Indeed, Lukas (1980, 1981) reported that the earliest brainstem auditory evoked potentials (BAEPs), with a latency of just a few milliseconds from stimulation, and presumably generated in the cochlea itself or in the early portions of the auditory pathway, were already influenced by attention manipulations. Similar results were reported by Eason et al. (1964) in the visual modality (in this case, using the electroretinogram). However, numerous subsequent attempts to replicate these findings failed, and methodological concerns were raised (for a review, see Hackley, 1993). For this reason, it is now accepted that the earliest auditory evoked potentials that are affected by attention have a latency of approximately 20–25 ms (McCallum, Curry, Cooper, Pocock, & Papakostopoulos, 1983). These are potentials that are likely to be generated in primary auditory cortex (Romani, Williamson, & Kaufman, 1982; Romani, Williamson, Kaufman, & Brenner; 1982; Woldorff et al., 1993) – in which case, selective attention seems to operate when the signal arrives at the cortex. Findings leading to similar conclusions have been obtained for the somatosensory modality (Michie, Bearpark, Crawford, & Glue, 1987).

In the visual modality, however, a different pattern of results emerges. In this case, the earliest responses that are usually attributed to cortical involvement (latency of approximately 50–70 ms) appear unaffected by selective attention manipulations (provided, of course, that eye-movements are not involved – Hansen & Hillyard, 1980; 1984; Mangun, Hillyard, & Luck, 1993). Attention effects occur only later, leading several investigators to speculate that attention effects emerge when the signal is transferred from primary visual cortex to surrounding cortical areas (Mangun et al., 1993; Martinez et al., 1999; 2001; see also Gratton, 1997, for optical imaging evidence of these phenomena). Source modeling efforts (Clark & Hillyard, 1996) and combinations of ERPs with other imaging methods (Heinze et al., 1994; Martinez et al., 1999) have provided support for this hypothesis. Further support has been brought forward recently by optical imaging data showing

that early attention effects (latency around 100 ms) are visible in extrastriate (area 19) but not in striate cortex (area 17; Gratton, 1997).

Additional recent studies have also explored the effects of attention on these early visual and auditory components in people that are selected according to specific characteristics. For example, Brumback, Low, Gratton, & Fabiani (2004) reported that individuals selected for having either very high or very low loaded working memory span differ in the amplitude of their auditory N1s and visual P150s in response to stimuli in simple oddball tasks. Similarly, Parasuraman, Greenwood, and Sunderland (2002) have examined the effects of the ApoE-4 allele on attention and brain activity.

Besides their role in studies of selective attention, early negativities such as the auditory N100 have also been used to investigate short-duration forms of memory such as sensory memory. These forms of memory can be analyzed by studying the effects of inter-stimulus interval (ISIs) and stimulus deviance. The effects of stimulus deviance on these early components will be reviewed in Section 4.2.3.1. Here we consider how these early ERP components are affected by ISI. Substantial evidence shows that both visual and auditory N100s are attenuated with repetition at short ISIs (e.g., Gratton et al., 2001; Sussman, Ritter, & Vaughan, 1999; Vaz Pato & Jones, 1999; Yabe, Tervaniemi, Reinikainen, & Näätänen, 1997; Yabe et al., 1998). However, when short, *unattended* trains of stimuli are used, at least for auditory stimuli, the N100 attenuation due to stimulus repetition requires at least 400 ms from the stimulus train onset to reach an effect (Sable et al., 2004). These observations are consistent with seemingly paradoxical effects reported by Budd and Michie (1994) using random ISIs, suggesting that N100 attenuation was less pronounced at ISIs *shorter* than 400 ms.

The Sable et al. (2004) data support the idea that the attenuation of the auditory N100 observed with fast stimulus repetition is not due to refractoriness of the sensory circuit per se, but rather to the engagement of an inhibitory circuit used to shut down the influx of irrelevant information (in a manner reminiscent of the pre-pulse inhibition observed for the blink reflex, or of the inhibition-of-return phenomenon in spatial attention work). Interestingly, several pieces of evidence indicate that these inhibitory events may require an intact prefrontal cortex (Knight & Graboweczyk, 1995) and are reduced in old adults (Fabiani et al., 2006; Golob et al., 2001).

4.3.2. The middle-latency cognitive components

So far we have discussed early ERP activity that is influenced by attentional manipulations. However, another set of ERP responses are influenced by the history (or sequence) of stimuli that precede the current eliciting event. Some of this activity appears to occur in an automatic fashion; that is, it occurs in response to both attended and unattended events. The most well-characterized of this type of ERP response is the mismatch

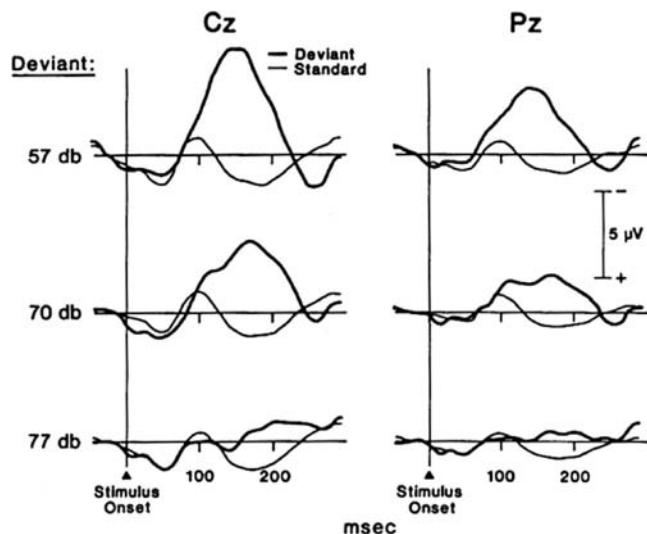

Figure 4.8. The effects of deviance on “mismatch negativity.” A standard (80 db) tone was presented on 90% of the trials and a deviant tone (57, 70, or 77 db, in different blocks) was presented on 10% of the trials. The ERP to the standard is indicated by the thin line in each panel; the ERP to the deviant tone is indicated by the thick line. As the degree of mismatch between stimuli increases, the mismatch negativity also increases. (The magnitude of the difference between standard and deviant ERPs increases.) (Copyright 1987, Blackwell Publishers. Adapted with permission of the author and publisher from Näätänen & Picton, 1987.)

negativity or MMN (Näätänen, 1982; Ritter et al., 1995). Because the MMN occurs even in the absence of attention, it has been associated with some form of pre-attentive (or sensory) memory. Other ERP responses – such as the N200s and the P300 – are sensitive to changes in the stimulus sequence, but only occur in response to attended stimuli. These latter components can therefore be considered optional responses, and are associated with post-attentive forms of memory (short-term memory or working memory). In the next two sections we will describe research on the MMN and on the N200s, while research on the frontal (novelty) P3, parietal P300 (or P3b), and slow waves will be reviewed in the section on late positivities.

4.3.2.1. The MMN. The MMN was first described by Näätänen, Gaillard, and Mäntysalo (1978; for extended reviews see Näätänen, 1992; Näätänen & Alho, 1995; and Ritter, Deacon, Gomes, Javitt, & Vaughan, 1995). The MMN is typically studied using a passive auditory oddball paradigm. In this paradigm subjects are presented with two auditory stimuli, or classes of stimuli, that occur in a Bernoulli sequence. The probability of one stimulus is generally less than that for the other, but the subject's attention is not devoted to the series of tones, but to another task, such as reading a book or watching a silent movie. To derive the MMN, the average waveform elicited by the standard (frequent) stimuli is subtracted from that of the deviant (rare) stimuli. This subtraction yields a negative component, with an onset-latency as short as 50 ms, and a peak latency of 100–200 ms (see Figure 4.8).

This component is usually largest at frontal and central electrode sites, and inverts in polarity at the mastoids (when the reference electrode is on the nose tip; e.g., Alho, Paavilainen, Reinikainen, Sams, & Näätänen, 1986). This evidence of polarity inversion, as well as intracranial recordings in animals (Csepe et al., 1987; Javitt et al., 1992; Javitt, Steinschneider, Schroeder, Vaughan, & Arezzo, 1994) dipole modeling in humans (Scherg, et al., 1989), and optical recordings in humans (Rinne et al., 1999) suggest that the primary auditory cortex and/or the immediately adjacent areas may be the brain generators of the MMN.

An MMN is elicited whenever the standard and deviant stimuli are discriminable on any of a number of features (such as pitch, intensity, and duration; see Näätänen, 1992 for a review). Its onset latency and amplitude are both dependent on the ease of discriminating the stimuli from one another (i.e., the more discriminable the stimuli, the larger the amplitude of the MMN and the shorter its onset latency – see Figure 4.8). However, it is usually necessary to present a few (2–3) standards in order for a deviant stimulus to elicit an MMN (Cowan, Winkler, Teder, & Näätänen, 1993). In addition, a MMN is elicited with an inter-stimulus interval (ISI) of up to 10 sec between a standard and a deviant stimulus (Böttcher-Gandor, & Ullsperger, 1992). Finally, the amplitude of the MMN is larger for stimuli that differ along more than one dimension, than when they differ on only one dimension (see Ritter et al., 1995).

Recent studies have shown that the MMN is sensitive to high-level, experience-driven discriminations, such as those between native and foreign language phonemes (Näätänen & Alho, 1995), as well as word and grammar processing (Pulvermüller, Shtyrov, Kujala, & Naatanen, 2003; Pulvermüller & Shtyrov, 2004).

Taken together, these characteristics suggest that: (a) the MMN may reflect the operation of a “mismatch detector” (hence the label “mismatch negativity”); (b) because the MMN is obtained even when the subject is not attending the stimuli, it is likely to be related to the automatic and pre-attentive processing of deviant features (cf. Treisman & Gelade, 1980); (c) the MMN may be based on a type of memory that is transient in nature, as an MMN is not recorded after long ISIs; and (d) because the presence of more than one deviant feature affects the amplitude of the MMN, the MMN may reflect the outcome of a comparison in which multiple features can be processed in parallel, including features that are relatively high-level and experience-driven. Thus, it has been suggested that the MMN may be used as an index of the operation of an early, pre-attentive sensory memory (echoic memory; Näätänen, 1992; cf. Cowan, 1995; Ritter et al., 1995).

Some additional evidence, however, suggests that the memory that underlies the MMN may be of longer duration than previously thought (Cowan et al., 1993) and that the sensory memory underlying the MMN and that investigated in behavioral tasks may be different (Ritter

et al., 1995; Cowan, 1995). One final problem in using the MMN as an index of sensory memory is that, contrary to behavioral evidence, a visual analog of the MMN has been difficult to obtain (Pazo-Alvarez, Cadaveira, & Amenedo, 2003). However, recent data obtained with optical imaging suggest that early memory effects (with a latency comparable to that of the MMN) can be observed in primary visual cortex and/or adjacent areas (Gratton, 1997; Gratton, Fabiani, Goodman-Wood, & DeSoto, 1998; Fabiani et al., 2003).

4.3.2.2. The N200s. The label “N200” (or N2) is used to refer to a family of negative components that are similar in latency, and whose scalp distribution and functional significance vary according to modality and experimental manipulations. For instance, different N200s can be observed for the visual modality (with maximum amplitude at occipital recording sites) and for the auditory modality (with maximum at the central or at frontal recording sites). In many experimental situations, the amplitude of the N200 appears to reflect the detection of some type of mismatch between stimulus features, or between the stimulus and some previously formed template. The N200 differs from the MMN in that the subject’s attention is usually engaged, and the “standard template” for the comparison process may be actively generated by the subject.

Squires, Squires, and Hillyard (1975) first described the N200 in a paradigm in which they manipulated stimulus frequency and task relevance independently, and found that the N200 was larger for rare stimuli. Subsequent research has shown that several types of N200 can be described, even within the same modality (e.g., Gehring et al., 1992). Specifically, Gehring et al. (1992) used a two-stimulus visual paradigm in which the first stimulus provided information about the most likely feature to be present in the second stimulus, thus creating expectations for specific stimulus features. They observed a larger N200 (with a frontal distribution) when the features in the second stimulus mismatched with the subject’s expectancies created by the first stimulus, than when the stimulus features were consistent with these expectancies. This paradigm differs from the typical MMN paradigm in that “expectancy” for particular features is dissociated from the physical presentation of the stimuli themselves. Therefore, the memory template to which the current stimulus is compared is generated internally, and is not the result of previous presentations of the template itself. In the same paradigm, Gehring et al. also presented stimuli that comprised either homogeneous or heterogeneous features, and observed a larger N200 (with a central distribution) for the heterogeneous than for the homogeneous stimuli.

The N200 has also been used in the investigation of mental chronometry. In particular, Ritter, Simson, Vaughan, and Macht (1982) and Renault (1983) have observed that the latency of this component covaries with reaction time. The high correlation between N200 latency and reaction

time may reflect the importance of feature discrimination processes (signaled by the N200) in determining the latency of the overt response. However, the subtraction technique used by Ritter et al. (1982) to derive their measures of N200 must be interpreted with caution, because the latencies of the components in the original waveforms differ. Furthermore, motor potentials, which are characterized by a large negativity, will also covary quite strictly with reaction times. Thus, it is important to disambiguate the N200 component from motor potentials when the former component is used in the study of mental chronometry.

4.4. The late cognitive ERPs: memory and language effects

In this section, we review a sample of the research dealing with two major families of endogenous components, the P300 (and similar late positivities) and the N400 (and other language-related components). For reasons of space we do not discuss in detail other late components, particularly a group of Slow Waves. Currently, the functional significance of the slow waves is largely unknown. However, see Sutton and Ruchkin (1984) and the research on the O-wave (Section 4.1.1.2) for further information.

4.4.1. The P300 and other late positivities

In this section, we focus on studies of the relationship between late positive components (including the P300, the frontal P3 or P3a, and other positive components) and memory. These studies have focused on three types of effects: (a) effects that are associated with deviant, relevant items; (b) effects related to the memorability of items (in memory paradigms involving either direct or indirect memory tests); and (c) effects obtained during the retrieval of items (i.e., at the moment in which the direct or indirect memory test is administered).

4.4.1.1. Late positivities elicited by deviant stimuli: The "classic" P300. As mentioned earlier, deviant items in an oddball paradigm elicit early and middle latency negative ERP activity. In addition, if the subject is attending the stimuli, they also elicit various types of late positivities (with a typical latency exceeding 300 ms). The first of these positivities to be identified was the P300 (also labeled P3 or P3b; Sutton, Braren, Zubin, & John, 1965), which is elicited by task relevant oddball stimuli and is maximum at posterior (parietal) scalp locations.

After more than 30 years of research on the P300, there is still no conclusive indication of the brain sources underlying this scalp-recorded activity. The research conducted so far suggests that the P300 may result from the summation of activity from multiple generators, located in widespread cortical and possibly subcortical areas (Knight, Scabini, Woods, & Clayworth, 1989; Johnson, 1988; 1989; 1993; Halgren et al., 1980; McCarthy et al., 1997). There has been some evidence that at least one of these sources may be located in the medial-temporal lobes (Okada, Kaufman, &

Williamson, 1983; Halgren et al., 1980). However, lesion data from animals (Paller et al., 1988) and humans (Johnson, 1988; 1989; 1993) indicate that it is unlikely that the scalp-recorded P300 is entirely generated in this area, as this component can still be recorded in the presence of medial-temporal lesions. In addition, Knight et al. (1989) reported that lesions of the temporo-parietal junction in certain conditions affected the amplitude of the scalp P300. Further, brain imaging studies using variants of the oddball paradigm indicate that target stimuli elicit activity in a widespread network that includes the middle-frontal gyrus, the superior and inferior temporal lobe, and the temporal-parietal junction (Huettel & McCarthy, 2004; Kiehl et al., 2005; Laurens, Kiehl, & Liddle, 2005). All of these areas may contribute to the scalp recorded P300.

In contrast to the uncertainty about its neural origin, extensive information has been accrued on the factors that affect the amplitude and latency of the P300. For example, Duncan-Johnson and Donchin (1977) reported that P300 amplitude is sensitive to stimulus probability, provided that the stimuli are relevant to the subject's task. If the events occur while the subject is performing another task, then even rare events do not elicit the P300 (Figure 4.9; see also Johnson & Donchin, 1978; Gratton et al., 1990). Further research indicated that it is *subjective*, rather than objective, probability that controls the amplitude of the P300 (Squires, Wickens, Squires, & Donchin, 1976). Finally, Polich and Margala (1997) showed that omission of frequent but non-target items does not influence the amplitude of the P300 to the target items.

In addition, the P300 can be elicited by stimuli or stimulus classes in any modality, and the stimuli can be very diverse, as long as the subject is able to classify them unambiguously (Kutas, McCarthy, & Donchin, 1977; Towle, Heuer, & Donchin, 1980; Sutton, Tueting, Zubin, & John, 1967). Finally, in another series of studies, Donchin, Kramer, and Wickens (1986; see also Sirevaag, Kramer, Coles, & Donchin, 1989) demonstrated that the amplitude of the P300 is related to the processing resources demanded by a particular task. In a dual-task situation, P300 amplitude to primary-task events increases with the perceptual/cognitive resource demands, while the P300 response to the concurrent secondary-task decreases.

Research on the latency of the P300 has focused on the identification of those processes that have elapsed prior to its elicitation. Donchin (1979) proposed that P300 latency may reflect stimulus evaluation or categorization time. This idea was supported by the observation that the correlation between P300 latency and reaction time is higher when subjects are given accuracy rather than speed instructions. Furthermore, as categorization becomes more difficult, P300 latency becomes longer (see Figure 4.10: Kutas, McCarthy, & Donchin, 1977). Finally, it appears that the P300 latency is more dependent on the completion of processes of stimulus evaluation and categorization than on those related to the current overt response. Several studies (McCarthy & Donchin, 1981; Magliero,

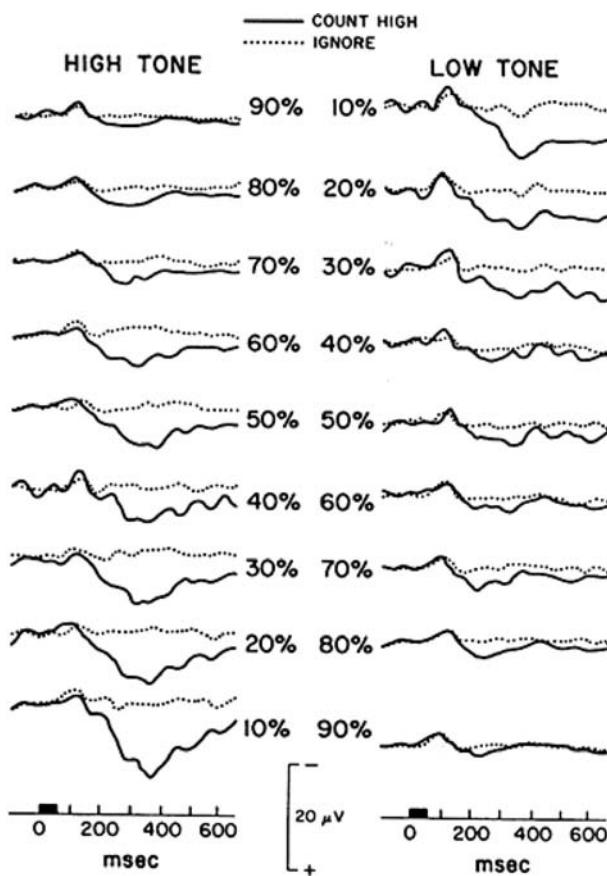

Figure 4.9. Grand-average ERP waveforms at Pz from 10 subjects for counted (high – left column) and uncounted (low – right column) stimuli (tones), with different a priori probabilities. The probability level is indicated by a percentage value beside each waveform. Waveforms from a condition in which the subjects were instructed to ignore the stimuli are also presented for a comparison. The occurrence of the stimulus is indicated by a black bar on the time scale. Positive voltages are indicated by downward deflections of the waveforms. Note that P300 amplitude is inversely proportional to the probability of the eliciting stimulus ("probability effect"), and, at the same probability level, P300 is larger for counted than uncounted stimuli ("target effect"). (Copyright 1977, Blackwell Publishers. Reprinted with permission of the author and publisher from Duncan-Johnson & Donchin, 1977.)

Bashore, Coles, & Donchin, 1984; Ragot, 1984; Verleger, 1997) demonstrate that manipulations that should affect the duration of response-related processes (i.e., stimulus-response compatibility) have relatively little effect on P300 latency (although a small effect is sometime observed; Ragot, 1984; Verleger, 1997), whereas manipulations of stimulus complexity have a large effect.

These observations led Donchin (1981; Donchin & Coles, 1988a,b) to propose that the P300 may be a manifestation of a process related to the updating of models of the environment or context in working memory. Such an updating will depend on the processing of the current event but will also have implications for the processing of and the response to future events (including the subsequent memory for the event itself). Other theories of

the functional significance of P300 have been offered by Desmedt (1980), Rösler (1983), Verleger (1988), and more recently by Nieuwenhuis, Aston-Jones, and Cohen (2005). Both Desmedt and Verleger proposed that the P300 may be related to the termination or "closure" of processing periods, whereas Rösler proposed that the P300 may reflect controlled processing.

All of these theories provide a good account of the eliciting conditions for the parietal P300. Donchin's context updating hypothesis has also been used to generate predictions about the "future" consequences of the elicitation of a large (or small) P300 at a particular trial. Tests of these predictions have been taken as a validation benchmark for the "context updating" hypothesis. Because other theories did not generate competing hypothesis, it is difficult to determine whether or not they are confirmed by these data. Several data sets have been used to test predictions derived from the context updating model of P300. Klein, Coles, and Donchin (1984) reported that musicians with perfect pitch did not show a P300 in response to rare tones (but only to visual oddball stimuli), as templates of these tones would be available to them without updating. Along similar lines, Brumback, Low, Gratton, and Fabiani (2005)

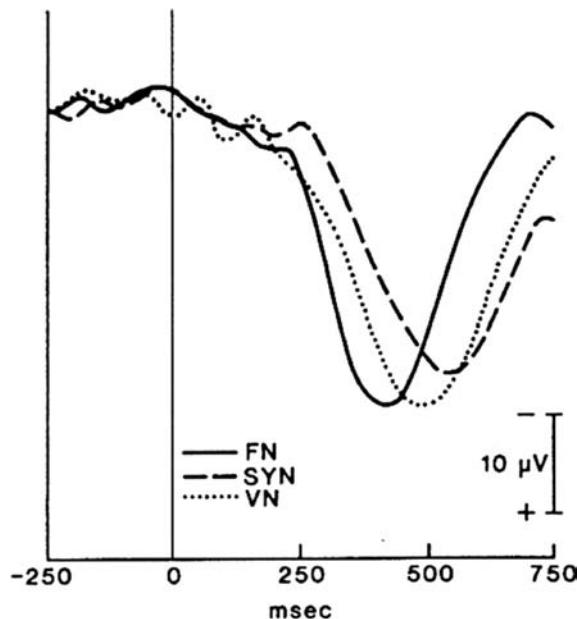

Figure 4.10. ERP waveforms at Pz averaged across subjects for three different semantic categorization tasks. The solid line indicates ERPs obtained during a task in which the subjects had to distinguish between the word DAVID and the word NANCY (the FN condition). The dotted line indicates ERPs obtained during a task in which the subjects had to decide whether a word presented was a male or a female name (the VN condition). The dashed line indicates ERPs obtained during a task in which the subjects had to decide whether a word was or was not a synonym of the word PROD (the SYN condition). These three tasks were considered to involve progressively more difficult discriminations. Note the latency of P300 peak is progressively longer as the discrimination is made more difficult. (Copyright 1977, AAAS. Adapted with permission of the author and publisher from Kutas, McCarthy, & Donchin, 1977.)

hypothesized that individuals with low working memory capacity would need to process changes in a sequence of random but equiprobable stimuli more than high-working memory subjects (as indexed by a larger P300 to sequential changes). This prediction was confirmed (see also Brumback et al., *in preparation*), suggesting that memory templates of targets stimuli are interfered with by the presence of other stimuli in low-span subjects.

Another data set used to validate the “context updating” hypothesis has been the research on the relationship between the amplitude of P300 elicited by an item and its subsequent memorability. This research will be reviewed in Section 4.4.1.3.

Statements relating to functional significance can be tested by an examination of the predicted consequences of variation in the latency or amplitude of the P300 for the outcome of the interaction between the subject and the environment. For example, if the P300 occurs after the stimulus has been evaluated, then the quality of the subject’s response to that event should depend on the timing of that response relative to the occurrence of the P300. Thus, Coles, Gratton, Bashore, Eriksen, and Donchin (1985; see also Donchin, Gratton, Dupree, & Coles, 1988) showed that, for a given response latency, response accuracy was higher the shorter the P300 latency (see Figure 4.11).

The context updating hypothesis predicts further that, to the extent that the subject’s future behavior depends on the degree to which an event leads to a change in their model of the environment, that behavior will be related to P300 amplitude. There have been several studies that have demonstrated a relationship between the memorability of an event, assessed at some future time, and the amplitude of the P300 response to the event at the time of initial presentation (see Section 4.4.1.4). As another example, it has been shown that the subject’s future strategy as revealed in overt behavior can be predicted from the P300 response to current events (Donchin et al. 1988; Gratton, Coles, & Donchin, 1992). In particular, in a speeded choice reaction time task, the amplitude of the P300 following an error was related to the latency and accuracy of overt responses on subsequent trials.

Other components show characteristics similar to the P300: the Pe component observed in response-locked average on error trials (Falkenstein et al., 1995), and the P600 component observed as a result of syntactic anomalies (Osterhout, 1997). The actual relationship between these components and the P300 is still debated.

4.4.1.2. Late positivities elicited by novel stimuli: The “frontal” P3. Courchesne, Hillyard, and Galambos (1975), used a modified oddball task in which unrecognizable complex stimuli were unexpectedly interspersed within the oddball sequence. They found that the unexpected novel stimuli elicited a positivity with a latency similar to that of the classic P300, but with a more frontally oriented scalp distribution. Because this initial experiment, a number of additional studies (e.g., Knight, 1987; Friedman, Simpson,

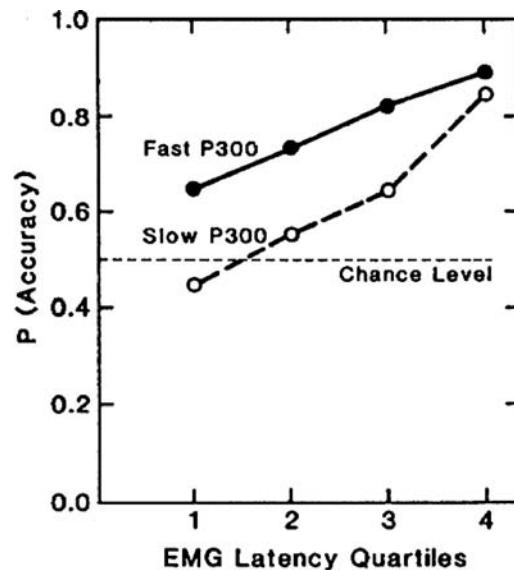

Figure 4.11. Accuracy of reaction time responses given at different latencies (“speed-accuracy functions”) for trials with “fast” and “slow” P300. Response latency (defined in terms of the onset of the EMG response) is plotted on the abscissa. The probability that a response would be correct is plotted on the ordinate. Note that the probability of giving a correct response increases as response latency increases. At very short response latencies, responses are at a chance level of accuracy (.5). At long response latencies, responses are usually accurate. The speed/accuracy function for those trials with P300 latency shorter than the median latency (“fast P300” trials) are indicated by solid lines. The speed/accuracy function for those trials with P300 latency longer the median latency (“slow P300” trials) are indicated by dashed lines. Note that, for each response latency, the probability of giving a correct response is higher when the P300 on that trial (reflecting the speed of stimulus processing on that trial) is fast than when it is slow. (Copyright 1985, The American Psychological Association. Reprinted with permission of the publisher from Coles, Gratton, Bashore, Eriksen, & Donchin, 1985.)

& Hamberger, 1993; Yamaguchi & Knight, 1991) have confirmed that a frontally oriented P3 is elicited by deviant stimuli that are exceedingly rare and unexpected within the context, and for which there is no previously formed memory template (novel stimuli). As a consequence, the frontal P300 elicited by these stimuli has also been labeled the “novelty P3.”

The relationship between the frontal and parietal P300 has been subject to debate, with some researchers taking the two to be completely different components (see Donchin & Coles, 1988a) and others taking them to be variations of the same component (e.g., Pritchard, 1981). Spencer et al. (1999) have used a combination of spatial and temporal PCA to argue for the independence of the frontal and parietal P300. McCarthy and colleagues (e.g., Kirino, Belger, Goldman-Rakic, & McCarthy, 2000) recorded fMRI during paradigms resembling the novelty oddball task, and found that novel stimuli elicit activation in more ventral frontal areas than the target (and rare) items. Recently, Fabiani and Friedman (1995) have shown that *all* attended deviant items elicit frontal P3s when the

stimuli are first presented (i.e., during a practice block). However, with subsequent repetitions of the same stimuli the scalp distribution of the P3 reverts to a parietal maximum as typical for the "classic" P300 in young adult subjects. Interestingly, older adult subjects do not show this scalp distribution change over time, and produce a frontally focused P3 in response to all deviant and novel stimuli (see also Friedman & Simpson, 1994).

Fabiani and Friedman (1995) proposed that the frontal P3 may be elicited by items for which no memory template is available (and "orienting" may be required), and that it diminishes when a template is formed (i.e., with repeated presentations of the same stimuli). Older subjects or subjects with frontal lobe dysfunction may have problems forming and/or maintaining the stimulus template and therefore exhibit a frontal P3 even in response to deviant stimuli that are repeated a number of times. Knight (1984; 1997) found that the frontal portion of the novelty P3 is suppressed in patients with frontal lobe lesions. This, in turn, suggests that the presence of a frontal P3 to subsequent repetitions of deviant items may be associated with frontal lobe dysfunction, as measured by neuropsychological tests (e.g., Wisconsin Card Sorting Test, see Fabiani, Friedman, & Cheng, 1998).

4.4.1.3. ERP effects associated with subsequent memory.

The relationship between P300 and memory has been tested in various paradigms. For example, Karis, Fabiani, and Donchin (1984) recorded ERPs to words presented in a series that contained a distinctive word (an "isolate"; cf. von Restorff, 1933). The isolation was achieved by changing the size of the characters in which the word was displayed. As is well documented (von Restorff, 1933; Wallace, 1965), isolated items are better recalled than are comparable non-deviant items (the von Restorff effect). The isolated items, being rare and task-relevant, can be expected to produce large P300s. Thus, it was predicted that the recall variance would be related to the very factors that are known to elicit and control P300 amplitude. Karis et al. (1984) found that the magnitude of the von Restorff effect depends on the mnemonic strategy employed by the subjects. Rote memorizers (i.e., subjects who rehearse the words by repeating them over and over) showed a large von Restorff effect, and poor recall performance, relative to elaborators (i.e., subjects who combine words into complex stories or images in order to improve their recall). For all subjects, isolates elicited larger P300s than nonisolates. For rote memorizers, isolates that were subsequently recalled elicited larger P300s on their initial presentation than did isolates that were not recalled. This relationship between recall and P300 amplitude was not observed in elaborators (see Figure 4.12). It is noteworthy that the amplitude of a frontal-positive slow wave was correlated with subsequent recall in the elaborators, suggesting that this component may be related to the degree of elaborative processing.

Karis et al. (1984) interpreted these data as evidence that all subjects noticed the isolated words and reacted

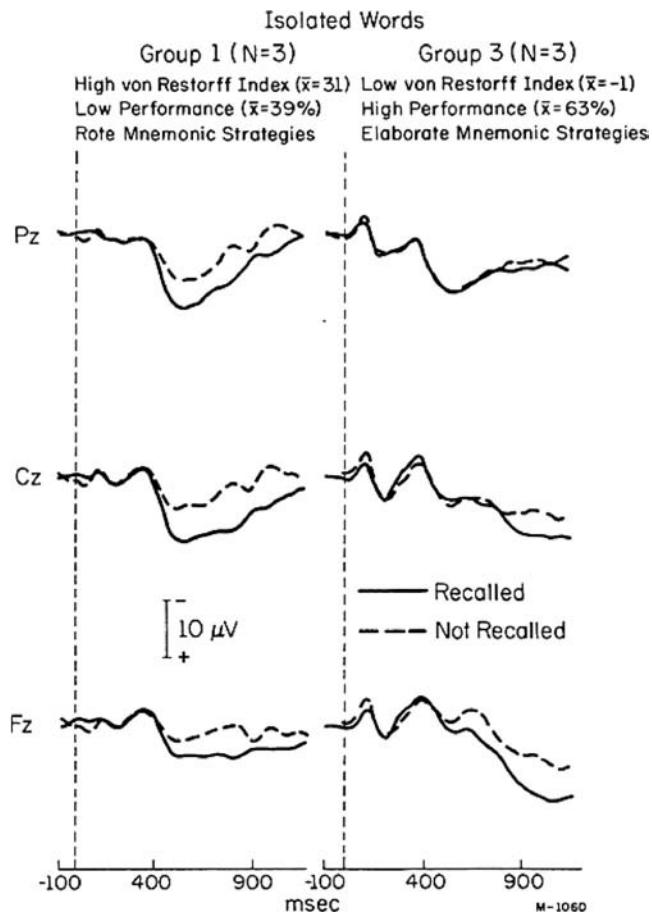

Figure 4.12. ERPs elicited by "isolated" words that were later recalled (solid line) or not-recalled (dashed line). The left column shows ERPs for subjects who used rote mnemonic strategies; the right column shows ERPs for subjects who used elaborative strategies. Note that the amplitude of P300 is related to subsequent recall for the rote memorizers, but not for elaborators. (Copyright 1986, Elsevier Science Publishers. Reprinted with permission of the publisher from Fabiani, Karis, & Donchin, 1986b.)

by updating their memory representations and producing large P300s. However, differences among the subjects emerged when they tried to memorize the stimuli by using different types of rehearsal strategies. When subjects used rote strategies, changes in the stimulus representation, induced by the isolation and manifested by P300, made it easier to recall the word. For the elaborators, whose recall depended on the networks of associations formed as the series were presented, the effects of the initial memory activation and updating manifested by P300 were not noticeable, because they were overshadowed by the more powerful elaborative processing that occurred after the time frame of P300.

The hypothesis that the relationship between P300 amplitude and subsequent recall depends on the mnemonic strategy used by the subject was supported by subsequent studies in which the effects of strategies were investigated by: (a) manipulating instruction on a within-subject basis (Fabiani, Karis, & Donchin, 1990); (b) demonstrating that, in children who do not spontaneously

use elaborative strategies, the P300/memory relationship is evident in all subjects in the absence of strategy instructions (Fabiani, Gratton, Chiarenza, & Donchin, 1990); and (c) showing that the P300/memory relationship is clearer in adults in incidental memory paradigms (i.e., when the memory test is unexpected and mnemonic strategies are unlikely to be used; Fabiani, Karis, & Donchin, 1986). Finally, Fabiani and Donchin (1995) investigated the P300/memory relationship in the case in which words are semantically isolated, and also studied the effects of the type of orienting task given during the von Restorff paradigm. They found that both semantic and physically isolated words that were subsequently recalled elicited larger P300s than those that were not, and that the type of orienting task given to the subjects had an effect on whether an isolation effect was obtained or not.

The memory effects that can be observed in the ERP during study are not limited to isolated or rare items. In several recent studies, memory paradigms have been used that do not capitalize on stimuli for which the P300 is expected to be enhanced – that is, paradigms in which neither the distinctiveness nor the probability of occurrence of the stimuli to be memorized are manipulated. A seminal study in this respect is that by Sanquist, Rohrbaugh, Syndulko, and Lindsley (1980), which found that larger amplitude P300s (or late positive components) were elicited, in a same-different judgment task, by stimuli that were correctly recognized in a subsequent recognition test. Johnson, Pfefferbaum, and Kopell (1985) recorded ERPs in a study-test memory paradigm. They reported that the P300 associated with subsequently recognized words was slightly, but not significantly, larger than that elicited by nonrecognized words.

Paller, Kutas, and Mayes (1987) recorded ERPs in an incidental memory paradigm in which the subjects were asked to make either a semantic or a nonsemantic decision, and were subsequently, and unexpectedly, tested for their recognition or recall of the stimuli. They found that ERPs elicited during the decision task were predictive of subsequent memory performance, being more positive for words subsequently recalled or recognized than to words not recalled or recognized. Similarly, Paller, McCarthy, and Wood (1988) recorded ERPs in two semantic judgment tasks, which were followed by a free recall and by a recognition test. ERPs to words later remembered were again more positive than those to words later not remembered, even though the memory effect was smaller for recognition than for recall. Neville, Kutas, Chesney, and Schmidt (1986) recorded ERPs to words that were either congruous or incongruous with a preceding sentence in a task in which subjects were asked to judge whether or not the word was congruent with the sentence. They found that the amplitude of a late positive component (P650) predicted subsequent recognition.

Paller and colleagues called the larger positivity for items later memorized than for items not memorized the *Dm* (or Difference based on subsequent memory; Paller et al.,

1987). They used this terminology to stress the possibility that this difference may not be associated with a parietal P300, in part because the scalp distribution of the effect does not correspond exactly to that of the P300. In subsequent studies, Paller and colleagues (Paller, Kutas, Shimamura, & Squire, 1987; Paller, 1990) attempted to determine whether the *Dm* can be observed in indirect (priming) memory tasks as well as direct memory tasks, or whether it is specific to one form of memory. The results were ambiguous: in the first study (Paller et al., 1987) the *Dm* effect was evident for the direct tasks as well as for the indirect test (stem completion), but in a subsequent study (Paller, 1990) it was only evident for the direct memory tasks. Rugg (1995) summarized a large body of research investigating the relationship between ERPs and the subsequent memory, and concluded that there is an undisputed relationship between a late positivity in the ERPs and the subsequent memory for these items. However, whether or not the “subsequent memory effect” is in fact entirely due to an increased P300 is still subject to debate. It is possible that more than one memory effect may in fact be observable in the ERP, and its nature and scalp distribution may depend on whether or not the memory tasks emphasizes explicit memory instructions and/or the distinctiveness/probability aspects of items. It is important to emphasize that memory is a complex phenomenon that can be influenced by a multitude of variables and that can be probed with a number of different tests. Thus, it is unlikely that a single component of the ERP can be identified as *the* memory component. It is much more likely, and indeed more interesting, that a series of ERP components will prove to be significant in different memory tasks.

Several investigators have recently focused on differences in the scalp distribution of effects as a function of stimulus dimension. For instance, Mecklinger and Müller (1996) presented subjects with a visual recognition paradigm, in which stimuli varied in both position and shape. In different blocks, subjects compared the study and test stimuli on the basis of one of the two dimensions. The interest was in the differences between the potentials elicited by the same stimuli in the two tasks. These changes in the ERP were interpreted as being due to differential use of brain structures for memorization of the shape and position dimensions. The shape task was associated with a posterior (occipital) P200 component, which was not observed for the spatial memory task. In addition, Mecklinger and Muller replicated the P300 and frontal slow wave effects first reported by Karis et al. (1984), although the P300 had a different scalp distribution in the two tasks.

4.4.1.4. ERP effects associated with the repeated presentations of a stimulus. Since the 1970s, ERPs have been recorded in paradigms testing the recognition of a previously presented item. Some of these early studies employed the Sternberg memory search paradigm, in which the subject is first presented with a short list of items to be memorized (the memory set), and is then

presented with test items (one at a time) and is asked to indicate (using a speeded response) whether or not each item belongs to the memory set. Whereas most of this research focused on variations in the latency of P300 as a function of the number of items in the memory set (e.g., Ford, Pfefferbaum, Tinklenberg, & Kopell, 1982), it was generally observed that positive (yes) responses were associated with larger P300s (or more positive waveforms) than negative (no) responses. This phenomenon was later replicated in studies using a more traditional recognition paradigm (e.g., Karis et al., 1984).

Several investigators have attempted to determine whether the ERPs elicited by test items can be used to validate the so-called *two-process* model of recognition. According to this model, successful recognition may occur either because subjects experience the conscious recollection of having previously seen the test item, or because the item was familiar (although the subject could not recollect explicitly the previous encounter with the test item). The distinction between recollection and familiarity (see Tulving, 1985) has now become a central issue in the investigation of conscious (or explicit) and unconscious (or implicit) processes. A popular paradigm for this research involves using a recognition test that requires subjects to indicate whether they experienced recollection or familiarity when confronted with the test items (i.e., distinguish between REMEMBER and KNOW judgments). Using this paradigm, Smith (1993) observed that a larger P300 (or positivity) was observed for items for which the subjects indicated explicit recollection than for items for which they only experienced familiarity. Items for which a negative response was given elicited the smallest P300s. Smith (1993) interpreted these findings as indicating that the larger positivity is associated with the conscious recollection experience. However, alternative interpretations are possible, including one that assumes that the memory trace is stronger for items that are recollected than for items that are judged familiar. P300 would then be related to the "strength" of the memory trace, rather than to conscious experience. Another explanation was advanced by Spencer, Vila, and Donchin (1994), who suggested that different patterns of results were obtained by different subjects who performed the task in different ways, and that some of the amplitude differences obtained by Smith (1993) may also have been due to latency differences in the averaged waveforms.

Another body of research has focused on the effect of repeating task relevant items in tasks in which memory is not directly tested. As for the recognition paradigm, the repeated items are associated with increased positivity with respect to non-repeated items (e.g., Besson, Kutas, & Van Petten, 1991; Hamberger & Friedman, 1992; Rugg, 1990; for a review see Rugg, 1995). The interpretation of this finding is unclear. Rugg (1995), summarizing a large body of research, suggests that the increased positivity reflects a reduction of the N400 that is obtained after repeated presentations of a particular item (see next sec-

tion), rather than an increase in the amplitude of a positive component. He interprets this reduction in N400 as a manifestation of a context integration process: the first presentation of an item that is "out-of-context" requires processing, which is less required at its subsequent presentations. However, direct tests of this hypothesis have provided ambiguous results (for a discussion, see Rugg, 1995).

In the last few years, investigators have begun to shift their attention from establishing whether the P300 (and other ERP components) are related to various aspects of memory processes to using ERP components to address various types of issues in the memory literature. For instance, several investigators have examined whether the P300 or other ERP components can be used to determine whether subjects have previously encountered a particular stimulus (e.g., Farwell & Donchin, 1991; Johnson & Rosenfeld, 1992). A related question is whether ERPs can be used to separate true recognition from high-confidence false alarms (e.g., Fabiani et al., 2000; Gonsalves & Paller, 2003; Nessler & Mecklinger, 2003) – an issue of interest for understanding illusory memory phenomena (Roediger & McDermott, 2000). In this case, the basic claim is that ERPs can distinguish between different types of memory traces – those left by sensory processes and those associated with semantic processes. ERPs have also been used to separate processes associated with familiarity from those associated with recollection (e.g., Gonzalves & Paller, 2000). Again, the idea is that different types of brain processes underlie these two types of judgments, with familiarity judgments requiring only previous exposure to a particular item and recollection judgments requiring associations between the item and the particular context in which the item was experienced. These associations should in principle require additional processing, with consequent differences in brain activity at the moment of retrieval. A similar type of research has focused on the difference between recognition processing and judgments of order of stimulus presentation (Fabiani et al., 1999) or source memory (e.g., Trott et al., 1997; 1999).

Note that whereas repetitions of verbalizable items are usually associated with increased positivities, this does not appear to be the case for visual material that cannot be verbally categorized. For instance, Gratton, Corballis, and Jain (1997) reported a more negative ERP at parietal locations for old than for new test items in a recognition task using novel line patterns (see also Rugg, Soardi, & Doyle, 1995; Van Petten & Senkfor, 1996). In one experiment, Gratton et al. (1997) used divided-field presentations during the study phase, and foveal presentations during test. They showed an increased temporal negativity during the test phase (when the stimuli were presented centrally) that was systematically contralateral to the side at which the stimuli were presented at study. They interpreted their findings as evidence of a hemispheric organization of visual memory. This finding has been recently expanded to working memory paradigms (Gratton et al., 1998; Fabiani

et al., 2003; Shin, Fabiani, & Gratton, 2006), in which lateralized parieto-occipital effects are found to differentiate between items that were presented at study to the left or right of fixation. These lateralized potentials can be considered evidence for the re-activation of sensory memory traces during the retrieval process.

Another example of negative activity (this time larger at right frontal locations) associated with recognition processes has been reported by Friedman (1990). Although the significance of this activity is yet unclear, it is possible that it might be related to retrieval processes. Note that a negativity associated with retrieval processes had also been described by Wijers, Mulder, Okita, and Mulder (1989) in a combined visual/memory search paradigm.

4.4.2. The N400 and other language-related ERP components

In this section we will review a number of ERP components that appear to index various linguistic processes (for a more extended review see Kutas, 1997; this volume). The first of these components to be described is the N400, originally recorded in a sentence reading task by Kutas and Hillyard (1980a). In this paradigm, words are presented serially and the subject is asked to read them silently in order to answer questions about the content of the sentence at the end of the experiment. In two studies reported by Kutas and Hillyard (1980a), 25% of the sentences ended with a semantically incongruous (but syntactically correct) word. These “semantic oddballs” did not elicit a P300 response, as was expected, but rather a centro-parietal negativity peaking around 400 ms that came to be known as the N400. The amplitude of this response appeared to be proportional to the degree of incongruity: moderately incongruous words (“he took a sip from the waterfall” had a smaller N400 than strongly incongruous words (“he took a sip from the transmitter”). Kutas and Hillyard (1982) reported that the N400 to incongruous endings was slightly larger and more prolonged over the right than the left hemisphere (see also Kutas, Van Petten, & Besson, 1988). Recent evidence from intracranial recordings suggests that one important source for the N400 may be the parahippocampal anterior fusiform gyrus (McCarthy, Nobre, Bentin, & Spencer, 1995; Nobre, Allison, & McCarthy, 1994; see also Kutas, Hillyard, & Gazzaniga, 1988, for N400 in commissurotomy patients).

The basic incongruity effect reflected by the N400 has been replicated and extended, using variations of the sentence reading paradigm described above. One aim of these studies has been to determine whether the N400 is a specific manifestation of semantic processing, or whether it is elicited, for example, by other kinds of deviance. Kutas and Hillyard (1980b) showed that an N400 is elicited by semantic deviations, whereas a late positive complex (P300) is elicited instead by physical deviations in the same paradigm. In addition, Kutas and Hillyard (1983) inserted a number of semantic and grammatical anomalies in prose passages. They found that large N400s were

THE PIZZA WAS TOO HOT TO...

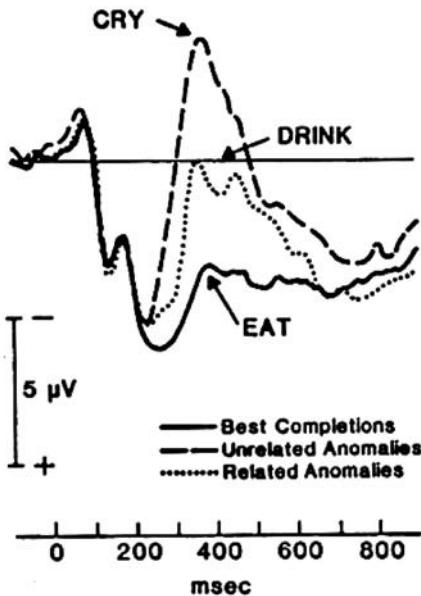

Figure 4.13. The effects of anomalous sentence endings on the N400. The ERPs (from Pz) depicted in the figure were recorded following visual presentation of words that varied in their relationship to the previous words in the sentence. For example, for sentences such as “The pizza was too hot to...”, three endings were possible. *Best completion:* “eat”; *Related anomaly:* “drink”; *Unrelated anomaly:* “cry.” Note that the N400 component is only present for anomalies, and is larger for unrelated than for related anomalies. (Reproduced with permission of the author and publisher from Kutas & Van Petten, 1988.)

associated with the semantic anomalies embedded in the text, but not with the grammatical errors. Besson and colleagues also found that anomalies in music elicited positivities rather than N400 responses (Besson & Macar, 1987; Besson, Faïta, & Requin, 1994). Thus, the N400 seems to be relatively specific to violations of semantic expectations.

However, the N400 does *not* seem to be a semantic “anomaly detector.” Instead, Kutas and Hillyard (1984) found that the amplitude of the N400 is closely related to the subject’s expectancy of the terminal word (cloze probability), but insensitive to sentential constraints (i.e., to the number of possible alternative endings). Kutas, Lindamood, and Hillyard (1984) also found that anomalous words that were semantically related to the sentence’s “best completion” (e.g., “the pizza was too hot to drink”) elicited smaller N400s than anomalous words unrelated to the best completion (e.g., “the pizza was too hot to cry”; see also Federmeier and Kutas, 1999). This suggests that degree of semantic relatedness is an important determinant of the N400 (see Figure 4.13), and, indeed, the N400 is also sensitive to semantic relations between words in pairs or in list format (semantic priming effects; e.g., Bentin, McCarthy, and Woods, 1985; Holcomb, 1988). For words out of context or in relatively weak contexts (including early in a sentence, before the context is established), N400 amplitude is also a function of word characteristics, such

as frequency (Van Petten and Kutas, 1990; Van Petten and Kutas, 1991), and of repetition (Van Petten et al., 1991).

Rather than being a response to semantic “oddballs,” then, the N400 seems to be part of the normal brain response to stimuli that carry meaning, or potentially do so. N400 responses are observed not only during reading, but also in the auditory modality (e.g., McCallum, Farmer, & Pocock, 1984; Connolly, Phillips, Stuart, & Brake, 1992) as well as in American Sign Language (ASL; Neville, 1985), and to nonverbal stimuli such as line drawings, pictures, movies, and faces (Ganis, Kutas, & Sereno, 1996; West & Holcomb, 2002; Sitnikova, Kuperberg, & Holcomb 2003; Barrett & Rugg, 1989). N400s of large amplitude are also observed to pronounceable pseudowords, including those that are not clearly derived from real words (Deacon, Dynowska, Ritter, & Grose-Fifer J., 2004), suggesting that activation of specific meaning information is not necessary for an N400 to be elicited. One interpretation of the N400 is that it reflects search through and/or activation of information stored in long-term memory (see Kutas & Federmeier, 2001 for a review).

Irrespective of its precise functional status, however, N400 has proven an important tool for testing theories and models of semantic activation and integration processes, for single words, sentences, and larger elements of discourse (see Kutas et al., this volume).

Several other ERP components have been observed in response to language processing. For example, a positivity, the P600 (sometimes called the syntactic positive shift, or SPS) is elicited by syntactic anomalies of a variety of types (e.g., Neville et al., 1991; Osterhout & Holcomb 1992); some take this to be within the family of late positivities, sensitive to probability, that includes the P300 (Coulson, King, & Kutas, 1998). A left anterior negativity (LAN) has been associated with other types of structural or referential difficulty, and has been linked by some to working memory (e.g., Kluender & Kutas, 1993). In addition, some slow-developing sentence-wide effects are visible when low-pass filtering is applied to the ERP encompassing an entire sentence (e.g., King & Kutas, 1995). Kutas et al. (this volume) provides more detail.

5. THE SOCIAL AND APPLIED CONTEXT

So far, we have discussed a number of experimental manipulations that affect various ERP components and allow investigators to make inferences about the cognitive significance of the electrical brain activity observed at the scalp. Our brain, however, is also processing emotions and attitudes, and plays a fundamental role in maintaining vital bodily functions (see Kutas & Federmeier, 1998, for an extended discussion of an integrated view of brain function). Thus, it is not surprising that emotional and social factors may also influence the latency and amplitude of ERP components. For example, experimental instructions are an important determinant of endogenous components. In fact, strategy instructions (e.g., Fabiani et al.,

1986), speed-accuracy instructions (e.g., Kutas, McCarthy, & Donchin, 1977), bargaining (e.g., Karis, Druckman, Lissak, & Donchin, 1984), and pay-off manipulations (e.g., Karis, Chesney, & Donchin, 1983) have all been shown to affect the ERP waveform.

As another example, Cacioppo and colleagues have conducted a series of psychophysiological studies of social attitudes, and advocate the use of psychophysiological measures especially in those cases in which subjects do not want to (or are unable to) talk about their attitudes (Cacioppo, Petty, Losch, & Crites, 1994; Cacioppo, Crites, Gardner, & Berntson, 1994; 1995; Cacioppo, Crites, Berntson, & Coles, 1993). Similarly, several investigators have recently used ERPs to investigate stereotypes and racial biases (Bartholow, Dickter, & Sestir, 2006; Amodio et al., 2004; and Ito, Thomson, & Cacioppo, 2004), as well as reactions to incongruous information in person perception (Bartholow et al., 2001, 2003; Bartholow & Dickter, 2007). A review of this social neuroscience perspective can be found in a recent chapter by Cacioppo and colleagues (Cacioppo, Lorig, Nusbaum, & Berntson, 2004).

Several researchers have investigated the effects of emotional stimuli on the ERP. By and large, the data have been interpreted in terms of emotion effects on cognitive processing. For instance, Vanderploeg, Brown, and Marsh (1987) compared the ERP responses to faces and words that did or did not convey emotional meanings, and found that P3 was larger for neutral faces. Kestenbaum and Nelson (1992) compared the ERP elicited by angry and happy faces in seven-year old children and adults, and found different effects of valence on P3 amplitude (see also Stormark, Nordby, & Hugdahl, 1995). Recently, Naumann and colleagues (Diedrich, Naumann, Maier, & Becker, 1997; Naumann, Bartussek, Diedrich, & Laufer, 1992; Naumann et al., 1997) have tried to identify ERP components specifically related to emotion rather than to cognitive processes. Their approach is based on an attempt to manipulate independently the emotional valence and the cognitive demands imposed by the stimuli. However, the results remain ambiguous, and the issue of whether there are ERP components that are specifically related to emotional processes is still open. One candidate seems to be a late, often sustained, right-lateralized posterior positivity that is enhanced for pictures with emotional content and, while modulated by a variety of task-related factors (many similar to those that modulate the P300), seems to be related to the intrinsic motivational significance of these stimuli (e.g., Schupp et al., 2000; Junghofer, Bradley, Elbert, & Lang, 2001).

There are now a considerable number of studies using ERPs in more applied areas. This includes work in human factors, for which we refer the reader to Kramer (this volume), as well as work on the use of ERPs in “lie detection” and on the effects of alcohol on the ERP. Studies of “lie detection” and ERP use a logic similar to that proposed by Cacioppo et al. (1994) in that stimulus words or phrases relating to a crime may be categorized in one way if the

information they represented was unknown to the individual, but in another way if the information was known. The role of the ERPs, then, is to identify the categorization rule being used by the subject, who may otherwise be unwilling to reveal his/her "guilty knowledge." Both the P300 (e.g., Farwell & Donchin, 1991) and the N400 (e.g., Boaz et al., 1991) have been used within this context.

As a final example of a more applied use of ERP research, investigators have been examining the effects of alcohol on P300 and other ERP components (such as the MMN and the O-wave) in the hope of (a) identifying possible biological markers of high risk to develop alcoholism (e.g., Polich & Bloom, 1988; Jaaskelainen, et al., 1996; Eckardt et al., 1996; for reviews, see Jaaskelainen, Näätänen, & Sillanaukee, 1996; Porjesz & Begleiter, 1996); or (b) identifying the acute effects of alcohol on cognitive and social processes, including person perception (Bartholow et al., 2003) and racial stereotypes (Bartholow et al., 2006).

6. SUMMARY AND CONCLUSIONS

In summary, research conducted over the past four decades has established the ERP as one of the main tools available to cognitive neuroscientists. The advantages of ERPs include their exquisite temporal resolution, relatively low cost and portability, and their high level of sensitivity to – and specificity for – aspects of cognitive processing. These qualities have allowed ERPs to be applied to the investigation of a number of theoretical issues that are relevant to cognitive psychology and cognitive neuroscience. Recently, several other neuroimaging techniques have flanked ERPs as tools for investigating the function of the human brain. However, rather than replacing ERPs as a method of choice, it appears that a combination of different approaches (including not only imaging methods but also neuropsychological and neurophysiological data) may provide a more complete description of the mind-brain system than the use of one technique alone.

Application of Transcranial Magnetic Stimulation (TMS) in Psychophysiology

BRUCE LUBER, ANGEL V. PETERCHEV, TERESA NGUYEN, ALEXANDRA SPORN,
AND SARA H. LISANBY

INTRODUCTION

In the past, much of the research in traditional experimental psychology came down to differences in accuracy and reaction time, and this paucity of measures often led to the inability to choose between competing theories. The promise of psychophysiological experimentation on humans lay in the extra measures it provided, opening a window to the mind by examining brain response. The drawback usually lay in the fact that the physiological evidence discovered was in general correlative: measured changes in brain activity could only suggest psychological relationships. The relatively recently developed technique of transcranial magnetic stimulation, or TMS, offers a way of noninvasively designing psychophysiological experiments that produce causal evidence linking brain with behavior. TMS involves the use of brief magnetic pulses to induce current flow in cortical tissue near the surface of the head, stimulating neurons in a focal region, generating a brief disruption of neural processing typically attributed to temporary, virtual lesions (Pascual-Leone et al., 2000). Actively affecting local cortical processing in this way, within the context of behavioral experimentation and brain imaging, allows causal relationships to be established.

1. THE HISTORICAL CONTEXT FOR PSYCHOLOGICAL INTEREST IN TMS

Historically, the development of magnetic neural stimulation has trailed that of its electrical counterpart. This lag can be explained with the technological challenges of generating the requisite large and rapidly changing magnetic fields, in contrast to the relatively weak currents deployed in electrical stimulation. Faraday's discovery of magnetic induction in 1831 revealed the fundamental physical law that would enable magnetic neural stimulation. Since the work of Galvani and Volta in the 1790s, it had been known that electrical currents can stimulate nerves and muscles. Faraday discovered that a time-varying magnetic field can induce current in conductors. Hence, changing magnetic

flux could excite nervous tissue as well. Indeed, in 1896, the French physicist and physician d'Arsonval discovered that subjects experience visual phosphenes (flashes of light) when placed in a strong alternating magnetic field. This finding was subsequently confirmed by other researchers. It was later determined that the phosphenes originated in the retina which has a high sensitivity to electrical currents, and hence a low stimulation threshold. In 1959, Kolin and colleagues demonstrated for the first time that alternating magnetic field can stimulate nerves in addition to the retina, by looping a frog sciatic nerve around the pole of an electromagnet and observing intense contraction of the gastrocnemius muscle. Soon after, Bickford and Fremming used pulsed magnetic field to elicit twitches in intact animals and humans, and asserted that this resulted from eddy currents induced in the vicinity of motor neurons.

In 1981, a team at the University of Sheffield in the United Kingdom led by Barker stimulated superficial nerves with single, short-duration magnetic pulses, and recorded the potentials evoked in nearby muscles. The Sheffield group developed their stimulator further, and in 1985 through the pioneering work of Jalinous, they accomplished transcranial magnetic stimulation of the human motor cortex, resulting in muscle contraction in the subject's hands. A few years earlier, Merton and Morton had demonstrated noninvasive transcranial electrical stimulation of the motor cortex. This technique is painful because it requires high voltages to be applied across the scalp to overcome the high electrical impedance of the skull. On the other hand, the magnetic field flux penetrates the cranium unobstructed, and causes no significant discomfort in the subject. The high impedance of the skull further results in a substantial spread of the current reaching the cortex from scalp electrodes, therefore deteriorating the focality of transcranial electrical stimulation. By contrast, the skull does not defocus the magnetically induced electric field. These aspects of magnetic induction constitute a core advantage in noninvasive brain stimulation. Consequently, despite its relatively recent development, TMS has spawned a wellspring of research and clinical applications. More extensive reviews of the history of TMS can be

found in Barker (2002), Walsh and Pascual-Leone (2003), and Geddes (1991).

2. THE ANATOMICAL AND PHYSIOLOGICAL BASIS OF THE SYSTEM AND THE RESPONSES OF INTEREST IN PSYCHOPHYSIOLOGY

2.1. Physical principles

TMS uses the principle of magnetic induction – the one that makes electrical transformers work – to produce transient electric currents in the brain. A coil of wire is placed over the head of the subject, and a large current pulse is delivered to the coil. This results in a brief, but powerful magnetic field generated around the coil. The magnetic field rises from zero to its peak value of over one Tesla in about a tenth of a millisecond. Following Faraday's law of magnetic induction, the changing magnetic flux generates an electric field which, in turn, induces current flow (eddy currents) in the conductive brain tissue. As a consequence of Lenz's law, the eddy currents in the brain under the coil flow in direction opposite to that of the current in the coil. These currents can produce a physiological response by depolarizing neuronal membranes, and thus triggering action potentials.

The TMS-induced electric field and eddy current distribution in the brain depends on a number of factors: the amplitude and shape of the coil-current waveform; the coil size, geometry, and orientation; and the conductivity profile of the head. The complex geometry of the brain, and the heterogeneity and anisotropy of its electrical properties make accurate computations of the electric field difficult. Studies modeling the head as a uniform conducting sphere arrive at two major conclusions (Branston and Tofts, 1991; Heller and van Hulsteyn, 1992). First, only electric fields parallel to the surface can be induced, and hence no radial (normal) field components exist. Second, the electric field maximum is always on the surface of the sphere. Local maxima can still exist inside the brain at the interface between regions with different conductivity, however the global maximum is always on the scalp. This basic fact, combined with the rapid falloff of the electric field strength away from the coil, confines magnetic stimulation to superficial areas of the brain. On the other hand, the rule that no electric field components normal to the scalp exist fails in more realistic models accounting for the brain's irregular geometry, as well as the heterogeneity and anisotropy of its tissue (Miranda et al., 2003; Wagner et al., 2004). These models suggest that the magnitude of the normal electric field component could be a significant fraction of the tangential field magnitude. Another conclusion of these studies is that CSF-filled lesions, such as the ones resulting from brain injury or stroke, can substantially distort the electric field and modify the site of neuronal activation. Further, the induced field in the tissue surrounding such an infarction can be significantly boosted. Therefore,

in both research and clinical settings, care should be exercised when subjects with brain pathologies are stimulated.

2.2. Physiological mechanisms

The electric field induced in the brain by a TMS pulse can depolarize or hyperpolarize the neuronal membranes, affecting the probability of firing of neurons under the coil. This is referred to as direct neuronal activation by TMS. To produce an action potential, the electric field must vary spatially along the length of a nerve fiber, resulting in transmembrane currents (Roth and Basser, 1990; Nilsson et al., 1992). The electric field geometries relative to the nerve fiber, which can induce membrane charges, are termed "activating functions." Transmembrane currents can result in either a straight nerve in a nonuniform field, or a bent or terminated nerve in a uniform field (Amassian et al., 1992; Maccabee et al., 1993; Abdeen and Stuchly, 1994). Because fibers in the cortex tend to be short and bent, TMS excitation is believed to occur at the location of the electric field maximum. By contrast, magnetic stimulation of long straight peripheral nerves takes place at the location of largest spatial derivative of the induced field. In the cortex, direct activation is most likely to occur at the bends and synaptic terminations of axons, whereas direct dendritic activation is considered unlikely at the stimulation levels commonly used (Nagarajan et al., 1993; Abdeen and Stuchly, 1994). Axonal excitation triggers both orthodromic and antidromic actions. Further, TMS can also activate neurons indirectly through transsynaptic interactions. Based on measurements in the hand area of the motor cortex, it has been estimated that the actual site of TMS excitation in the brain lies near the gray-white matter junction, which is located approximately 2 cm from the surface of the scalp (Epstein et al., 1990; Rudiak and Marg, 1994).

2.2.1. Motor cortex

The motor cortex is the most extensively explored part of the brain using TMS. The effect of TMS there can be easily quantified by the elicited motor evoked potentials (MEPs) in small hand muscles. The stimulation level with 50% probability of evoking an MEP with relaxed muscles is referred to as the motor threshold (MT), and the analogous metric with voluntary muscle contraction is called the active MT. The active MT is consistently lower than the MT. Two types of responses are identified in the MEP: direct (D) waves result from direct activation of the corticospinal axon, whereas indirect (I) waves arise from transsynaptic excitation of corticospinal neurons by cortical circuits (Terao and Ugawa, 2002). TMS at the motor threshold predominantly evokes I waves, but at higher intensities it may also evoke a D wave. The first I wave (I1) trails the preceding D wave by about 2 ms, whereas subsequent I waves (I2, I3, ...) arrive at increments of about 1.5 ms. The exact mechanisms of I-wave generation have not been elucidated (Ziemann and Rothwell, 2000), however, a recent

computational model of the thalamocortical motor system (Esser et al., 2005) has revealed a combination of intrinsic neuronal properties and circuit interactions that underlie this phenomenon. The orientation and direction of the current induced by TMS in the motor cortex affects the characteristics of the evoked response, which could be expected from the spatial sensitivity of the activating functions discussed above. Using a figure eight coil and a monophasic stimulus, the lowest threshold for MEPs from the hand area of the cortex is encountered when the induced current is in the posterior-anterior direction across the central sulcus (Brasil-Neto et al., 1992a; Di Lazzaro et al., 2004). This type of stimulation produces predominantly I waves. On the other hand, current induced in the latero-medial direction more easily recruits D waves (Di Lazzaro et al., 2004).

Thus, the application of a single TMS pulse can focally activate circuits in the motor cortex. A single TMS pulse can also produce modulation of cortical excitability over a short period of time, as demonstrated with the paired-pulse paradigm. Paired-pulse techniques use two subsequent TMS pulses, where the second one is used to probe for the excitability changes effected by the first one (Ziemann, 2002). The most common method is to apply first a subthreshold pulse, followed by a suprathreshold one. In normal subjects, delivering the pulse pair with an interval of 1 to 5 ms over the motor cortex results in a decrease of the amplitude of the MEP produced by the second pulse. On the other hand, interstimulus intervals of 10 to 20 ms yields an increase of the MEP amplitude (Kujirai et al., 1993; Ziemann et al., 1996). The MEP size changes are believed to result from intracortical inhibition and facilitation, respectively, via the activation of separate inhibitory and excitatory neuronal circuits in the motor cortex, which, in turn, connect synaptically to the output corticospinal cells (Ziemann, 2002).

While single-pulse TMS can modulate cortical excitability only in the short term, a train of magnetic pulses, referred to as repetitive TMS (rTMS), can produce long-term excitatory or inhibitory effects in neural circuits, which last beyond the stimulation interval. The neural response to rTMS is frequency sensitive. For instance, low-frequency (≤ 1 Hz) stimulation of the motor cortex has an inhibitory effect, whereas high-frequency stimulation (> 1 Hz) has an excitatory effect (Chen et al., 1997a; Berardelli et al., 1998; Pascual-Leone et al., 1998). Recently, it has been shown that motor cortex stimulation with theta-burst patterns (brief bursts of 50 Hz delivered at a 5 Hz) results in more intense and longer lasting modulation of motor evoked potentials than that seen with other delivery paradigms (Huang et al., 2005). Remarkably, in this study the stimulation was applied over a short period of 20 to 190 s, yet cortical excitability changes were observed for up to an hour. rTMS is believed to modulate excitability of cortical neurons by changing the effectiveness of synaptic interactions, analogously to electrically induced long-term potentiation (LTP) and depression

(LTD), however the exact mechanisms involved are not yet well understood (Terao and Ugawa, 2002; Huang et al., 2005).

2.2.2. Pulse types

The temporal characteristic of charge transfer to the neuronal membrane is determined by the TMS pulse shape and the membrane time constant. The time constants of neurons in the motor cortex and of peripheral alpha motor axons have been estimated to be around 150 μ s (Barker et al., 1991). For efficient stimulation, the induced electric field should have pulselwidth on the order of the membrane time constant. Indeed, most stimulator configurations have magnetic field rise and fall times in the 100 to 200 μ s range, yielding electric field pulselwidths in that range.

Available TMS devices usually produce one of three common types of magnetic pulse waveforms: monophasic, biphasic, and polyphasic. In the monophasic pulse, the current rises rapidly to its maximum value in about 100 μ s and then slowly decays to zero over about 800 μ s. Thus, the current in the coil flows in only one direction, and the corresponding magnetic field is unipolar. By contrast, in the biphasic pulse, the coil current completes a full cycle of a sinusoidal oscillation, with a typical period of around 300 μ s. Consequently, the magnetic field swings in both directions with almost equal amplitudes. Finally, the polyphasic pulse consists of a few periods of an exponentially decaying sinusoidal oscillation.

Monophasic pulses are usually used in stimulators in which the pulse repetition rate cannot exceed 1 Hz. On the other hand, biphasic pulses are implemented in rapid-rate stimulators that can produce pulse trains with frequencies of up to 100 Hz. Biphasic and polyphasic pulses accomplish stimulation with a lower peak magnetic field compared to monophasic pulses (Maccabee et al., 1998; Davey and Epstein, 2000; Kammer et al., 2001). However, because they produce electric fields with similar magnitudes in both polarities, oscillatory pulses tend to excite a larger population of neurons compared to monophasic pulses that induce electric fields with one preferential polarity. Further, optimal stimulation is achieved with the positive portion of the monophasic electric field, and, reversely, with the negative half-period of the biphasic electric field. Thus, the optimal coil current direction in biphasic stimulators is the opposite of that in monophasic stimulators. Finally, rTMS with monophasic pulses may produce stronger lasting changes of membrane excitability than biphasic rTMS (Antal et al., 2002; Sommer et al., 2002; Arai et al., 2004), possibly due to polarization effects of the predominantly unipolar induced electric field (Sommer et al., 2002).

2.3. Responses of interest to psychophysiology

The responses of interest to psychophysiology generated by TMS can be grouped into three categories, which

roughly follow a historical progression in their development. First are directly observable or phenomenological events caused by direct stimulation of primary motor and sensory cortex, such as finger twitches and phosphenes. Opposite effects can also be produced: behavioral omissions such as visual masking or speech arrest. The second category has to do with measured changes in performance of psychological tasks caused by TMS, for example, changes in reaction time or accuracy. The third category is changes in measured brain activity, such as EEG, PET, and fMRI. A fourth category can be added as well, which has to do with long-lasting neuromodulatory events, such as mood change in depressed persons or learning.

2.3.1. Directly observable or phenomenological events

The most obvious and easy to evoke TMS responses are caused by stimulation of primary motor cortex, and indeed these were the first to be historically observed (Barker et al., 1985). A TMS pulse of sufficient intensity placed at an appropriate scalp location over motor cortex can produce a muscle twitch. These are best measured with electromyography (EMG), in which electrodes are placed on the skin over the targeted muscle. A characteristic voltage change occurs with TMS induced muscle contraction, having a relatively constant onset latency (e.g., between 20–30 ms for the first dorsal interosseous muscle in the hand) and an amplitude related to TMS intensity. With a sufficiently focal coil, topographic mapping of motor cortex can be achieved with TMS (Brasil-Neto et al., 1992b). General cortical excitability is thought to be related to TMS induced motor response, and is typically measured using staircase methods to obtain a motor threshold. A number of aspects of the EMG-measured response to TMS have been explored. For example, response amplitude caused by a TMS pulse can be facilitated or inhibited by an immediately preceding pulse (Kujirai et al., 1993).

Aside from affecting motor systems, TMS can also generate sensory events, at least in the case of the visual system. In most people, occipital stimulation of enough intensity evokes phosphenes – short-duration unstructured flashes. The flashes tend to be colorless, although slight red or green tinges have been reported with increasing intensity. They are difficult to localize in the visual field, although they can be crudely mapped (Meyer et al., 1991; Kammer et al., 2005). Like motor thresholds, TMS phosphene thresholds can be reliably found using psychophysical staircase methods (Ray et al., 1998; Rauschecker et al., 2004) and may be related to cortical excitability (Stewart et al., 2001). At present, only in the visual modality have TMS evoked sensations been found: no observations of TMS induced sounds or somatic sensations with direct stimulation of primary auditory or somatosensory cortex have been reported.

Besides inducing observable events, TMS can also prevent behavioral or perceptual events from occurring. Such TMS-induced disruption is typically attributed to temporary, virtual lesions in the cortical regions directly stimu-

lated (e.g., Pascual-Leone et al., 2000). A straight-forward example in the motor system is speech arrest caused by trains of TMS to left frontal speech production regions (e.g., Pascual-Leone et al., 1991). In the visual system, a single pulse from a magnetic coil placed over the occipital cortex will reduce the visibility of a briefly presented target stimulus to the point where it cannot be identified, if the magnetic pulse is triggered in a time window centered around 80 to 100 ms after the visual presentation (Amassian et al., 1989). The effect of such a pulse has some of the properties of a (temporary) visual field scotoma (Kamitani and Schimojo, 1999).

2.3.2. TMS effects on psychological variables

TMS has been found to produce many subtle effects that can only be measured across many trials using performance variables commonly used in experimental psychology, such as reaction time (RT), accuracy, and discrimination (e.g., d'). For example, quantification of hits, misses, false alarms and correct rejections of visual target presentations while single pulses of TMS were applied to the frontal eye fields (Brodmann area 8) led to a determination that the TMS increased visual discrimination (d') in a backward masking task (Grosbras and Paus, 2003). Depending on the timing, frequency, and location of TMS application, in various tasks TMS has been shown to speed up or slow down RT, as well as increase or decrease accuracy. For example, trains of 20 Hz rTMS applied over Wernicke's Area immediately prior to a picture presentation sped picture naming RT (Sparing et al., 2001), whereas RT increased in a visual continuous performance task with single pulses of TMS over left dorsolateral prefrontal cortex applied 180 ms after target onset (Mottaghay et al., 2003). Trains of high-frequency rTMS applied to parietal cortex immediately before a mental rotation task increased accuracy (Klimesch et al., 2003), while similar trains presented during a visual working memory task decreased accuracy (Pascual-Leone and Hallett, 1994).

Systematic measurements of performance variables has resulted in an explosion of studies in recent years exploring functional aspects of the entire cerebral cortex, beyond primary motor and sensory areas. In the motor system, such studies include investigations of motor planning (Serrien et al., 2002; Kennerley et al., 2004), motor imagery (Pulvermüller et al., 2005), consolidation of motor learning (Muellbacher et al., 2002), cognitive and sensory interactions with motor cortex (Bonnard et al., 2003), and eye movement (O'Shea et al., 2004). The large amount of cerebral cortex devoted to it has made the study of visual perception quite amenable to TMS techniques. Many aspects of visual processes have been studied, from binocular (Saint-Amour et al., 2005) and motion discrimination (Matthews et al., 2001) to word recognition (Lavidor and Walsh, 2003), illusory contours (Brighina et al., 2003), and visuospatial processing (Aleman et al., 2002). Beyond motor and sensory systems, TMS effects have also been uncovered in higher order cognitive processing, in areas

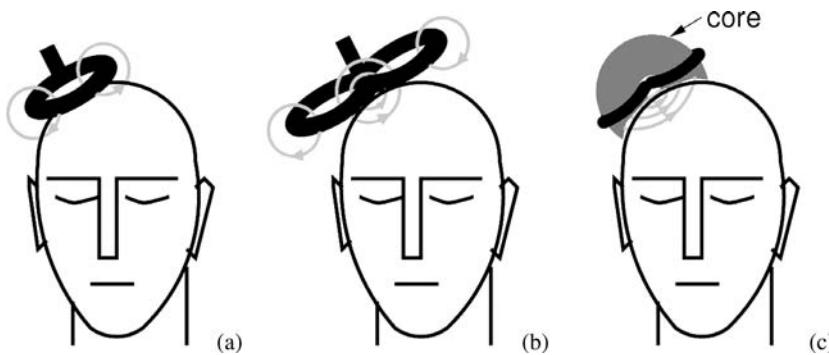

Figure 5.1. Common TMS coil types with corresponding induced electric field shape: *A* circular coil, *B* figure-eight coil, *C* figure eight coil with ferromagnetic core.

such as attention: (Rushworth et al., 2001), task switching (Rushworth et al., 2002), response selection (Hadland et al., 2001), and memory (both short term: Rami et al., 2003; Sandrini et al., 2003, and long term: Rossi et al., 2001), as well as mental imagery (Kosslyn et al., 1999; Sparing et al., 2001; Sparing et al., 2002) and language processing (Shapiro et al., 2001).

2.3.3. TMS induced changes in measured brain activity

While muscle responses and changes in performance measures supply indirect evidence of TMS-induced effects on the brain, in recent years technical improvements in PET, fMRI, and EEG have allowed direct observation of these effects. A closer coupling of TMS and brain imaging allows for a more precise examination of the brain/behavior relationships. It also enables exploration of the connectivity of the stimulated site and other parts of the network it is a part of. For example, 1 Hz TMS stimulation of the motor cortex not only produced activation of that region, but also correlated activation of locations known to be anatomically connected, such as same-hemisphere secondary motor region and supplementary motor area as well as primary and secondary somatosensory regions, and the homologous opposite hemisphere primary motor cortex (Fox et al., 1997). TMS stimulation at 1 Hz of the motor cortex activated the motor network similarly with fMRI, including the expected cortical regions in both hemispheres, and thalamus, basal ganglia, and cerebellum; moreover, this pattern of activation was indistinguishable from that generated by voluntary movement of the same muscles (Denslow et al., 2005). Topographic EEG recording showed the time course of motor network activation, beginning with primary motor cortex directly beneath the coil at 3 ms, with adjacent ipsilateral motor and premotor areas activated over the next 10 ms, and homologous contralateral motor areas active 20 ms post-TMS pulse (Ilmoniemi et al., 1997). The results from all three imaging modalities reflect the expected connectivity of the motor system. This, along with the Denslow et al. finding that TMS connectivity associated with involuntary muscle contractions matched connectivity under “normal” use of those muscles aids in building confidence that less understood networks associated with other behaviors might be successfully mapped using conjoint TMS and imaging techniques. Paus (2002) provides a review of such

explorations in frontal cortex; Paus (2005) reviews some of the advantages and limitations of the method.

3. THE TECHNICAL ISSUES INVOLVED IN DATA ACQUISITION

3.1. Stimulator design

A typical magnetic stimulator consists of five basic components: a charger, an energy-storage capacitor, a discharging circuit, a stimulating coil, and a control circuit (Jalinous, 2002; Ruohonen and Ilmoniemi, 2005). The charger converts AC line voltage to a high DC voltage to charge the energy-storage capacitor. The capacitor can then be connected to the coil through the discharging circuit, yielding a high-current pulse which, in turn, produces a strong transient magnetic field around the coil. Commonplace capacitor voltage, peak coil current, and peak magnetic field are as high as 3000 V, 10,000 A, and 2 T, respectively.

Two basic categories of TMS stimulators are currently available: single-pulse and rapid-rate. Single-pulse stimulators cannot repeat pulses at rates greater than 1 Hz. These stimulators typically produce monophasic pulses. On the other hand, rapid-rate stimulators can generate pulse trains with higher frequencies, reaching 100 Hz in the most advanced models. These stimulators are exclusively used in rTMS applications. They produce biphasic pulses that allow a substantial portion of the energy delivered to the coil to be recycled back to the capacitor for reuse in the subsequent pulse. High-quality, rapid-rate stimulators guarantee the uniformity of the pulse trains, as variability of the individual pulse amplitudes can compromise the safety and the outcome of the procedure. Finally, in paired-pulse paradigms, two magnetic pulses are delivered within as little as 2 ms of each other (Ziemann, 2002). To accomplish such a short interstimulus interval, the outputs of multiple stimulators can be combined within a special device to deliver pulses to a single coil (Jalinous, 2002).

3.2. Coils

Figures 5.1A–C show some TMS coils in common use. The circular TMS coil (Barker et al., 1985) is depicted in Figure 5.1A. Typical circular coils for humans have a 9 cm

mean diameter. Pulsing current through the loop produces magnetic flux passing perpendicularly to the plane of the coil. The transient magnetic flux will induce a circular electric field parallel to the plane of the coil, with maximum strength immediately under the wire loop. The circular coil has poor stimulation focality due to the broad, circular electric field maximum obtained. The focality can be somewhat improved by placing only one edge of the coil over the scalp. Roth et al. (1991) calculated the electric fields induced by a number of circular coil configurations in a three-layer spherical head model.

The figure eight coil (Ueno et al., 1988) is shown in Figure 5.1B. In this configuration, two circular coils carry current in opposite directions, and their magnetic fields are constructively combined at the point where the loops meet. The resulting electric field pattern is more focused than that of the circular coil. One measure of focality is the area of tissue with electric field strength of over half the peak value. Thielscher and Kammer (2004) estimated that for a common commercial figure eight coil with a 7 cm mean loop diameter, placed 1.5 cm above a spherical model of the cortex with radius of 8 cm, the focality on the cortical surface is 35 cm². This model also yields electric field strength of 66% and 33% of the surface value, at 0.86 cm and 2.34 cm depth in the cortex, respectively. While these measures of electric field focality are an important metric for characterizing coils, they are only indirectly related to the actual functional focality of TMS. The functional focality depends on a number of parameters, such as the electric field distribution, the orientation of the neural fibers, and the pulse shape. Topographic mapping studies of the human motor cortex, using a figure eight coil with 4.5 cm loop diameter, suggest a practical spatial resolution of TMS of 0.5 cm (Brasil-Neto et al., 1992b).

There exist variations of the figure eight coil, such as the double-cone coil, where the two loops form a 95° angle, and have larger diameters. The double-cone coil can stimulate brain regions located 3–4 cm in depth from the scalp surface, such as the leg area of the motor cortex, but is less focal than the figure eight coil. In general, larger coils tend to provide deeper field penetration, but have poorer focality. For efficient stimulation, it is important that the coil is comparable in size or smaller than the dimensions of the targeted body part (Weissman et al., 1992). For example, scaled-down coils should be used for TMS in children and animals with small crania. Small coils should also be used for peripheral nerve stimulation. For example, figure eight coils with loop diameters down to 2.5 cm are used for animal studies and for peripheral nerve stimulation. The implementation of even smaller coils is constrained by technical limitations.

The coils described above are referred to as air-core coils. A more efficient TMS coil can be implemented by introducing a high-permeability ferromagnetic (iron) core in the figure eight configuration (Figure 5.1C). The iron-core coil (Epstein and Davey, 2002) has larger penetra-

tion depth and induced electric field strength, and higher energy efficiency, compared to air-core coils. These advantages stem from the property of the core to focus the magnetic field to the subject's head. One potential disadvantage of ferromagnetic core materials is that they saturate at field strengths of about 2 T.

A number of practical considerations have to be kept in mind when choosing and deploying TMS coils: Most air-core coils tend to heat up when used with high-energy, high-frequency pulse trains. Commercial coils have built-in thermal sensors that shut the device down if the coil temperature exceeds a safe limit. Special air-cooled and water-cooled coils have been developed for use with high-power trains. Iron-core coils are more efficient and tend to heat up less.

3.3. Safety

In and of themselves, magnetic fields do not pose any discernable risk to humans (National Research Council, 1996). The greatest potential risk in the use of TMS is seizure. Up to 1996, five seizures were reported in neurologically sound, healthy subjects in the early development of rTMS procedures (Wassermann, 1998). These seizures appeared to be the result of excessive stimulator intensity, pulse frequency and train duration and too short inter-train intervals, in various combinations, and resulted in the establishment of safety guidelines for each parameter (Wassermann, 1998). Since the publication of these guidelines, no seizures have been reported in normal participants in TMS studies staying within the suggested safe boundaries.

Higher frequencies of rTMS are most closely associated with seizure risk. Seizures have not been reported when using low frequency TMS (pulses given at a rate of 1 Hz or less, including single-pulse TMS) in healthy subjects. However, single-pulse and paired-pulse TMS have resulted in seizures at rates of up to 2.8% and 3.6%, respectively, in patients with epilepsy (Schrader et al., 2004). Thus, participants should be screened carefully for epilepsy and family history of epilepsy (and neurological status in general), even for low frequency TMS studies.

While quite specific about stimulator intensity, pulse frequency and train duration, the published guidelines were not so clear on length of inter-train intervals. It is now generally accepted that ITI's of greater than or equal to 5 seconds are considered safe for high frequency stimulation (Chen et al., 1997b).

Intensity of TMS used should be tied to the individual's motor threshold. The motor threshold is an estimate of cortical excitability, and is thus thought to be related to seizure susceptibility. However, it should be kept in mind that the motor threshold is only an estimate of general cortical excitability, because it is highly dependent on the distance of the coil to motor cortex, and thus to skull thickness, which is quite variable even in the same individual (McConnell et al., 2001). There is also evidence

that cortical reactivity itself varies from region to region (Kahkonen et al., 2004).

Aside from seizure, other adverse effects of TMS include headache and hearing effects. Stimulation over superficial muscles and nerves can result in headaches and local muscle aches, especially with high-frequency TMS. Cramped conditions extended in time within frameless stereotaxic apparatus can also lead to head and body aches. In addition, with TMS animal studies have shown permanent increases in auditory threshold in animals (Counter et al., 1990) and transient increases in humans (Pascual-Leone et al., 1992), leading to the recommendation that all participants wear ear plugs with TMS exposure.

In addition to neurological damage, there are other reasons for exclusion from TMS investigations. Because TMS can heat and move metal, anyone with metallic implants in the head (excluding the mouth) should not participate in TMS studies. Neither should persons with implanted pacemakers or other medical devices, as TMS can disrupt their circuitry. Also, as the effects of TMS on developing bodies are unknown, children and pregnant women should not participate.

4. THE STANDARDS AND METHODS FOR THE QUANTIFICATION AND ANALYSIS OF THESE PHYSIOLOGICAL EVENTS

Investigation of TMS effects on the motor system usually involve measurement of motor evoked potentials (MEPs) using electromyography (EMG). Guidelines for the use of EMG are available elsewhere (e.g., Fridlund and Cacioppo, 1986). Even when not doing motor system research, most TMS studies involve EMG measurement because the choice of stimulator intensity for each participant is governed by his or her motor threshold (MT). As such, EMG recording in TMS will be illustrated within a description of motor threshold procedures.

4.1. Motor threshold

Motor threshold is the minimum stimulus intensity required to produce a reliable MEP in a target muscle (see also Section 2.2.1). In TMS, the MT is the basic unit of dosing and is important in regards to safety. Finding the motor threshold begins with choosing a target muscle, which is usually the abductor pollicis brevis (APB) or first dorsal interosseus (FDI), and attaching recording and ground electrodes. Braiding the electrode wires will reduce artifact. The next step requires hunting for and locating the optimal spot on the scalp that will elicit a reliable MEP. Once the optimal spot is found, the procedure involves positioning the coil in place and finding the motor threshold intensity.

4.1.1. Coil types and coil orientation

With TMS, there are many commonly used coil types (see Section 3.2). Determining which coil type and stimulus location to use mainly depends on what target muscle

is being stimulated (Reid et al., 2002). For distal upper extremity muscles, use a circular coil with vertex localization or a figure eight coil with lateral localization. For proximal upper extremity muscles, use a circular coil with vertex localization. For lower extremity muscles, use either a circular coil or saddle-shaped figure eight coil with localization 2 cm anterior to vertex (Reid et al., 2002).

Excitability of the motor cortex also depends on the direction of the current and the current pulse waveform (Kammer et al., 2001). For monophasic stimulators (e.g., Magstim 200 and Dantec Magpro), the current direction should flow posterior to anterior. Thus, for stimulating the right hemisphere using circular coils centered over the vertex, a clockwise current gives better stimulation, and a counterclockwise current is better for left hemisphere stimulation (this is achieved by turning the coil over, which reverses the current's direction) (Rossini et al., 1994; Reid et al., 2002). If using figure eight coils, placement should be laterally to the vertex, tangentially over the skull/scalp, and perpendicular to the central sulcus (this can be achieved by having the handle of the coil rotated clockwise about 30–45° in the tangential plane) (Kammer et al., 2001; Reid et al., 2002; Awiszus, 2003). For biphasic stimulators (e.g., Magstim Rapid), the most effective current direction is opposite to that for the monophasic stimulators and so, biphasic stimulators are more powerful if their first phase crosses the motor cortex in an anterior to posterior direction (Kammer et al., 2001).

4.1.2. Different methods of threshold-estimation

Though motor threshold is a basic neurophysiological measure of cortical excitability, there are different methods to estimating the motor threshold. The methods vary in such aspects as determining the coil position, defining a reliable response, method of finding the threshold intensity, and number of consecutive stimuli delivered. In estimating the motor threshold, an international committee (IFCN) (Rossini et al., 1994) recommends the following procedure: (1) localize the coil on the frontoparietal region contralateral to the target muscle and move the coil around until the 'hot spot' where the threshold is lowest and the onset latency is shortest is found; (2) increase the stimulus intensity progressively at 5% steps until reaching a level that induces reliable (usually around 100 µV) MEPs in about 50% of 10–20 consecutive stimuli and define this as the excitability threshold. A method recommended by Mills and Nithi (1997) involves placing the coil over a point 5 cm lateral to the vertex on the interaural line for the coil position and averaging the lower threshold (maximum intensity at which 10 stimuli do not produce a response) and upper threshold (minimum intensity at which 10 stimuli all produced a response). In their method, a positive response was any recognizable response of >20% µV amplitude at a latency of 17–30 ms. Another method recommends first finding a spot that elicits the largest response by moving the coil around a few centimeters then decreasing the stimulus intensity by 5% increments until reaching an intensity when fewer than 50% of

six consecutive stimuli elicits a response >20 μ V amplitude. The threshold is the lowest intensity when there are at least three of six responses (Reid et al., 2002). (Ascending and descending methods of threshold estimation will yield different results (Reid et al., 2002). A fourth type of threshold-estimation is “adaptive threshold-hunting” (Awiszus, 2003). This procedure estimates threshold continuously throughout the stimulus sequence, where the stimulus strength that is to be used for the next stimulus is calculated from the information obtained from the previous stimuli (Awiszus, 2003). An example of this procedure is the Maximum-Likelihood Strategy using Parameter Estimation by Sequential Testing (MLS-PEST).

4.1.3. Comparison studies of motor threshold

A few studies have compared the different methods of determining the motor threshold. In terms of coil positioning, Conforto et al. (2004) compared the positioning used by Mills and Nithi (1997) (standard position of 5 cm lateral to vertex on the interaural line) to hunting for the optimal position. In this study, the optimal position was found by moving the coil anteroposteriorly and mediolaterally in relation to the standard position in steps of 0.5 cm. They found that the motor threshold was lower at the optimal position than at the standard position. In two studies (Pridmore et al., 1998; Conforto et al., 2004) compared estimating the motor threshold based on visual movement of the hand to a method based on MEP responses. Pridmore and colleagues found that both methods yielded similar results (<10% difference in percentage of total machine output), and, though not significant, the motor threshold obtained by visual movement was often less than one that was obtained by a neurophysiological method. In contrast, Conforto et al. (2004) did find a significant difference in the two methods. The MEP-obtained motor threshold was lower than the motor threshold obtained by the visual movement method. In this study, they also found that performing six instead of ten consecutive trials (i.e., finding reliable responses in 3 out of 6 trials or in 5 out of 10 trials) did not produce differences in motor threshold measurements. Comparison studies (Awiszus, 2003; Mishory et al., 2004) have also examined the efficacy of the different methods of threshold-estimation. Awiszus (2003) compared the IFCN, Mills-Nithi, and MLS-PEST methods and found that the IFCN method was the least accurate and most time consuming whereas the MLS-PEST method was more accurate and less time consuming than the IFCN and Mills-Nithi methods. Mishory et al. (2004) also found the MLS-PEST method to be faster and it used fewer pulses to estimate the motor threshold than a method that was a modification of the IFCN method.

4.2. Experimental issues in TMS

Due to the extremely short duration of TMS pulses, TMS application, particularly in single or paired pulse situations, can be fit into traditional psychological tasks measuring accuracy or RT without change, essentially adding

another independent variable for TMS condition. For example, exacting perceptual psychophysical procedures have been used to obtain visual contrast sensitivity thresholds with and without the presence of occipital TMS, in order to provide evidence for the idea that masking effect of TMS is due to an increase in contrast sensitivity most likely caused by the addition of neural noise (Kammer and Nusseck, 1998). In another example, the use of TMS provided evidence that two primary properties of visual motion, speed and direction, can be analyzed independently in the brain (Matthews et al., 2001). In this case, a psychophysical paradigm had already been developed to examine speed and direction discrimination separately in the same set of moving stimuli, using discrimination and bias measures derived from signal detection theory (Matthews and Qian, 1999). Occipital single pulse TMS resulted in large shifts in the bias measure: with TMS, participants became biased to make the choice of slower (as opposed to faster), regardless of the actual speed of the stimulus. Bias in the case of direction discrimination was unaffected by TMS. In effect, TMS altered perceived speed, making stimuli appear to move more slowly, without changing perception of motion direction. This study illustrates one of the best uses of TMS in psychophysiology: employing it within a well-developed experimental paradigm in order to use interruption of brain processes to help decide between theoretical alternatives (in this case, on the independence of speed and direction processing) that have been difficult or impossible to determine with behavioral evidence alone.

On the other hand, a great deal of care must be taken in adapting TMS to this use, as magnetic stimulation has strong superficial effects that can be distracting and disruptive to a finely tuned task paradigm. With TMS, subjects are quite aware that they are part of a physiological as well as a psychological experiment. The pulse creates a sharp clicking noise, quite audible even with earplugs (note: bone transmission of sound as well). There is a somatic sensation in the scalp directly beneath the coil, usually described as a tapping or thumping. Depending on the particular superficial nerves and muscles near the coil, magnetic pulses can produce startling and even painful contractions locally and in the jaws, face, and neck. Study participants must be monitored quite closely, for obvious humane reasons but also to determine the extent the superficial effects of TMS may be interfering with task performance. There is a great degree of intersubject variability both in physical anatomy and in distractibility and pain thresholds, suggesting that pain and discomfort ratings for each scalp location used should be a normal part of the data collected.

It should be noted that not all the superficial effects of TMS are directly observable: some are quite subtle. For example, Pascual-Leone et al. (1994) reported that in a simple RT task, a single TMS pulse to motor cortex immediately before the cue to respond could shorten response time. However, it was later demonstrated that the same simple RT facilitation could be produced by single pulses

applied to other parts of the head or neck, and by sham stimulation (Terao et al., 1997). Terao et al. suggested that what was actually being observed was intersensory facilitation (IF), a well-studied effect in which simple RT can be shortened if the cue signal is accompanied by a second stimulation, such as the auditory click of a TMS coil, or the physical sensation TMS causes in skin and superficial muscle.

4.2.1. Pulse timing contrasts

If even unobservable superficial effects can alter task performance, careful choice of control conditions that adequately account for them becomes paramount in a TMS experiment. It is clear that comparing a condition in which there was no TMS with a condition in which there was may not be sufficient. The best comparisons are made between conditions in which TMS occurred during the same task. This has usually been achieved in one of two ways: either by manipulating temporal or spatial aspects of TMS application, or by the use of sham TMS.

One way to compare the effects of TMS is to vary the time pulses are given relative to the timing of the task. One of the clearest examples of this was the first demonstration of the masking of visual stimuli by single magnetic pulses (Amassian et al., 1989). Participants were to identify triplets of letters presented for a few milliseconds in the center of a computer screen. At various times relative to the stimulus presentation, ranging from 0 to 200 ms, a TMS pulse was applied occipitally. Subjects were not able to identify the letters when TMS pulses occurred in a time window centered around 80 to 100 ms after the visual presentation, whereas they had no such difficulty at points outside this window. A physiological explanation is relatively straightforward: the window of visual disruption corresponds to the time when target information initially reaches visual cortex and processing there has begun. Stimulation at time points outside this period has little or no effect on the neural processing underlying letter identification, and performance with stimulation at these outside time points can be used to measure the relative effects of disruption. However, choice of “inactive” time points can be problematic. For example, the single-pulse TMS study of visual motion mentioned previously (Matthews et al., 2001) followed the active/inactive time point strategy. It was initially thought that a condition with pulses 0 ms after stimulus onset could serve as a comparison point, because, as in Amassian et al., these pulses could not affect task-related processing, as they occurred well before visual information reaches visual cortex. Unfortunately, processing in the task was disrupted at this time (as it also had been in a previous TMS study of visual motion: Beckers and Zeki, 1995), and further experimentation was necessary to establish a point 200 ms prior to the onset of the visual stimulus as nondisruptive. In general, because the time course of neural processing underlying performance in a given task is unknown (and is often the goal of the study), the choice of reference time points can

not be determined *a priori* and can only be approached empirically.

4.2.2. Topographic contrasts

Another way to compare the effects of TMS on a task is to stimulate at multiple scalp sites. This is in general done one site at a time, although it is possible to use two coils on the head simultaneously. The most straight forward comparison is between an “active” site (i.e., one where TMS is expected to affect measured behavior) and an “inactive” site. For example, in a visuomotor task in which the participant was to point in a clockwise or counter-clockwise direction by an instructed amount, 20 Hz rTMS to left or right posterior parietal cortex caused RT to be prolonged compared to RT when TMS was applied to the vertex of the head (Bestmann et al., 2002). In this case, TMS to the vertex, which overlies motor leg areas, was not expected to affect task performance and thus was considered an inactive control site. Another approach is a double-dissociation technique, in which sites are chosen where opposite effects are expected to occur with different tasks. In one study for example, a spatial working memory task was disrupted by 1 Hz rTMS to dorsomedial prefrontal cortex but not to ventrolateral prefrontal cortex, while a working memory task using faces as stimuli was disrupted by 1 Hz rTMS to ventrolateral prefrontal cortex but not to dorsomedial prefrontal cortex (Mottaghy et al., 2002). Although comparison of effects across sites is a valid approach, care must be taken in choosing sites that have similar superficial effects, keeping in mind that distracting or painful stimulation can also alter task performance.

4.2.3. Sham TMS contrasts

Use of sham TMS provides another way to observe TMS effects. For example, when 1 Hz rTMS was applied to a left prefrontal site, verb production (but not noun production) was slowed, whereas no such slowing occurred with sham TMS applied at the same location (Shapiro et al., 2001). A valid sham should simulate the ancillary aspects of TMS, such as scalp stimulation and acoustic artifact, as closely as possible to actual TMS but should not result in cortical stimulation. The most common sham conditions angle the coil off the head so that the magnetic field stimulates scalp muscles and produces an acoustic artifact, but presumably does not induce current in the cortex. In this case, the coil should be placed perpendicular to the head, as positions angled less than 90° do result in substantial cortical stimulation (Lisanby et al., 2001). Although use of sham conditions eliminates variation due to different stimulation sites or different times of stimulation used in other comparison methods, it does introduce a new problem in that sham does not feel the same, or, if the coil is visible, does not look the same, as real TMS. This is an especially difficult problem in clinical experimentation, as it can remove the blind from the participant. It also is problematic when observing task performance, as sham stimulation is in general much less distracting. One promising approach is the

use of coils that can be electronically switched between the sham and verum condition (Ruohonen et al., 2000). In the figure eight configuration, the currents in the two loops can be switched to flow in the same direction (verum condition) or in opposite directions (sham condition) at the coil center. In the latter case, the electric field under the coil center is reduced to zero, while peripheral field strength is increased: currents are not induced in underlying cortex, but auditory and somatic effects are comparable to actual TMS.

4.3. Spatial targeting

Initially, placement of TMS coils was done by hunting over likely regions where stimulation would create observable effects (e.g., lateral areas near the head's vertex for motor stimulation of the hand) and finding a point of optimal effect. Unfortunately, this method is limited to stimulation of primary motor and sensory areas. Investigators quickly adapted the International 10/20 System for EEG electrode placement for coil placement, as imaging studies have provided some idea of what portions of the cerebral cortex underlie standard electrode sites (e.g., Homan et al., 1987). For example, Harris and Miniussi (2003) wanted to stimulate right and left posterior superior parietal lobe, and marked two points, one halfway between P3 and CP3, and the other halfway between P4 and CP4, as the best estimated scalp locations corresponding to that region in left and right hemispheres. Such use of 10/20 coordinates do provide reasonable estimates of cortical locations to target TMS. However, there is considerable variability between individuals in the relationship between 10/20 scalp sites and the underlying cortex (Homan et al., 1987). A much more reliable (although expensive) method has become available in recent years: using a frameless stereotaxic system involving coregistration of the TMS coil to individual structural high-resolution T1 MRI scans. Hardware/software systems have been developed that offer real-time 3-D display of cortical localization as the TMS coil is moved across the scalp. An infrared camera is used to continuously monitor the location in space of the subject's head and of the TMS coil, via sensors attached to each. Coregistration is achieved by mapping the spatial coordinates of head landmarks (e.g., tip of nose and pre-auricular points), found optically, with their corresponding coordinates in a 3-D reconstruction of the head in MRI space. The coil can then target locations in space that correspond to desired locations in the individual's brain. The position of the coil relative to the participant's head is kept rigid within a subject and coil holder, and minute deviations in position can be monitored and corrected online.

The use of MRI and frameless stereotaxy allows a further step in targeting TMS coils: moving from merely spatial positioning to functional positioning. In this case, sites of activation found in a single individual's fMRI can be targeted, achieving a close complementarity of functional imaging and TMS. This is an important development,

as large individual differences are expected in the locus of specific cortical processes, especially those involved in higher cortical functions. For example, Herwig et al. (2003) scanned subjects while they performed a working memory task. Prefrontal and parietal sites in each subject were selected from the resulting fMRI images by finding the maximally activated voxel in each region. These sites exhibited considerable inter-individual variation, ranging frontally across Brodmann Areas 4, 6, 8, 9 and 44, and parietally across areas 7 and 40. Using this information, three seconds of 15 Hz rTMS was applied to those sites and to homologous control sites in the opposite hemisphere, and TMS was found to increase error rates in the task with prefrontal stimulation at the chosen site relative to the control site.

The Herwig et al. study illustrates an ideal experimental context for the use of TMS. A psychological paradigm was utilized whose effects have been parametrically explored since the late 1960s, high resolution physiological activation data were obtained on an individual basis with fMRI, and targeting was achieved with structural MRI and stereotaxic apparatus. The only thing missing was physiological information regarding decisions on when to stimulate, which can be provided by EEG or MEG. Overall, use of TMS in an imaging context in this way allows researchers to investigate links between brain and behavior in a causal way that, with imaging alone, had been only correlative.

The last step in experimental synthesis combining imaging techniques and TMS is to use them simultaneously, such that the physiological effects of employing TMS can be more directly observed, and regional and temporal brain/behavior relationships can be more closely studied, using a "perturb and measure" approach (Paus, 2005). Simultaneous TMS is now possible in the main imaging modalities, as technical problems involving the large magnetic fields of TMS have been overcome. For example, EEG amplifiers are timed to switch on and off with TMS pulses so that they are not swamped by induced currents, allowing high density topographic EEG to be recorded beginning less than a millisecond after a pulse (Ilmoniemi et al., 1997). Similar success has occurred in MRI, where special head and coil holders must be manufactured and the timing of TMS pulses and MRI fields carefully interleaved (Bohning et al., 1997; Bohning et al., 1998) and PET, where TMS pulses even at 40% stimulator intensity can distort the image (Fox et al., 1997; Paus et al., 1997; Paus, 1999).

4.4. Dynamic targeting

The temporal resolution of a TMS pulse is quite high in a psychophysiological context, on the order of a millisecond. The duration of its effects on nervous tissue is more problematic. Amplitudes of EMG responses to single pulses applied to motor cortex can diminish markedly when stimuli are not separated by a large enough intertrial interval (at least 5–10 s). Some effects of a session of TMS can last an hour (Grafman, 2000). Thus the time resolution of TMS

effects depends on what effects are being measured, and the existence of longer-lasting effects should be factored into design of TMS experiments. However, given the duration of effects seen in such work as TMS masking of visual stimuli, where effects last just a few tens of milliseconds (e.g., Amassian et al., 1989) deciding on when to stimulate can be as important as where to stimulate.

Dynamic targeting of TMS consists of estimating two parameters: the critical time point (or points) during the processing of a task, and the duration of stimulation necessary to achieve an effect. If a single pulse alone can create a behavioral effect, it is the most preferable stimulus, both because that effect can then be linked to processing that occurs over a short span of a few tens of milliseconds, and because a single pulse causes the least behavioral disruption to a task and the least discomfort for the subject. As mentioned previously, single pulses have been used with great success at every level, from stimulation of primary visual cortex, where single pulses at 80 ms post stimulus onset disrupted processes involved in simple visual identification (Amassian et al., 1989; Masur et al., 1993; Miller et al., 1996; Corthout et al., 1999) to stimulation of parietal association cortex, where single pulses at 160 ms post stimulus onset disrupted processes involved in self-recognition (Lou et al., 2004).

Pairs of pulses judiciously timed can also reveal information about the timing of processing (Amassian et al., 1993). For example, in Juan and Walsh (2003) a visual search task was used that had two levels of difficulty: targets that were easy to identify among distractors, and targets that were much harder to distinguish. Pairs of pulses to primary visual cortex between 0 and 120 ms (e.g., occurring at 0 and 100 or 80 and 120 ms) after stimulus onset decreased discriminability for both easy and hard targets, while pulse pairs at 200 and 240 ms did so for the difficult targets. The timing of the behavioral effects suggested that the first visual area is used more extensively with more difficult visual search, and led to some interesting speculations regarding processing in the visual cortical hierarchy.

Single pulses or a pairs of pulses are sometimes not enough to create an effect. As mentioned above, Bestmann et al. (2002) looked at RT in a visuomotor task while TMS was applied to left or right posterior parietal cortex. Initially, they found that single pulses delivered at different times (100, 250, and 800 ms after stimulus onset) did not affect RT. Although this result did not exhaust the list of potential pulse times, it did suggest to the authors that single pulses might not be enough to work in their paradigm, and they tried multiple pulses occurring at 100, 150, 200, and 250 ms (i.e., 4 pulses of 20 Hz rTMS) after the visual stimulus, sacrificing more detailed study of the chronometry of the processes involved in the visuomotor task. The 100–250 ms window was chosen based on peak parietal activation seen with the task using MEG. This duration and frequency of stimulation proved sufficient to increase RT in the task. Further experimentation might indicate whether a short train of pulses is required to alter per-

formance, or whether single pulses (at 150 or 200 ms) or perhaps pairs of pulses would be sufficient. Juan and Walsh (2003) used a different dynamic targeting strategy in the visual search task. They began with 10 Hz trains lasting for 500 ms, and assumed the train would disrupt processing in the first visual area during its course. When the train began with the onset of the visual stimulus, discrimination was disrupted for both easy and hard targets. However, when the train began 100 ms after onset, only discrimination of hard targets was affected. Armed with the knowledge that primary visual cortex participation was only needed up to the first 100 ms for easy targets but longer for more difficult ones, the researchers proceeded to explore the chronometry of the search for hard targets in more detail using paired pulses. Both the Bestmann et al. and the Juan and Walsh studies illustrate heterogeneous approaches to dynamic targeting, alternatively expanding and contracting the range of pulses over time periods likely, according to other studies, to be sensitive to TMS. Until there is a deeper understanding of the interaction of TMS and large populations of cortical neurons, these empirically driven strategies remain a necessary aspect of TMS experimental design.

5. THE RELEVANT THEORIES UNDERLYING PSYCHOLOGICAL INFERENCES BASED ON THESE PHYSIOLOGICAL EVENTS

While the results of a TMS experiment can establish a causal link between brain regions and behavior, much of the theoretical work centers upon how brain regions are affected by TMS to achieve such links. TMS affects the brain by short-term disruption, short-term facilitation, and longer-term modulation of neural processes.

5.1. Short-term disruption

One of the earliest and most straightforward conceptions of TMS action is that in the case where ongoing cortical processing is occurring, TMS can interfere with it. Ordinarily, neurons fire in a coordinated way as they process information, while a TMS pulse results in firing that is most likely random with respect to this coordinated activity: noise is added to the patterned processing, interfering with it. In the visual system, this added neural noise due to TMS has been measured as increases in visual contrast threshold (Kammer and Nusseck, 1998). A TMS pulse of large enough intensity could overwhelm all ordered processing, rendering an area momentarily useless. This state reflects the concept of a temporary “lesion” generated by TMS. Conversely, where minimal processing is occurring in a cortical region, such as in visual cortex with eyes closed or in motor cortex controlling hand muscles when the hand is at rest, the noise created by TMS might make itself evident in the former case as a phosphene, and in the latter case as a muscle twitch. The effects of single and paired pulse TMS on motor cortex have been modeled

using a sophisticated computer simulation of 33,000 neurons, both excitatory and inhibitory, arranged according to known anatomy into a multi-layered cortex with over five million intra- and inter-layer synaptic connections (Esser et al., 2005). The cortical outputs of the model cortex after TMS “pulses” accurately reflected such output seen *in vivo* in animal research. Computer simulations such as this may ultimately supply much needed understanding of the responses by local cortical circuitry to TMS, helping to guide choices of TMS parameters such as intensity, pulse train duration, and time of stimulation.

5.2. Short-term facilitation

Recently, TMS has been found to enhance performance in a number of tasks, including choice reaction time (Evers et al., 2001), picture naming (Topper et al., 1998), mental rotation of 3-D objects (Klimesch et al., 2003), backward masking (Grosbras and Paus, 2003), Stroop (Hayward et al., 2004), recognition memory (Kohler et al., 2004), and analogical reasoning (Boroojerdi et al., 2001). Performance enhancement has been seen in some studies in accuracy measures (Klimesch et al., 2003; Kohler et al., 2004), whereas other studies reported decreases in reaction time (RT) without change in accuracy (Topper et al., 1998; Boroojerdi et al., 2001; Evers et al., 2001; Sparsing et al., 2001). Presumably, TMS-induced enhancements in these studies reflect facilitation of neural processing in localized cortical regions, rather than disruption, though this has not been definitively proven.

What might the mechanism be? Two explanations have been proposed, one relying on the disruptive aspects of magnetic stimulation, and the other on possible neural activation. In the former case, processing which normally actually interferes with performance is disturbed by TMS. For example, TMS applied to a superior occipital site resulted in an improvement in performance in a visual search task (Walsh et al., 1999). The task involved searching for a target composed of a conjunction of features also present in a set of distractors (e.g., the target might be a red letter “T” among a set of red “A’s and green “T’s). When one of the features of the search was direction of motion, TMS given over the occipital site, identified as a motion analysis area, delayed response (Walsh et al., 1998). On the other hand, TMS applied to the same site decreased RT when the conjunction target among the moving stimuli was based on form and color rather than motion. This suggests a competition among the various visual cortical areas that process different properties of incoming stimuli in parallel. In the case where information about the movement of the stimuli was irrelevant, disruption of the flow of movement information from the occipital site may have decreased the total processing time necessary. This sort of improvement through subtraction may also have occurred in a study of TMS effects on a Stroop task (Hayward et al., 2004). In that study, TMS applied to anterior cingulate cortex negated the addition to RT caused by Stroop interfer-

ence. This suggested that this region is involved with evaluative processes that are not necessary in this task, such that their disruption allowed overall processing of the stimulus to be faster.

A second mechanism known as “post-tetanic facilitation,” posits that TMS delivered just prior to task-related neural processing increases cortical excitability in a way that can enhance performance under some conditions. Direct electrical stimulation of cortical neurons in non-human primates has been shown to enhance task performance. For example, direct stimulation of neurons in the frontal eye fields (FEF; Brodmann’s Area 8) during the 100 ms prior to the dimming of a visual target improved its detectability (Moore and Fallah, 2001). Correspondingly, single-pulse TMS to the FEF in humans 12 to 50 ms before a visual target in a backward masking task enhanced its discriminability (Grosbras and Paus, 2003). Trains of TMS pulses can extend facilitatory effects on subsequent neural response. For instance, 5 Hz TMS delivered for four seconds increased cortical excitability in primary motor cortex for 600–900 ms after its offset (Berardelli et al., 1998). Five Hz TMS trains to motor cortex have been shown to produce lasting effects on cortical excitability as measured by electrophysiological response (Peinemann et al., 2000) and with PET imaging (Siebner et al., 2000). In another study, 5 Hz TMS applied to somatosensory cortex immediately before a tactile discrimination task significantly improved performance (Ragert et al., 2003). The mechanism behind such enhancement is unknown. One suggestion is that a local increase in excitability, perhaps produced by a temporary increase in the amplitude of excitatory post-synaptic potentials (e.g., Iriki et al., 1989), may lead to a larger neural response, and thus serve to lower thresholds, increase discriminability, or facilitate EMG amplitudes. Another possibility is that TMS affects the oscillatory dynamics of brain networks, perhaps by generating a resonance with local alpha activity (Klimesch et al., 2003). Studies have shown task performance to be positively correlated with the size of local alpha activity occurring prior to task processing and with the depth of alpha desynchronization after the onset of task-related stimuli (e.g., Neubauer et al., 1995). Klimesch et al. (2003) demonstrated that a train of parietal TMS applied at an individual’s peak alpha frequency (about 10 Hz) immediately before a mental rotation task increased both performance accuracy and the depth of alpha desynchronization. This manipulation by TMS of both oscillatory activity and task performance points to the functional relevance of alpha activity.

5.3. Long-term modulation

Experimental effects of TMS are generally short lasting, under some circumstances they have been known to last up to an hour (Grafman, 2000). On the other hand, there is growing evidence that TMS can have much longer lasting effects on the central nervous system, lasting at least over

a period of weeks. These effects have been seen in clinical trials investigating the effect of TMS on psychiatric illnesses such as depression, schizophrenia, and OCD. By far the most studies have been of depression.

In depressed patients, the positive effects of rTMS usually last for several weeks (sometimes months) after the course is completed. Treatment typically targets dorsolateral prefrontal cortex (DLPFC). It is accessible to TMS and highly connected with other target structures, such as anterior cingulate regions. The majority of the clinical studies use high-frequency (10–20 Hz) rTMS in the left DLPFC area, the rationale being that activation of that area will lead to lasting changes in the neurocircuitry involved in mood regulation. However, some studies were done with the use of low frequency rTMS to the right prefrontal cortex (Klein et al., 1999; Lisanby et al., 2002; Fitzgerald, 2004; Kauffmann et al., 2004). An argument for using low frequency rTMS to right DLPFC is based on evidence from imaging studies that the left and right hemispheres have opposing roles in mood regulation (Davidson and Hugdahl, 1995). In depression left hypofrontality is accompanied by a relative right-sided overactivation. In addition, for safety reasons, it is better to use low frequency TMS as there is less seizure risk associated with it. A direct comparison between left prefrontal activation and right prefrontal inhibition failed to show any significant difference in efficacy (Fitzgerald et al., 2003; Lisanby, 2003). However, high-frequency right prefrontal rTMS has no antidepressant effect, moreover, in one study it induced tearfulness in some of the depressed subjects (Loo and Mitchell, 2005).

Disregulation of a network that includes prefrontal, cingulate, parietal, and temporal cortical regions as well as parts of the striatum, thalamus, and hypothalamus has been implicated in depression. Most of the available neuroimaging studies of neurocircuitry in depression show decreased blood flow and decreased glucose metabolism in the frontal cortical area (Baxter et al., 1989; Sackeim et al., 1990; Mayberg, 2002; Mayberg, 2003b). Cognitive deficits in depression have been attributed to this so called “hypofrontality.” In addition to the deficits in metabolism in frontal cortical areas, depressed patients have increased activity in anterior cingulate cortex, limbic, and subcortical regions (Mayberg, 2003a). Antidepressant pharmacological treatment appears to normalize these deficits (Kennedy et al., 2001), and degree of normalization has been shown to be associated with clinical response (Mayberg et al., 2000). Functional inhibition of the anterior cingulate was found to be associated with treatment response to antidepressants (Drevets et al., 2002; Mayberg, 2002). There is also strong evidence that mood control in humans is lateralized, i.e. left and right hemispheres have different, and even opposing actions. For example, in a study by Tormos, normal volunteers were asked to think either happy or sad thoughts while a single-pulse TMS was applied to their motor cortex on the left or right side. Thinking sad thoughts increased motor poten-

tials evoked by left-hemispheric stimulation, while thinking happy thoughts facilitated motor potentials evoked by right-hemispheric TMS and decreased the amplitude of those evoked by left-hemispheric TMS (Tormos et al., 1997).

It was shown that high-frequency (10–20 Hz) rTMS over the left prefrontal cortex increases cerebral blood flow (CBF) in frontal cortex and related subcortical circuits, while low-frequency rTMS decreases CBF in the same brain structures. Daily rTMS for two weeks of 20-Hz rTMS over the left prefrontal cortex at 100% MT induced persistent increases in rCBF in bilateral frontal, limbic, and paralimbic regions. Low-frequency rTMS produced more circumscribed decreases in the right prefrontal cortex (Speer et al., 2000). In another study, in addition to changes in the right prefrontal cortex, slow rTMS over the right DLPFC was shown to produce significant rCBF increase in the contralateral PFC, contralateral ventral striatum, and ipsilateral anterior cingulate, thus affecting major areas involved in mood regulation (Post et al., 1999; Ohnishi et al., 2004).

One of the possible explanations of the differential effects of high- and low-frequency TMS, and especially rTMS is that it induces lasting changes similar to long-term synaptic potentiation (LTP) and depression (LTD) (Post et al., 1999; Speer et al., 2000). Major depressive disorder is associated with dysregulation of various physiologic systems. These physiologic systems are regulated by the major neurotransmitters implicated in the etiology of mood disorders – norepinephrine, serotonin, and dopamine (Szuba et al., 2000). Brain serotonergic systems have been found to play a central role in depression. Thus, increase of serotonin synaptic availability underlies antidepressant efficacy of most pharmacologic agents. In animal studies, rTMS was shown to produce effects similar to antidepressant treatment in humans. rTMS reduced immobility time in the Forced Swim Test (Sachdev et al., 2002) and enhanced apomorphine-induced stereotypy, similar to electroconvulsive therapy (Lisanby and Belmaker, 2000). In common with several pharmacological antidepressant treatments, chronic rTMS was shown to reduce the sensitivity of post-synaptic 5-HT_{1A} receptors in the hypothalamus (Gur et al., 2004), caused downregulation of 5-HT₂ receptors in the frontal cortex (Ben-Shachar et al., 1997; Ben-Shachar et al., 1999), and upregulation of N-methyl-D-aspartate (NMDA) receptors in the ventromedial hypothalamus, basolateral amygdala, and parietal cortex (Kole et al., 1999).

6. CONCLUSION

TMS can no longer be characterized as merely a novel technology with great promise. Over the past two decades, as it has successfully been integrated into both behavioral and imaging paradigms, it has developed into a useful investigational tool for psychophysiology. Aside from its clinical promise, it has shown its value in studies encompassing all

of experimental psychology, from perception and action, to language and mental imagery, learning, and memory, and attention and executive processing. As magnetic field targeting and physiological models of TMS action become more precise, TMS will continue to evolve into an ever more powerful technique for exploring cortical processing and causal hypotheses linking brain and behavior.

The Lesion Method in Cognitive Neuroscience

MICHAEL KOENIGS, DANIEL T. TRANEL, AND ANTONIO R. DAMASIO

INTRODUCTION: HISTORICAL CONTEXT

Scientific consideration of brain-behavior relationships can be traced to a number of seminal observations beginning more than a century ago (see Benton, 1988, for review). Individual landmark cases have often provided the initial footing for mapping complex cognitive abilities onto discrete brain areas. In the 1860s, Paul Broca (1865) reported on the patient known as "Tan," who developed an inability to produce speech following damage to the left front part of the brain. The discovery led to the suggestion, at the time quite radical, that humans speak with the left side of the brain. A few years later, Carl Wernicke reported a complementary finding: damage to the posterior part of the left hemisphere rendered patients unable to comprehend speech, while leaving speech production relatively unaffected. Integrating these findings, Wernicke formulated a remarkably prescient neurological model of language (Wernicke, 1874), the essence of which is still a leading heuristic in clinical neurology and neuropsychology. About the same time, John Harlow (1868) reported on the case of Phineas Gage, who developed a bizarre, seemingly unbelievable focal impairment in personality and social conduct following an accident in which an iron bar was shot through the front part of his brain, destroying prefrontal cortex bilaterally.

The study of brain-behavior relationships enjoyed another period of remarkable progress following World War II, due in some measure to the ravages of war, which provided a grim service to researchers by producing a large number of suitable subjects for careful experimentation – persons who had sustained focal and stable brain wounds that could be correlated with performances on cognitive tests (Newcombe, 1969). This approach, in fact, which has come to be known as the "lesion method," has remained a methodological workhorse in systems level cognitive neuroscience.

Other developments, centered on key case studies, also helped shape the field. In 1957, Scoville and Milner reported for the first time on the patient known as HM, who developed severe and permanent anterograde amne-

sia (learning impairment) following bilateral resection of the mesial temporal lobes, which was done to control intractable epilepsy. Careful neuropsychological studies of HM yielded a number of key breakthroughs in our understanding of the neural basis of memory, and in particular, focused attention on the role of the mesial temporal region, especially the hippocampus and adjacent cortices, in memory. Studies by Roger Sperry, in collaboration with Joseph Bogen and Michael Gazzaniga (e.g., Sperry, 1968; Gazzaniga, 1987), sparked interest in the dramatic differences between the two hemispheres of the brain. These investigators showed that "split-brain" patients, who had undergone surgical separation of the two hemispheres for control of seizures, retained two more or less separate modes of consciousness, one in the left hemisphere which was language-based and operated in sequential, analytical style, and one in the right hemisphere which was spatially based and operated in gestalt, holistic style. In the modern era, the trend has continued with prototypical cases such as EVR (Eslinger & Damasio, 1985), NA (Squire & Moore, 1979; Teuber et al., 1968), Boswell (Damasio, Eslinger, et al., 1985), and SM (Adolphs & Tranel, 2000).

The emphasis on case studies in neuropsychology prompted understandable concern that findings might not generalize or might not even prove repeatable. Largely, this criticism has been assuaged in modern era studies, in which it has been possible to assemble larger groups of brain-damaged patients and to put various hypotheses to rigorous empirical test. Nonetheless, the attacks of skeptics performed the important function of calling attention to factors such as intelligence, age, gender, and handedness, in neuropsychological research. Other contentious issues in the field include the debate between localizationists and anti-localizationists, the notions of redundancy and equipotentiality, and the ideas of "centers" and "networks" (Geschwind, 1964; Lashley, 1950; see Benton & Tranel, 2000, for review). These debates have been constructive in focusing the field on key issues and in fueling theoretical refinements, and on the practical side, they have facilitated the development of empirically driven rehabilitation programs.

It is worth highlighting some of the themes that have dominated the history of cognitive neuroscience. Consider the age-old debate between localizationists and anti-localizationists, which was firmly joined more than a century ago. The localizationist side was exemplified (some might say caricatured) by the notion of phrenology, a system of brain-behavior relationships articulated by Franz Josef Gall and Johann Spurzheim in the late eighteenth and early nineteenth centuries. Gall and Spurzheim (Spurzheim, 1815) outlined in detail how 27 different cognitive functions and personality traits were subserved by specific brain regions. Phrenology was based on skull saliences, and bumps on the skull were used as clues about underlying brain specialization. For example, Gall noted that his classmates with superior memory had prominent eyes, and reasoned that this was the result of overdevelopment of underlying brain regions important for memory. The notion of phrenology has been highly controversial since its inception. Not only did the phrenological maps contain a degree of detail about cerebral localization that far outstripped the empirical evidence, but the evidence itself – correlations between skull bumps and mental capacities – bordered on the absurd. Another problem with phrenology was the inclusion of traits such as “God and religion” and “love for one’s offspring.” Not only was there poor consensus about the meaning of such constructs, but they also had religious connotations that attracted moracious criticism, especially from those disturbed by the anti-dualistic nature of Gall’s position.

The anti-localizationist position was exemplified by investigators such as Pierre Flourens, who argued that all parts of the brain subserved all perceptual, intellectual, and volitional functions equally (Flourens, 1846). Flourens supported his claims with results from ablation experiments, which showed that the crucial factor determining how an organism was affected by brain damage was the extent of tissue removed (size of lesion), and not the location. Complete removal of brain lobes resulted in a complete loss of function; large but incomplete damage created a partial loss of function; but with smaller removals, there was a complete recovery of function. The findings emphasized the notion of redundancy in brain-behavior relationships, a concept that was recapitulated several decades later in Karl Lashley’s notion of equipotentiality (e.g., 1929).

In short, localizationists assigned specific functions to specific brain regions, whereas the anti-localizationists insisted that the cerebral hemispheres operated as a unity, without specific specialization of function. This debate has been revisited at regular junctures throughout the twentieth century, often in ways that resembled the polemics of the nineteenth century. For example, discoveries such as those of Broca and Wernicke were countered by experiments such as those of Lashley (e.g., 1929), which demonstrated that all areas of the cerebral cortex were equally important for complex learning and memory. Echoing the ideas of Flourens, Lashley argued that the degree of behav-

ioral impairment following a brain lesion was simply proportional to the amount of brain tissue that had been destroyed, with location being less important or perhaps entirely irrelevant. Lashley emphasized the key ideas of redundancy and equipotentiality.

A somewhat different form of redundancy was postulated by Hughlings Jackson (1870, 1873) in his hierarchical conception of the organization of the nervous system. In Jackson’s scheme, sensory and motor functions were represented at each “level,” with more complex aspects of function being represented at the highest level of nervous structure. However, the highest level also included nerve fibers from lower levels, making for “multiple representation” of a function at that level. Consequently, a lesion at the highest level left many fibers intact and produced less (or no) impairment in some functions as compared to the same lesion placed at a lower level. “Hence large destroying lesions in the hemisphere will result in no palsy, whereas palsy will follow lesions equally large in the corpus striatum. No fact is better recognized than that a large part of one cerebral hemisphere may be destroyed when there are no obvious symptoms of any kind” (Jackson, 1870, 1873, reprinted in Clarke & O’Malley, 1968). Thus Jackson invoked a redundancy of neural elements to explain the sparing of certain elementary functions following brain injury. Jackson’s dictum implied that the behavioral capacities of a brain-lesioned patient were more an expression of the properties of the spared regions of the brain than of the lesioned area. The idea was applied primarily to account for differences in the extent of recovery from motor and speech impairments that were observed between younger and older patients, but in principle it could apply to all individual differences in brain capacity.

Interestingly, the fundamental idea championed by Gall, namely, that specific brain regions are specialized for specific mental functions, has probably turned out to be more right than wrong. In fact, a sort of “neo-phrenology” is very much alive and well today – for instance, one would be hard pressed to distinguish between some claims being made currently, for example, that a religious “center” has been discovered in a particular region of the left temporal lobe (Ramachandran et al., 1997), and some of the ideas elaborated in Gall’s phrenological system. We would caution against such extreme claims, but at the same time, there is no question that over the last couple of decades, systems neuroscience has yielded a cascade of breakthroughs supporting remarkably detailed brain-behavior relationships, with a degree of precision that would have been virtually impossible to predict in the era prior to the advent of modern neuroimaging.

THE LESION METHOD

Historical context aside, the lesion method remains a rich and powerful source of knowledge regarding the neural underpinnings of cognition and behavior (A. Damasio & H. Damasio, 1994; H. Damasio & A. Damasio, 2003). The

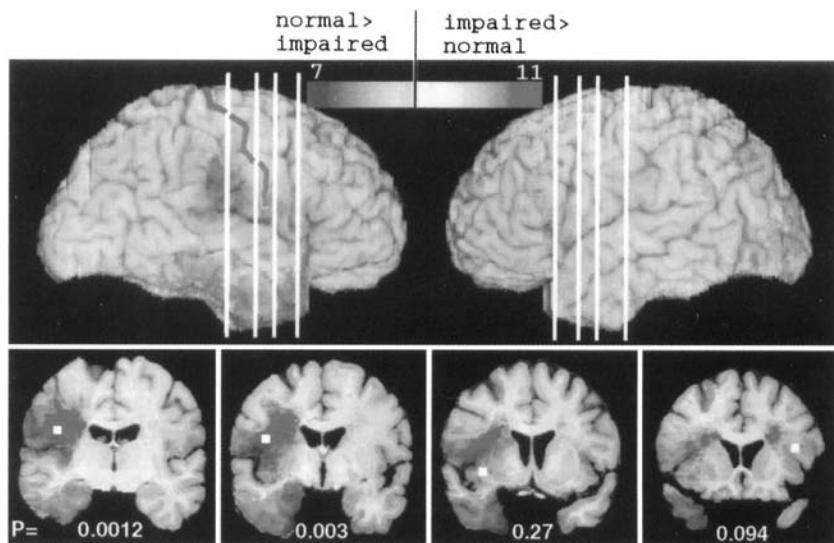

Figure 6.1. Lesion overlap map created with Map-3. In this study 108 subjects performed emotion recognition task. Color (scale at top) encodes the difference in the density of lesions between the subjects with the lowest and those with the highest scores. Thus, red regions correspond to locations at which lesions resulted in impairment more often than not, and blue regions correspond to locations at which lesions resulted in normal performance more often than not. *p* values indicating statistical significance are shown in white for voxels in four regions (white squares) on coronal cuts (bottom) that correspond to the white vertical lines in the 3-D reconstructions (top). (From Adolphs et al., 2000, used with permission.) (See color plate.)

lesion method refers to an approach whereby a focal area of brain damage is correlated with the development of a defect in some aspect of cognition or behavior, and then an inference is made that the damaged brain region is part of the neural substrate for the impaired function. In hypothesis-driven investigations a lesion acts as a *probe* with which the validity of a particular brain-behavior hypothesis can be tested. In humans, obviously, the scientist does not have true control over the lesion, and must rely instead upon the availability of suitable experimental lesions. This does not have to compromise the power of the approach, however, provided it is applied in the context of several important parameters. The following is a brief summary of the lesion method as practiced in our laboratory (see H. Damasio & A. Damasio, 2003).

We believe there are five prerequisites for optimal practice of the lesion method: (1) the availability of detailed structural imaging of the human brain *in vivo*; (2) a reliable method for neuroanatomical analysis of lesions; (3) a suitable pool of subjects from which to draw, allowing selection of experimental and control subjects in such a way as to remove confounding influences of factors such as age, education, IQ, and socioeconomic status; (4) the availability of methods for reliable cognitive measurements; and (5) testable hypotheses concerning the neural basis for specific cognitive and behavioral functions. So long as these prerequisites are satisfied, the lesion method can produce important new insights into brain-behavior relationships.

Neuroanatomical analysis of brain lesions has been greatly facilitated not only by the availability of fine-

grained neuroimaging techniques like magnetic resonance imaging (MRI), but also by the development of analysis techniques that allow precise and reliable mapping of brain lesions. The “template system” developed by Damasio and Damasio (1989) is an example of such a technique. This system has been replaced by an even more powerful approach that is based on a technique known as Brainvox (Frank et al., 1997). Brainvox involves three-dimensional reconstruction of the human brain from high-resolution MRI, permitting the investigator to identify, *in vivo*, every major gyrus and sulcus of the brain, to slice and reslice the brain in whatever incidence necessary for anatomical analysis, and to define and quantify, in three dimensions, the degree of overlap of brain lesions from various subjects. Three-dimensional maps of lesion overlap can be created with a technique called “Map-3.” Map-3 entails the transfer of individual lesions onto a normal reference brain, while taking into account the lesion’s relation to sulcal and gyral landmarks.

After multiple individual lesions are fitted to the reference brain, the lesions are superimposed to form a lesion overlap map. A region of maximal overlap can then be determined on the basis of the superimposition of individual lesions (Figure 6.1). Using Map-3, lesion commonalities between brain-damaged subjects can be characterized at a level of precision far greater than previously available, allowing rigorous probing of putative brain-behavior relationships. Lesion overlaps can function as either the independent or dependent variable (see H. Damasio et al., 1996; Tranel, Damasio, & Damasio, 1997a, for examples of this approach).

Traditionally, the lesion method was implemented primarily in case studies, and this imposed certain limitations on the findings, especially if they proved difficult to replicate. This weakness has been substantially remedied, however, with more recent work involving large groups of brain damaged subjects, where it has been possible to generate conclusions that are based on subject groups comparable in size to those used in traditional psychological experiments (cf. H. Damasio et al., 1996; Tranel et al., 1994; Tranel, Damasio, & Damasio, 1997a; Saygin et al., 2003; Karnath et al., 2004). Striking case studies will continue to fuel new hypotheses and insights regarding brain-behavior relationships, and the astute clinician/scientist will take advantage of opportunities to explore interesting new leads in individual patients, but the days of relying almost exclusively on single cases are well behind us.

Although significant technological advances have enhanced the practice of the lesion method, a carefully

designed and well-controlled cognitive experiment is at the heart of reliable and valid application of any technique to study brain-behavior relationships. Following the tradition of the eminent neuropsychologists who founded the field during the middle part of this century (Benton, 1988; Newcombe, 1969; Teuber, 1968; Weiskrantz, 1968; Zangwill, 1964), modern clinical and experimental neuropsychologists continue to develop and refine a wide variety of cognitive tasks which can be used to measure precisely higher-order functions of the brain such as memory, perception, attention, speech, emotion, and decision making. The specification of detailed methods for conducting neuropsychological evaluation has contributed also (Lezak, 1995; McKenna & Warrington, 1996; Milberg, Hebben, & Kaplan, 1996; Reitan & Wolfson, 1996; Tranel, 1996).

The refinement of neuropsychological assessment and cognitive experimentation follows a long tradition in clinical psychology of careful, standardized measurement of psychological functions. The principal consideration is that the measurements take into account a variety of demographic factors that are common and often potent influences on performance in cognitive tasks, including age, gender, and educational and occupational background. Over the past few decades, the field of clinical neuropsychology has provided wealth of information to deal with this challenge (Benton et al., 1983; Lezak, 1995; Spreen & Strauss, 1990). This information has not only allowed individual case application as required in clinical diagnosis, but has facilitated the power of experimental applications by allowing the removal of unwanted variability in dependent measures.

Despite the historical preeminence of the lesion method in cognitive neuroscience and the more recent advances made in its practical implementation, there remain significant limitations that warrant the development of alternate experimental methods for mapping brain-behavior relationships. First, lesion patients are generally only available to scientists working in close collaboration with a medical center. Critical components of a successful lesion research program include a substantial neurological patient population, structural neuroimaging facilities, standardized neuropsychological assessment of patients, and reliable referral to the research program by clinicians. And, only a limited number of neurological patients are suitable experimental subjects. Subjects must have a clearly demarcated, discrete lesion, with no comorbid or preexisting neurologic or psychiatric condition. Pathologies causing suitable lesions include nonhemorrhagic infarct, herpes simplex encephalitis, and surgical ablation of benign tumors or epileptic foci. However, these pathologies do not sample the brain equally: infarcts most often affect lateral cortical areas and spare medial and basal structures; encephalitis targets the limbic system; tumors tend to arise in convexities; and epileptic foci are usually in temporal lobe. In addition, localizable lesions (often centimeters in diameter) are generally large relative to the functional units of

the brain. A given lesion may encompass multiple cortical and/or subcortical areas. (Hence the necessity of group studies and lesion overlap analysis to disambiguate which area of damage is the cause of observed cognitive defects). Furthermore, cognitive defects could be due to damage to white matter tracts connecting non-lesioned areas, rather than to the loss of adjacent gray matter. In addition, cognitive functions subserved by multiple brain areas may be less susceptible to damage to a single area. That is, a lesion will only reveal if an area is *necessary* for a function; residual ability may be due to incomplete damage or a separate, independent, and still-intact neural system. Lastly, functional and anatomical variability among brains, which can be exaggerated by the presence of a lesion, complicates the comparison of multiple subjects.

FUNCTIONAL NEUROIMAGING

In recent years, functional neuroimaging (and functional magnetic resonance imaging (fMRI) in particular) has emerged as the most widespread method of exploring brain-behavior relationships in cognitive neuroscience. The basis of fMRI is the localized increase in blood flow to the sites of increased neural activity. fMRI allows precise localization of these changes in blood flow during cognitive testing, so activation of a particular brain area can be associated with a particular cognitive function. The merits of this method are evident when contrasted with the lesion method. fMRI is noninvasive and readily accessible to non-medical scientists. Using fMRI, experimenters can visualize areas of brain activation while subjects with *normal* cognitive function perform tasks in the scanner. Thus, investigation of brain-behavior relationships is not limited to a single discrete area of damage. Whereas the lesion method can only identify areas that are necessary for a task, fMRI can theoretically reveal all the brain areas involved in a particular function, including those areas where naturally occurring lesions are rare or function is redundant. Furthermore, fMRI activation maps offer superior spatial localization to the lesion method. Whereas lesions may be many centimeters in diameter and encompass multiple functional modules, fMRI activation loci can be resolved with sub-centimeter accuracy. Future technological developments will only enhance fMRI's capability. Stronger and faster-switching magnets will yield images with better spatial resolution in shorter amounts of imaging time. Combining fMRI data with data from electroencephalogram (EEG) or magnetoencephalogram (MEG), which measure neural activity with millisecond temporal resolution, may yield dynamic brain activation maps that reflect both the timing and location of neural activations.

Despite these benefits, several limitations preclude functional neuroimaging from becoming the sole method of investigating brain-behavior relationships. The generation of an fMRI activation map requires that the brain activity in one state (baseline task) be "subtracted" from the brain

activity in another state (activation task). Functional neuroimaging only allows identification of areas that are more active in one state than another. Activations are diminished when the baseline task engages the process of interest, and superfluous activations may result when the activation task engages processes unrelated to the task requirements. Activation maps must be interpreted cautiously, with due consideration of the baseline and activation tasks in the experiment. In no case does an activation map reveal which brain areas are *necessary* or *critical* for a particular task. Furthermore, practical factors limit the range of cognitive abilities and neuroanatomical areas that can be explored with functional neuroimaging. Because the subject is physically confined in the scanner and head motion is the primary cause of data distortion, the subject's behavior is generally limited to a button press response. Due to inhomogeneities in the magnetic field near air/tissue interfaces, it is generally difficult to obtain fMRI data in the orbitofrontal cortex and temporal poles. This signal loss is not a problem in positron emission tomography (PET; another functional neuroimaging technique measuring blood flow in the brain), but PET's utility is limited by the rigidity of the experimental design: tasks must be performed in minute-long blocks and subject participation is restricted by exposure to radioactivity.

Clearly, neither the lesion method nor functional neuroimaging alone stands to address every question of brain-behavior relationship in cognitive neuroscience. Each method entails fundamental and practical limitations, and individual research questions may be best addressed using one method or the other, or a combination of the two. In the *following section*, we present research from several domains of cognitive function, with particular emphasis on how the lesion method and functional neuroimaging have been employed to varying degrees to answer (and raise) research questions in each domain.

TOPICS IN COGNITIVE NEUROSCIENCE

The following discussion of selected topics in cognitive neuroscience is not intended to be comprehensive, but instead, we have chosen several topics that illustrate the application of the experimental methods described in the previous sections. Specifically, we focus on examples from the domains of memory; decision-making and social conduct; emotion recognition; attention; and cognitive control.

Memory

Memory refers to knowledge that is stored in the brain, and to the processes of acquiring, storing, and retrieving such knowledge. Clearly this is a broad concept, and theorists have partitioned the field along multiple dimensions (e.g., long-term vs. short-term, declarative vs. non-declarative, encoding vs. consolidation vs. recall). Without exhausting the myriad of data relating to the neural bases of the

many proposed memory subtypes, we will illustrate several examples of how the lesion method and functional neuroimaging have been applied to the study of memory.

Long-term declarative memory. As mentioned earlier, the pioneering study on the neural basis of memory was the case report of HM, who suffered a striking anterograde amnesia following bilateral resection of the mesial temporal lobes (hippocampus and adjacent entorhinal, perirhinal, and parahippocampal cortices) (Figure 6.2). Amnesia is an impairment of memory, and it refers specifically to an impairment in the ability to learn new information or to retrieve previously acquired knowledge. The impairment of learning is known as anterograde amnesia, whereas the impairment in retrieving previously acquired knowledge is known as retrograde amnesia, with the demarcation being the point in time at which neurological disease begins. As evidenced by continued study of mesial temporal lesion patients (HM and others), damage to some or all of the mesial temporal structures produces characteristic patterns of amnesia (Cohen & Eichenbaum, 1993; Corkin, 1984; Curran & Schacter, 1997; Damasio, Eslinger, et al., 1985; Mishkin, 1982; Squire, 1992a; Tranel & Damasio, 1995; Zola, 1997). First, there is a consistent (albeit imperfect) correspondence between the side of damage and the type of learning impairment; thus, unilateral lesions tend to produce material-specific amnesia. Specifically, left-sided lesions produce defects primarily in the learning of verbal information (e.g., words, written material), and nonverbal information is largely spared; conversely, right-sided lesions produce defects primarily in the learning of nonverbal material (e.g., complex visual and auditory patterns), and verbal information is largely spared (e.g., Milner, 1972). Second, the mesial temporal region is critical for the acquisition of new information (anterograde memory), but its role in the retrieval of previously learned knowledge (retrograde memory) is minimal. That is, the ability to retrieve information that was acquired prior to the onset of the lesion is usually spared following damage to mesial temporal structures (Cohen & Eichenbaum, 1993; Corkin, 1984; Damasio, Eslinger et al., 1985; O'Connor et al., 1995). Third, structures in the mesial temporal region are crucial for the acquisition of declarative information, that is, knowledge that can be "declared" or brought to mind for conscious inspection, for example facts, words, names, and faces. However, these structures do not appear to be necessary for the acquisition of nondeclarative information, that is, knowledge such as sensorimotor skills (e.g., skiing, dancing) that cannot be declared or brought to mind (Corkin, 1965; Gabrieli et al., 1993; Thompson, 1986; Tranel & Damasio, 1993; Tranel et al., 1994). Fourth, short-term memory (retention on the scale of seconds to minutes) is spared in these patients. In short, patients with damage confined to structures in the mesial temporal region will manifest anterograde amnesia for long-term declarative knowledge, with the material type

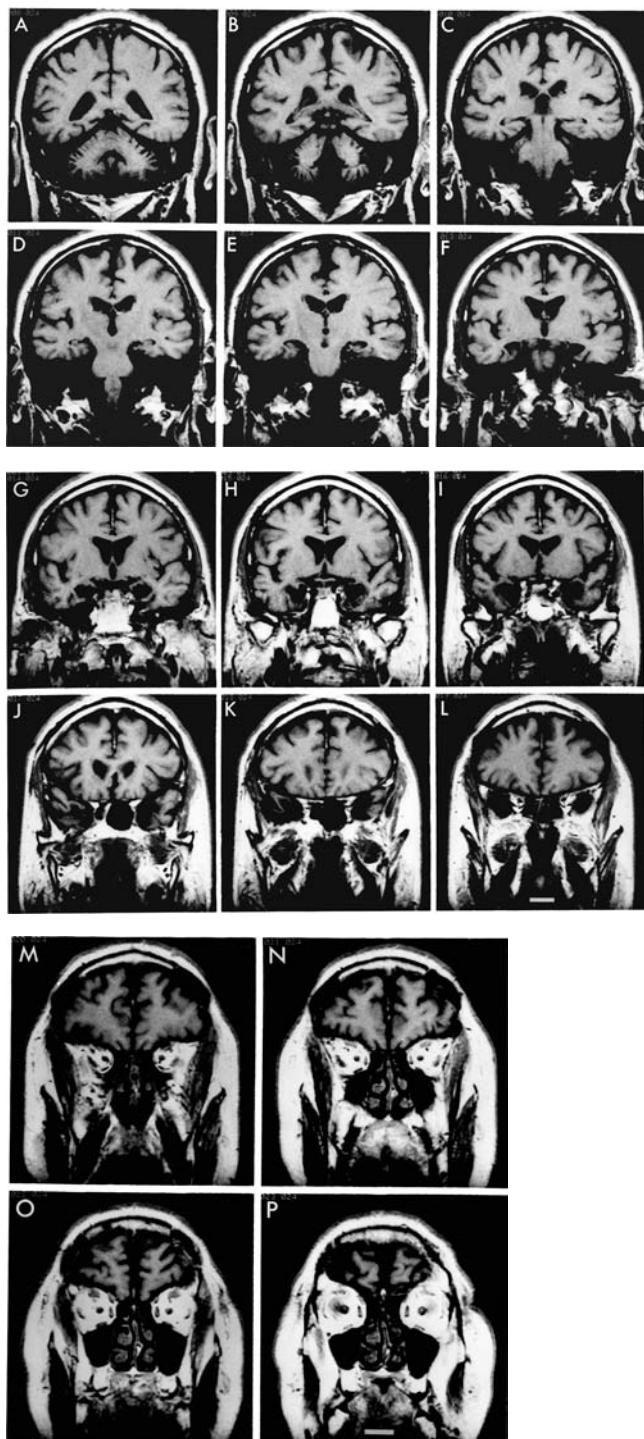

Figure 6.2. T1-weighted series of coronal sections arranged from caudal (A) to rostral (P) to show the extent of the lesion in H. M. (From Corkin et al., 1997, used with permission.)

(verbal versus nonverbal) influenced by the side of lesion. The precise role of various mesial temporal lobe structures in memory function has not been definitively established through human lesion studies, but there is evidence that damage restricted to hippocampus proper is sufficient to cause an enduring anterograde amnesia (Rempel-Clower et al., 1997; Zola-Morgan et al., 1986).

By contrast, damage to nonmesial portions of the temporal lobe (anterior, inferior, and lateral temporal lobe) is associated with a long-term declarative memory defect encompassing the retrograde compartment (Cermak & O'Connor, 1983; Cohen & Squire, 1981; Kapur, 1993; Kapur et al., 1994; Kopelman, 1992; Markowitsch et al., 1993; Squire & Alvarez, 1995). If the damage spares the mesial temporal region, in fact, the memory defect may be confined to the retrograde compartment (Kapur, 1993; Kapur et al., 1994; Markowitsch et al., 1993; see Hodges, 1995, for review). Frequently, retrograde amnesia affects retrieval of knowledge for unique material more than knowledge for nonunique material. For instance, a patient may have difficulty retrieving detailed information about unique episodes such as the birth of children, the purchase of a home, or facts about public events; however, the patient will remain capable of retrieving nonunique knowledge such as the meanings of words, and the meaning of nonverbal stimuli such as common entities and actions. As in anterograde amnesia, there appears to be a laterality effect regarding the specialization of the left side for verbal material, and parallel specialization of the right side for nonverbal material. Hence, damage to the left anterior temporal region produces an impairment in the retrieval of words for unique entities (proper nouns), without affecting the capacity to retrieve nonverbal conceptual knowledge about those entities (H. Damasio et al., 1996), and damage to the homologous right temporal region will produce an impairment in the retrieval of conceptual knowledge for unique persons, but not an impairment in the retrieval of unique names (Tranel, Damasio, & Damasio, 1997a).

These lesion studies indicated dissociable roles of mesial and non-mesial temporal cortices in long-term declarative memory: encoding and consolidation is associated with hippocampus and adjacent cortices, whereas storage and/or retrieval is associated with anterior, inferior, and lateral temporal cortices. Additional lesion studies of long-term declarative memory have identified two other critical brain areas: basal forebrain and the diencephalon.

The basal forebrain, situated immediately behind the orbital prefrontal cortices, comprises a set of bilateral paramidline gray nuclei which include the septal nuclei, the diagonal band of Broca, the nucleus accumbens, and the substantia innominata. Damage to this region is frequently caused by ruptured aneurysms of the anterior communicating artery or of the anterior cerebral artery. One problem in studying this condition is that most of the affected patients have surgical clips that preclude magnetic resonance imaging, limiting the anatomical analysis that can be performed.

Patients with damage to the basal forebrain manifest a characteristic amnesia that may include deficits in the association of individual features or events, especially with respect to time, as well as a propensity for confabulation, for example, making up fantasy stories about various bizarre adventures that have no basis in fact (Alexander & Freedman, 1984; Damasio, Graff-Radford, et al., 1985;

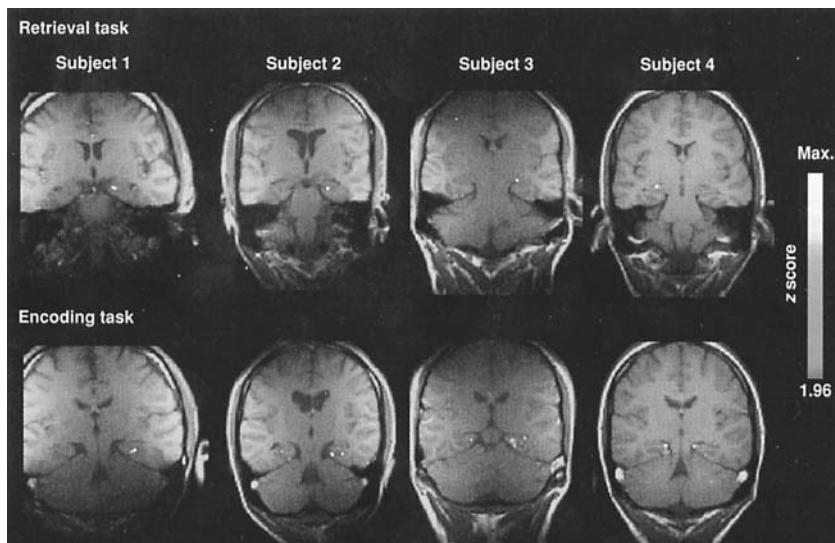

Figure 6.3. Mesial temporal lobe activations during memory encoding and retrieval. The top row shows activations in the subiculum of the hippocampus during the retrieval memory task that were greater for words corresponding to previously seen than unseen line drawings (Subjects 1, 2, and 3) or greater for line drawings corresponding to previously seen than unseen words (Subject 4). The bottom row shows activations in the parahippocampal cortex during the encoding memory task that were greater for novel than for repeated color scenes (Subjects 1, 2, and 3) or greater for novel than for repeated line drawings (Subject 4). (From Gabrieli et al., 1997, used with permission.) (See color plate.)

Deluca & Diamond, 1995). In a direct test of the role of the basal forebrain in the temporal binding of memories, Tranel and Jones (in press) assessed the ability of basal forebrain patients to place various autobiographical memories accurately on a “time-line” of their life. Their performance was compared to patients with mesial temporal lobe damage; patients with damage outside basal forebrain, mesial temporal lobe, and diencephalon; and normal control subjects. Relative to the other groups, basal forebrain patients were significantly impaired in their ability to situate autobiographical memories on a time-line of their lives. It is noteworthy that basal forebrain and mesial temporal lobe patients were comparably impaired in their ability to recall autobiographical events, but only the basal forebrain group exhibited impairment in placing the recalled events in the correct temporal context. These findings highlight a role for the basal forebrain in establishing the temporal relationship of events in memory.

Structures in the diencephalon, particularly the dorsomedial nucleus of the thalamus and the mammillary bodies, have also been shown to play an important role in memory in lesion studies. Damage to these structures produces a severe anterograde amnesia that resembles the amnesia associated with mesial temporal damage. Characteristically, there is a major defect in the acquisition of declarative knowledge, with sparing of learning of non-declarative information. However, more so than with the amnesia associated with mesial temporal lesions, diencephalic amnesia may involve the retrograde compartment as well. This retrograde amnesia tends to have a “temporal

gradient,” so that retrieval of memories acquired closer in time to the onset of the lesion is more severely affected, whereas retrieval of more remote memories is better preserved. Severe alcoholism and stroke are two frequent causes of damage to the diencephalon (Butters & Stuss, 1989; Graff-Radford, Tranel, et al., 1990). The amnesia that develops after prolonged alcoholism is part of a distinctive condition known as Wernicke-Korsakoff syndrome, which has been extensively studied from both neuroanatomical and neuropsychological perspectives (e.g., Victor et al., 1989).

So, in the domain of long-term declarative memory, lesion studies have proven remarkably effective in delineating the critical neural structures. But, significant questions remained unanswered by lesion studies. For example, what are the different contributions of individual mesial temporal lobe structures (e.g., parahippocampal cortex versus hippocampus proper)? Or, are there other cortical areas that are recruited, but not necessary, for memory tasks? Subsequent fMRI studies have yielded answers to some of these questions. Gabrieli et al. (1997) scanned subjects during the encoding and retrieval portions of a memory test. During encoding there was greater activation of posterior mesial temporal lobe (parahippocampal cortex) for novel stimuli than for familiar stimuli, whereas during retrieval there was greater activation of anterior mesial temporal lobe (subiculum of hippocampus) for successfully remembered items. (Figure 6.3). In a similar design using a list of words as stimuli, Wagner et al. (1998) found that left parahippocampal cortex activation during encoding was greater for words that were subsequently recalled successfully, compared to nonremembered words. In addition, Wagner et al. found that activation of an area in left frontal cortex during word encoding also correlated with retrieval success. In a related finding, Kelley et al. (1998) observed that encoding of words produced left-lateralized dorsal frontal activation, whereas encoding of unfamiliar faces produced homologous right-lateralized activation. More recent studies highlight the role of parietal cortex in memory retrieval: activity of posterior parietal cortex has been associated with retrieval success for picture and sound stimuli (Shannon and Buckner, 2004; Konishi et al., 2000; Leube et al., 2003).

Clearly, the current understanding of the neural substrates of long-term declarative memory has benefited from both lesion and functional imaging studies. Although lesion studies laid the foundation in identifying the critical structures, functional imaging studies confirmed, but more importantly, extended the neural model. It is

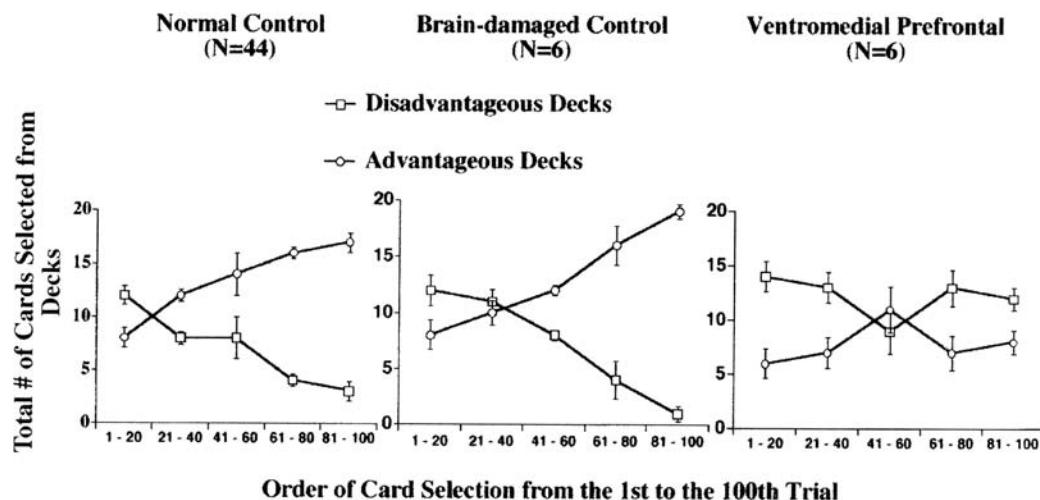

Figure 6.4. (Top) Card selections on the Iowa Gambling Task as a function of group (normal control, brain-damaged control, ventromedial prefrontal damage), deck type (disadvantageous versus advantageous), and trial block. The two control groups gradually shifted their response selections towards the advantageous decks, and this tendency became stronger as the game went on. The ventromedial prefrontal subjects did not make a reliable shift, and continued to opt for the disadvantageous decks even during the latter stages of the game, when controls had almost completely abandoned choosing from the disadvantageous decks. (Bottom) Lesion overlap map of patients with defective IGT performance and "acquired sociopathy." Areas of greater overlap appear darker. (From Tranel, 2002, used with permission)

noteworthy that the majority of findings contributed by each method are nonredundant. As an illustration of this point consider the following four observations: (1) Human lesion studies could not reliably distinguish separate roles of anatomically adjacent structures such as hippocampus and parahippocampal cortex (compare Figures 6.2 and 6.3), (2) Lesion studies could not identify the role of prefrontal and parietal areas in encoding and retrieval, respectively, (3) Functional imaging studies could not distinguish the relative importance (i.e., necessity) of each activated area, and (4) Functional imaging could not identify the unique role of the basal forebrain nuclei in the temporal binding of memories or the involvement of the diencephalon.

Working memory. Whereas lesion studies were a principal methodology for establishing the neural bases of long-term declarative memory, functional imaging has been the primary tool for identifying the substrates of working memory. Working memory refers to a short window of mental processing, on the order of seconds to minutes, during which information is held "on-line" and operations are performed on it – a sort of "mental scratch pad" (Baddeley, 1992). In essence, working memory is a temporary storage and processing system used for problem solving and other cognitive operations that take place over a limited time frame.

Functional imaging studies have robustly implicated the prefrontal cortex, particularly the dorsolateral sector, in the mediation of working memory (Cohen et al., 1997; Courtney et al., 1997; Courtney et al., 1998; Jonides et al., 1993; McCarthy et al., 1994; Smith et al., 1995). As in the case of long-term declarative memory, there is evidence

for left- and right-sided specialization: left prefrontal cortex is preferentially activated during retention of verbal information, whereas right prefrontal cortex is preferentially activated during retention of nonverbal or spatial information (Smith et al., 1996). During maintenance of information in working memory, dorsolateral prefrontal cortex exhibits linearly increasing activation in response to increasing working memory load (Narayanan et al., 2005; Braver et al., 1997) and greater activation of dorsolateral prefrontal cortex during working memory retention is associated with increased accuracy at recall after distraction (Sakai et al., 2002). Although prefrontal activation is the most robust finding in working memory neuroimaging studies, multiple studies have demonstrated the additional activation of parietal cortex (Pessoa et al., 2002; Zahran et al., 1999; Rowe and Passingham, 2001; Cohen et al., 1997).

Lesion studies of working memory are less compelling and straightforward than their neuroimaging counterparts. Studies by Reverberi et al., Bechara et al., and Ferreira et al. illustrate this point. Reverberi et al. (2005) observed working memory impairment in patients with damage restricted to either inferior medial prefrontal cortex or left lateral prefrontal cortex, but not in cases of right lateral prefrontal cortex damage. Bechara et al. (1998) found that patients with posterior ventromedial or right dorsolateral/superior medial prefrontal lesions were impaired on a test of working memory, but patients with damage to anterior ventromedial or left dorsolateral/superior medial prefrontal cortex were not. Ferreira et al. (1998) found that a group of patients with dorsolateral prefrontal damage were impaired relative to normal controls and temporal lobe patients on a working memory test

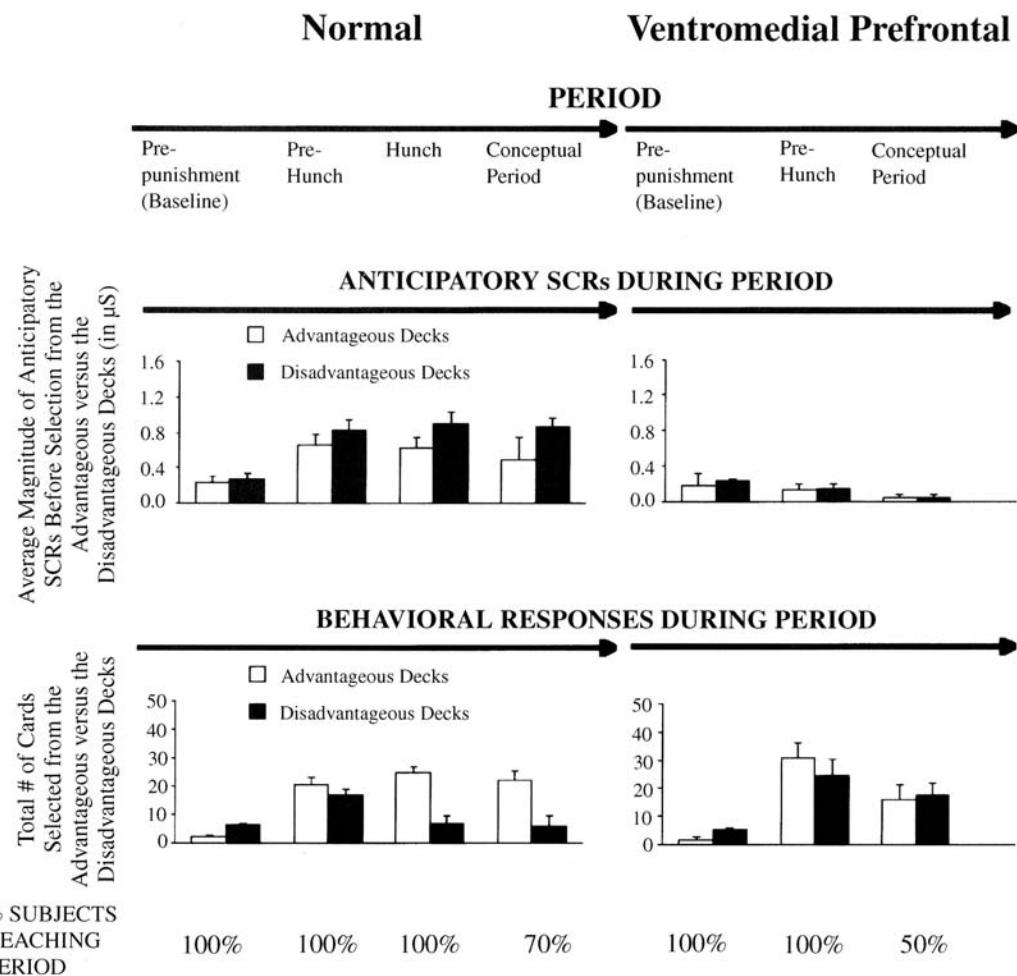

Figure 6.5. Psychophysiological (anticipatory skin conductance responses) and behavioral (card selection) data for control subjects ($n = 10$) and subjects with ventromedial prefrontal lesions ($n = 6$), as a function of four “knowledge periods” (see text). Control subjects, even before they knew anything consciously about how the game worked (pre-hunch period), began to generate anticipatory SCRs and shift their selections away from the bad decks. In the controls, anticipatory SCRs, especially to the bad decks, became more pronounced as the game progressed, and the subjects shifted almost exclusively to the good decks. The ventromedial subjects never produced anticipatory SCRs, and they also continued to opt more frequently for the bad decks. The pattern occurred even in ventromedial subjects ($n=3$) who knew at a conscious level (conceptual period) how the game worked, and that some decks were good and some were bad. (From Bechara et al., 1997, used with permission.)

involving the free recall of spatial locations, but not on working memory tests involving the free recall of a temporal sequence or the recognition of spatial locations. In an effort to clarify the contribution of lateral prefrontal cortex to working memory, D’Esposito and Postle (1999) performed a meta-analysis of studies reporting the working memory performance of patients with lesions to the lateral prefrontal cortex. After analyzing the working memory performance of 166 lateral prefrontal patients from 11 studies, D’Esposito and Postle determined there was no significant deficit in working memory performance in these subjects, and therefore concluded that the prefrontal cortex does not make a *necessary* contribution to working memory capacity.

Data from studies of working memory, therefore, represent some lack of convergence between methods. Areas of

prefrontal cortex that yield robust, replicable activations in functional neuroimaging studies do not appear to be necessary for working memory because damage to these same areas does not reliably produce an impairment. Such a scenario does not require a denigration of one method in favor of the other (both are capable of producing valid data); rather, it will no doubt spark a host of theoretical refinements and new hypotheses to be investigated with both methods.

Priming. Another subtype of memory is the phenomenon of priming. Here, we would like to briefly describe one experiment that illustrates a creative use of functional neuroimaging to obtain a neural account of a long-known behavioral effect.

"Repetition priming" refers to the observation that repeated exposure to an object facilitates faster processing (e.g., naming, classification) of the object upon subsequent encounters. Interestingly, this form of learning is preserved in anterograde amnesia, indicating that it is not dependent on the mesial temporal lobe system (e.g., Cave and Squire, 1992). To investigate the neural correlates of object priming, Buckner et al. (1998) employed a rapid event-related fMRI paradigm in which subjects performed an object classification task ("Does this object move on its own or not?"). Object pictures were presented in the scanner. Prior to scanning, subjects were shown a subset of the objects, so during scanning some objects would be "novel" and others "repeated." Behavioral performance and the brain hemodynamic response were obtained for each object during the task. As expected, classification performance was faster for repeated items, and the classification task (for novel and repeated items) was associated with widespread activations relative to a fixation baseline. Comparison of the hemodynamic responses for novel and repeated items revealed that a subset of areas activated by the object classification task was differentially activated for novel and repeated items, thereby suggesting that the priming-related task facilitation had selective neuroanatomical substrates. Novel and repeated items elicited comparable activations in primary visual cortex (associated with early retinotopic visual processing) and motor areas (associated with response initiation and execution), but a reduction in activation for the repeated items was observed in extrastriate and inferotemporal cortex (associated with higher order visual processing and visual object representation) as well as left dorsolateral prefrontal cortex and anterior cingulate cortex (associated with effortful response monitoring and selection). These data suggest that experience-dependent reductions in neural activations associated with object representations are the neuroanatomical correlate of enhanced behavioral performance ("priming") for those objects. The brain-behavior relationship delineated in this study would have been impossible to ascertain using the lesion method. As in the Wagner et al. (1998) study of long-term declarative memory (which showed that parahippocampal activity for individual words during encoding predicted subsequent recall success), only through a functional imaging paradigm that allows comparison of the healthy brain's responses to individual stimuli, could the neural mechanism for repetition priming be elucidated.

Decision-making and social conduct

As alluded to earlier in the mention of Harlow's seminal case of Phineas Gage, throughout the history of neuropsychology investigators have called attention to the dramatic changes in social behavior that occur in relationship to injuries to the prefrontal region of the brain (e.g., Brickner, 1934; Eslinger & Damasio, 1985; Harlow, 1868; Hebb & Penfield, 1940; Luria, 1969; Stuss & Benson, 1986). As case reports accrued over the past century, it became apparent

that the affected patients have a number of features in common (see Damasio & Anderson, 1993): inability to organize future activity and hold gainful employment, diminished capacity to respond to punishment, a tendency to present an unrealistically favorable view of themselves, a tendency to display inappropriate (or absent) emotional reactions, and normal intelligence. Several of these features are highly reminiscent of the personality profile associated with sociopathy, and in fact, we have gone so far as to dub this condition "acquired sociopathy" (Damasio, Tranel, & Damasio, 1990b).

Others have called attention to such characteristics in patients with ventromedial prefrontal cortex (VMPC) damage. For example, Blumer and Benson (1975) noted a personality type that characterized patients with orbital damage (which the authors termed "pseudo-psychopathic"), in which salient features were puerility, a jocular attitude, sexually disinhibited humor, inappropriate and near-total self-indulgence, and complete lack of concern for others. Stuss and Benson (1986) emphasized that such patients demonstrate a remarkable lack of empathy and general lack of concern about others. The patients tend to show callous lack of concern, boastfulness, and unrestrained and tactless behavior. Other descriptors include impulsiveness, facetiousness, and diminished anxiety and concern for the future.

Patients with VMPC lesions and "acquired sociopathy" demonstrate a proclivity to make decisions and engage in behaviors that have negative consequences for their well-being. The patients are usually not destructive and harmful to others in society (a feature that distinguishes the "acquired" form of the disorder from the standard "developmental" form); however, they repeatedly opt for courses of action that are not in their best interest in the long run. They make poor decisions about interpersonal relationships, occupational endeavors, and finances. In short, they act as though they have lost the ability to ponder different courses of action and then select the option that promises the best blend of short- and long-term benefit. What makes this manifestation all the more striking, and what has defied simple explanation ever since the days of Harlow, is the fact that most of the patients retain normal intelligence, conventional memory, language, perception, attention, and so on. In other words, there are no obvious neuropsychological impairments that might account parsimoniously for the erratic behavior.

The rich clinical descriptions outlined above indicate a central role for VMPC in decision-making and social conduct. More systematic laboratory exploration of these patients' deficits suggests a neural mechanism by which VMPC exerts its influence in this cognitive domain. One of the primary experimental paradigms used to investigate decision-making behavior is the Iowa Gambling Task (IGT) (Bechara et al., 1994). The IGT was developed as a laboratory probe to detect and measure the decision-making impairments that are so blatant in the day-to-day lives of VMPC patients. Accordingly, the IGT factors in reward and

punishment (winning and losing money) in such a way as to create a conflict between immediate reward and delayed punishment (Bechara, Tranel, & Damasio, 2000). Choices in the task may be risky and uncertain because individual outcomes cannot be calculated. Success on the task depends critically on one's ability to develop "hunches" or "gut feelings" about good and bad decisions in real time.

The IGT consists of four decks of cards named A, B, C, and D. The subject chooses one card at a time from any of the four decks. Each card denotes a net gain or loss of money. The subject is stopped after 100 card selections, but s/he is never aware of when the task will end. The object of the IGT is to maximize profit on a loan of play money. The key manipulation is that the decks are pre-programmed so two decks are "good" in the long run (i.e., continuous selection from these decks results in a net gain of money) and 2 decks are "bad" in the long run (i.e., continuous selection from these decks results in a net loss of money). However, the immediate reward of the bad decks is greater than the good decks, but so is the eventual punishment. So, through variable experiences of reward and punishment with each deck, the subject must formulate a plan of action that is advantageous in the long run (i.e., pick mostly from the good decks). Over the course of the 100 selections, the normal course of behavior is that subjects learn to avoid the bad decks and choose predominantly from the good decks. VMPC patients, on the other hand, continue to select from the bad decks throughout the task. (Figure 6.4) Thus, the IGT captures the real-world defects in decision-making behavior observed in the VMPC patients.

To investigate the pathophysiological basis of the decision-making impairment associated with VMPC damage, Bechara et al. (1996) administered the IGT while recording skin conductance responses (SCRs), a sensitive index of psychosomatic arousal that is reliably elicited by stimuli with emotional or social valence. Both normal subjects and VMPC patients generated SCRs after picking a card and learning they won or lost money. However, as normal subjects progressed through the task they began to generate SCRs prior to the selection of cards, during the time in which subjects consider from which deck to choose. Furthermore, these anticipatory SCRs were larger before picking from a bad deck than picking from a good deck. By contrast, VMPC patients generated no SCRs prior to card selection.

In another instantiation of the IGT, Bechara et al. (1997) recorded SCRs but also intermittently interrupted the subject (every 10 card selections) to ask what the subject knew about the game. Four epochs were defined: (1) "pre-punishment," when the subject had sampled the decks but had not encountered any losses, (2) "pre-hunch," when the subject had encountered losses but had no idea how the decks were different, (3) "hunch," when the subject expressed uncertain guesses about some decks being riskier than others, and (4) "conceptual," when subjects could declare which decks were good and which were

bad. Card selection and anticipatory SCRs were compared for the four periods (Figure 6.5). In the pre-punishment period, both VMPC patients and normal subjects selected more from the higher paying bad decks. In the pre-hunch period, normal subjects developed anticipatory SCRs and began selecting more from the good decks. VMPC patients developed no pre-hunch anticipatory SCRs and continued to choose from the bad decks. In the hunch period, normal subjects continued to generate anticipatory SCRs and card selection shifted even more in favor of the good decks. VMPC patients never generated anticipatory SCRs and never reached a hunch period, but 50% reached the conceptual period. Remarkably, despite being able to articulate the relative long-term reward and punishment contingencies of each deck, VMPC patients reaching the conceptual period continued to choose disadvantageously. Conversely, 30% of normal subjects never reached the conceptual period, but still generated anticipatory SCRs and chose advantageously. These data suggest that the critical determinant of successful decision-making is not declarative knowledge, but a somatic signal mediated by VMPC and derived from prior experiences with reward and punishment.

The preceding discussion of acquired sociopathy and defective decision-making was based on neuropsychological studies of patients with *adult-onset, bilateral* VMPC damage. Hence, these studies bear no information on two fundamental considerations of brain-behavior relationships: laterality and development. The following two studies, respectively, discuss acquired sociopathy in these terms. To parse the relative contributions of right and left VMPC damage to acquired sociopathy, Tranel et al. (2002) studied a rare series of patients with focal, unilateral lesions to VMPC. In terms of social conduct (indexed by clinician and family ratings), decision-making (indexed by IGT), and personality (indexed by Iowa Rating Scales of Personality Change; Barrash and Anderson, 1993), the patients with damage restricted to right VMPC approximated the bilateral patients (impaired), whereas patients with damage restricted to left VMPC more closely approximated normal comparison subjects (nonimpaired), indicating that the right VMPC is critically involved in social conduct, decision-making, and personality, whereas the contribution of the left VMPC is less important.

To investigate the role of VMPC in the development of decision-making and social behavior, Anderson and colleagues have assembled the most complete clinical and neuroanatomical descriptions of cases with early-onset (prenatal, infancy, or childhood) VMPC damage, including two cases published in previous articles (Anderson et al., 1999, 2000).¹ These reports indicate that the cluster of antisocial traits common to these two early-onset cases (superficial charm, lying, stealing, manipulative, lack

¹ A larger series of cases has now been studied, and comparable results have been obtained; see Anderson, Barrash, Bechara, and Tranel, in press.

of remorse or guilt, shallow affect, lack of empathy, failure to accept responsibility, parasitic, poor behavioral controls, early behavioral problems, lack of realistic long-term goals, irresponsibility, juvenile delinquency, and promiscuity) surpasses that of adult-onset cases in scope and severity. Neuropsychological assessment of the two cases indicates both have intact basic mental abilities (like the adult-onset cases), but significant impairments in executive function, social/moral reasoning, and verbal generation of responses to social situations (unlike adult-onset cases, who are capable of generating appropriate responses to social and moral scenarios when presented in verbal, “off-line” format). As expected, both developmental patients exhibited defective decision-making on the IGT and failed to generate anticipatory SCRs. Even though the reported sample of early-onset damage subjects is small so far, the available data suggest that VMPC is critically involved in the acquisition of social and moral knowledge during development. Adult-onset VMPC patients, who presumably underwent normal social development, retain declarative access to social facts and “off-line” moral reasoning, but they lose access to emotional signals that are necessary to guide appropriate social and decision-making behavior in real-life, real-time situations. Early-onset VMPC patients seem to have never acquired factual social knowledge, nor do they have access to normal “on-line” emotional signals, resulting in an even greater level of impairment.

As a noteworthy aside, the result of *greater impairment* following *early damage* to VMPC runs contrary to a long-held heuristic of brain-behavior relationships: the Kennard Principle, which holds that functional recovery from brain damage is better when the injury occurs early in life. Lesion studies examining age of onset as an independent variable stand to bear important data regarding the neural bases of the development of specific cognitive abilities.

Clearly, the wealth of clinical, behavioral, psychophysiological, and neuroanatomical data linking VMPC to social conduct and decision-making illustrates the unique capability of the lesion method. Functional imaging studies of social behavior and decision-making processes are challenging for at least two reasons: (1) VMPC, apparently the primary substrate for such abilities, is difficult to image (due to magnetic susceptibility artifact) without sacrificing coverage of more distal regions of cortex, and (2) experimental paradigms involving social interactions or decision-making based on risk, reward, punishment, and uncertainty of future outcomes (like IGT) are often complicated, likely recruiting multiple cognitive systems with difficult-to-model dynamics, thus making an activation map based on subtraction of some other “baseline” task with similar properties difficult to interpret. Although neither challenge is insurmountable (see O’Doherty et al., 2001; Fukui et al., 2005), the lesion method has proven to be the primary experimental tool for elucidating brain-behavior relationships in this domain.

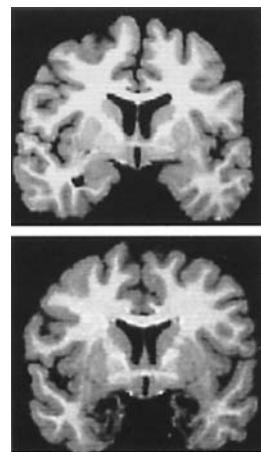

Figure 6.6. MRI of brain with normal amygdala (top) and SM’s brain (bottom). Note the restricted, yet complete, damage to the amygdala bilaterally in SM.

Emotion recognition

In contrast to the notable differences in what has been learned about memory and decision-making from lesion versus functional imaging approaches, the neuroanatomical correlates of emotion (particularly fear) recognition have been investigated in lesion and neuroimaging studies in parallel, with remarkably convergent results. Both methods implicate the amygdala as the key structure for the recognition of fearful expressions on faces.

This link has been firmly established in lesion studies, which have shown that bilateral amygdala damage impairs the ability to recognize fearful faces, despite intact perceptual abilities. Undoubtedly, the most informative subject in this respect has been patient SM. As a result of a rare disease, SM suffered brain damage that encompasses all nuclei of the amygdala bilaterally, as well as a small portion of the adjacent entorhinal cortex, yet spares all other subcortical and cortical structures (Figure 6.6), leaving her with essentially normal basic perception, memory, language, and reasoning insofar as these do not involve the processing of emotional material. SM is the most selective case of amygdala damage ever documented in a human subject. Over more than a decade of testing, SM has repeatedly exhibited a selective impairment in the ability to recognize fear from facial expressions, even though she is able to recognize fear from complex visual scenes and tone of voice, and she has normal visual perceptual abilities (Adolphs et al., 1994; Adolphs and Tranel, 2000). Subsequent group studies confirmed the finding that bilateral amygdala damage impairs recognition of facial expressions of fear (Calder et al., 1996; Broks et al., 1998; Adolphs et al., 1999).

Functional imaging research has revealed a complementary and equally robust finding: amygdala activation during the perception of fearful faces (Figure 6.7). Relative to viewing neutral or happy faces, fearful faces elicit amygdala activation during passive viewing (Breiter et al., 1996), subliminal (brief) viewing (Whalen et al., 1998), and during

Figure 6.7. Bilateral activation of amygdala in response to subliminal presentation of fearful faces compared to happy faces (From Whalen et al., 1998, used with permission). (See color plate.)

performance of unrelated tasks like gender discrimination (Morris et al., 1998).

Intriguingly, a recent study of SM has indicated a putative mechanism by which amygdala damage impairs the recognition of facial expressions of fear (Adolphs et al., 2005). Using a series of partially occluded faces, Adolphs et al. showed that the eye region is most informative area for identifying fear from faces. Eye-tracking was used to show that SM fails to look at the eye regions of static faces (all faces, not just fearful faces). Thus, her impairment in recognizing fearful faces could be simply explained by the fact that she does not spontaneously look at the region of the face that is particularly useful for identifying fear. Remarkably, a verbal instruction to attend to the eye regions of the faces improved SM's ability to recognize fear to normal levels (Figure 6.8). Absent such an instruction, her performance returned to its previous level of impairment. These data suggest a critical role for the amygdala in the mediation of visual attention, at least for faces.

Outside the domain of facial emotion recognition, functional imaging studies have indicated a broader, multimodal role for the amygdala in the detection of emotional stimuli. Amygdala activation has been reported in response to the sounds of laughter, (Sander and Scheich, 2001), crying, (Sander and Scheich, 2001), and vocal expressions of fear (Phillips et al., 1998), as well as to aversive smells (Zald and Pardo, 1997) and aversive tastes (Zald et al., 1998). Furthermore, both functional imaging (Cahill et al., 1995, 1998) and lesion (Adolphs et al., 1997) studies indicate a role for the amygdala in the enhancement of memory for emotional events. The wealth of lesion and neuroimaging data regarding the amygdala's involvement in emotional processing will no doubt fuel theoretical debate about the primary function of the amygdala and generate hypotheses to be tested with both methods.

Attention

Attention is a broad term in neuropsychology and cognitive neuroscience, with definitions ranging from sustained effort and concentration to visual inspection and saccade modulation. Here, the discussion of attention will be restricted the “spotlight” phenomenon of visual attention: visual information within the spotlight (a circumscribed region of visual space) is processed more quickly or more efficiently than information outside the spotlight. The neural basis of this spatially restricted attentional

effect has been revealed with fMRI, and not with lesion studies. Brefczynski and DeYoe (1999) used a task in which subjects fixated a central marker while spatial attention was directed to a cued target object that was moved to successively greater eccentricities relative to the central fixation. The progressive shift of covert attention to greater eccentricities was associated with a corresponding retinotopic shift of cortical activation, spreading across striate and extrastriate visual cortex (Figure 6.9). In a similar study, Tootell et al. (1998) had subjects continually fixate a central marker while spatial attention was directed to one of four corners of the visual field. Attention to a specific visual field location correlated with greater activity in the retinotopically corresponding location of visual cortex, with the greatest effect in extrastriate areas. These data demonstrate that attention modulation is a “top-down” effect in the brain; retinotopic areas active in visual perception are selectively enhanced when attention is directed to the corresponding location in visual space. Clearly, the lesion method would be unable to reveal this mechanism because damage to the neuroanatomical areas enhanced during attention would impair vision altogether.

Cognitive control

“Cognitive control” refers to the executive allocation of cognitive resources during focused mental effort. Dozens of neuroimaging studies implicate the dorsal anterior cingulate cortex (dACC) as a critical neural substrate for cognitive control (for reviews see van Veen and Carter, 2002; Allman et al., 2001; Duncan and Owen, 2000). dACC is reliably activated during tasks that require response selection from conflicting alternatives, like Go/No-go tasks and the Stroop task. (Pardo et al., 1990; Carter et al., 1995; Carter et al., 2000; Leung et al., 2000) The association

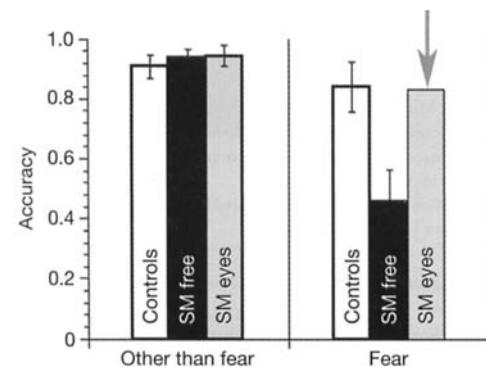

Figure 6.8. Instructed viewing of the eyes improves impaired fear recognition in SM. Accuracy of emotion recognition (\pm s.e.m.) for ten control subjects (white) and SM. Whereas SM's recognition of fear is impaired when she is allowed to look at the stimuli freely (SM free, black bars), her performance becomes normal relative to control subjects when she is instructed to fixate on the eyes (SM eyes, grey bar, red arrow). The impairment is specific to fear recognition (left panel shows mean recognition accuracy for all emotions other than fear). (From Adolphs et al., 2005, used with permission.)

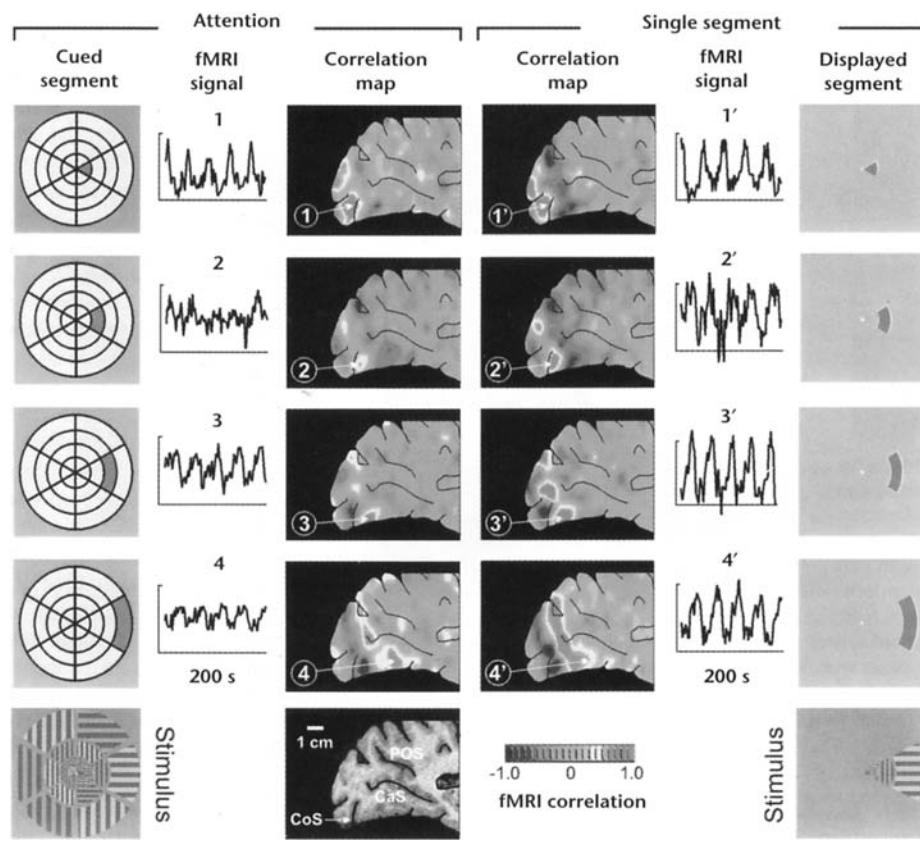

Figure 6.9. Retinotopic attentional modulation compared to activation evoked by cued targets alone. Cued segment (left column) shows schematic sequence of target segments cued for attentional scrutiny. Stimulus (bottom left) is actual target array. FMRI signal (left) shows signal modulation of individual voxels at sites indicated on adjacent correlation maps. Temporal phase shift of the signal at each site identifies the corresponding locus of attention. Correlation maps show sites where timing of modulation was positively correlated (red) or anti-correlated (blue) with the timing of attentional shifts. Displayed segment (right column) shows schematic sequence of single segments presented during otherwise identical control experiment. Composite of single segments shown in stimulus bottom right. FMRI Signal and correlation map on right show results of control experiment. Structural MRI (bottom) is a parasagittal section (13.6 mm left of midline) through occipital lobe in same plane as correlation maps. Sulcal landmarks; CaS, calcarine sulcus; CoS, collateral sulcus; POS, parieto-occipital sulcus. (From Brefczynski and DeYoe, 1999, used with permission) (See color plate.)

between dACC and cognitive control is patently evident from the neuroimaging studies, but the necessity of dACC for cognitive control is a separate question. Fellows and Farah (2005) directly addressed this issue by testing four patients with damage to dACC on the Stroop and go/no go tasks. Surprisingly, the dACC lesion patients, one of whom had bilateral damage, exhibited intact performance on the tasks. So despite the ubiquitous dACC activations observed in neuroimaging studies of cognitive control, a lesion study indicates that this structure is not a critical substrate for cognitive control. This is clearly an area where further work is needed to tease apart the particular roles of different neural structures in more elemental functions such as response selection and conflict monitoring.

Summary

From the tracks of research described above, it is readily apparent that the lesion method and functional neu-

roimaging offer distinct accounts of brain-behavior relationships. In some domains (long-term declarative memory, emotion recognition), imaging and lesion data may be convergent and complementary, but not redundant. In other domains (working memory and cognitive control), lesion studies have served to qualify the conclusions derived from functional imaging studies. In still other areas (priming, attention), functional imaging has provided exclusive insight into brain-behavior relationships, whereas the lesion method has been particularly productive in yet another field (decision-making and social conduct). Regardless of the precise contribution of each method to any individual research topic, it is clear that both methods have engendered inimitable knowledge in the study of brain-behavior relationships. Where these methods converge, theory can solidify and expand into novel branches of inquiry; where discrepancies exist, innovative conjecture and experimentation will soon follow.

CONCLUDING REMARKS

The lesion method has enjoyed a rich and fruitful history in the field of cognitive neuroscience. The lesion method has been, and continues to be, a unique and indispensable tool for investigating brain-behavior relationships. The advent of modern neuroimaging techniques has not only advanced the practice of the lesion method in its own right, but generated an entirely new class of data about the brain's function against which conclusions based on lesion data can be examined. These complementary forms of information have proven synergistic for the discovery of brain-behavior relationships: lesion findings spark neuroimaging hypotheses and vice versa. So long as the link between brain and behavior remains a curiosity worthy of experimentation, the study of brain-damaged patients will retain a central role.

The Electrodermal System

MICHAEL E. DAWSON, ANNE M. SCHELL, AND DIANE L. FILION

PROLOGUE: OVERVIEW

Electrodermal activity (EDA) has been one of the most widely used – some might add “abused” – response systems in the history of psychophysiology. Research involving EDA has been reported in practically all psychology, psychiatry, and psychophysiology research journals. The wide range of journals in which EDA research is published reflects the fact that EDA measures have been applied to a wide variety of questions ranging from basic research examining attention, information processing, and emotion, to more applied clinical research examining predictors and/or correlates of normal and abnormal behavior. The application of EDA measures to a wide variety of issues is due in large part to its relative ease of measurement and quantification combined with its sensitivity to psychological states and processes.

The purpose of this chapter is to provide a tutorial overview of EDA for interested students, researchers, and practitioners who are not specialists in this particular system. We begin with a historical orientation and then discuss the physical, inferential, psychological, and social aspects of EDA.

HISTORICAL BACKGROUND

The discovery of electrodermal activity. The study of psychological effects on the electrical changes in human skin began over 100 years ago in the laboratory of Jean Charcot, the French neurologist famous for his work on hysteria and hypnosis. Vigouroux (1879, 1888), a collaborator of Charcot, measured tonic skin resistance levels from various patient groups as a clinical diagnostic sign. In the same laboratory, Féhé (1888) found that by passing a small electrical current across two electrodes placed on the surface of the skin one could measure momentary decreases in skin resistance in response to a variety of stimuli (visual, auditory, gustatory, olfactory, etc.). The basic phenomenon discovered by Féhé is that the skin momentarily becomes a better conductor of electricity when external stimuli are presented. Shortly thereafter, the Russian

physiologist Tarchanoff (1890) reported that one could measure changes in electrical potential between two electrodes placed on the skin without applying an external current (see Neumann & Blanton, 1970, and Bloch, 1993, for interesting details regarding these initial discoveries). Hence, Féhé and Tarchanoff are said to have discovered the two basic methods of recording electrodermal activity in use today. Recording the skin resistance response (or its reciprocal, the skin conductance response) relies on the passage of an external current across the skin and hence is referred to as the *exosomatic* method, whereas recording the skin potential response does not involve an external current and hence is referred to as the *endosomatic* method. The present chapter will focus on the exosomatic method of recording *skin conductance level* (SCL) and *skin conductance response* (SCR) because this clearly is the method of choice among contemporary researchers (Fowles et al., 1981).

Issues in the history of EDA research. Several issues identified in this early research have been sources of considerable speculation and investigation throughout the history of research with this response system. One set of such issues concerns the mechanisms and functions of EDA. In terms of peripheral mechanisms, Vigouroux proposed what became known as the “vascular theory” of EDA (Neumann & Blanton, 1970). The vascular theory associated changes in skin resistance with changes in blood flow. Tarchanoff favored a “secretory theory,” which related EDA to sweat gland activity. This theory was supported later by Darrow (1927), who measured EDA and sweat secretion simultaneously and found the two measures to be closely related, although the phasic SCR would begin about one s before moisture would appear on the surface of the skin. Thus, it was concluded that activity of the sweat glands, not sweat on the skin per se, was critical for EDA. (Other lines of evidence indicating that sweat glands are the major contributors to EDA have been reviewed by Fowles, 1986, pp. 74–75.) It was generally known at the time that palmar sweat glands are innervated by the sympathetic chain of the autonomic nervous system, so EDA was said to reflect

sympathetic activation. In terms of more central physiological mechanisms, work by early investigators such as Wang and Richter indicated that EDA was complexly determined by both subcortical and cortical areas (for a review of this early research, see Darrow, 1937). Darrow also proposed that "the function of the secretory activity of the palms is primarily to provide a pliable adhesive surface facilitating tactual acuity and grip on objects" (1937, p. 641).

Issues surrounding the proper methods of recording and quantifying EDA also have been important in the history of this response system. Lykken and Venables (1971) noted that EDA has continued to provide useful data "in spite of being frequently abused by measurement techniques which range from the arbitrary to the positively weird" (p. 656). In fact, we would date the beginning of the modern era of EDA research to the early 1970s when Lykken and Venables proposed standardized techniques of recording skin conductance and standardized units of measurement. This was followed shortly by an edited book (Prokasy & Raskin, 1973) devoted entirely to EDA which contained several useful review chapters, including a particularly outstanding chapter by Venables and Christie (1973). Published around the same time were several other excellent reviews (Edelberg, 1972a; Fowles, 1974; Grings 1974). More recent reviews can be found in books by Boucsein (1992) and by Roy et al. (1993), as well as in individual chapters by Andreassi (2000), Fowles (1986), Hugdahl (1995), and Stern, Ray, and Quigley (2001).

Another issue of central importance concerns the psychological significance of EDA. From the beginning, this response system has been closely linked with the psychological concepts of emotion, arousal, and attention. Carl Jung added EDA measurements to his word-association experiments in order to objectively measure the emotional aspects of "hidden complexes." An American friend joined Jung in these experiments and enthusiastically reported that, "Every stimulus accompanied by an emotion produced a deviation of the galvanometer to a degree in direct proportion to the liveliness and actuality of the emotion aroused" (Peterson, 1907, cited by Neumann & Blanton, 1970, p. 470). About half a century later, when the concept of emotion was less in favor, Woodworth and Schlosberg (1954) devoted most of one entire chapter of their classic textbook in experimental psychology to EDA, which they described as "perhaps the most widely used index of activation" (p. 137). They supported this indexing relationship by noting that tonic SCL is generally low during sleep and high in activated states such as rage or mental work. The authors also related phasic SCR to attention, noting that such responses are sensitive to stimulus novelty, intensity, and significance.

Many of these issues have remained important for contemporary psychophysologists and are discussed in the remainder of this chapter. In the next section we present a summary of the contemporary perspectives regarding

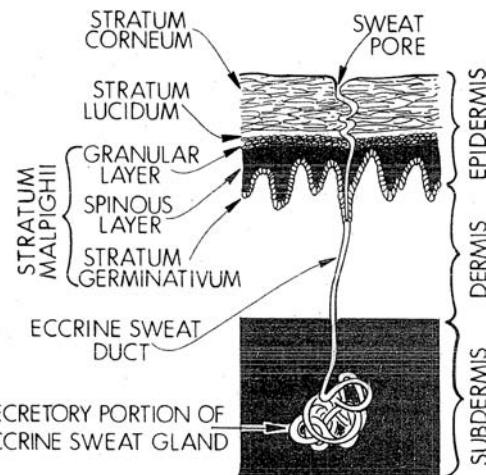

Figure 7.1. Anatomy of the eccrine sweat gland in various layers of skin. (Adapted from Hassett, 1978).

the basic physiological mechanisms and proper recording techniques of EDA.

PHYSICAL CONTEXT

Anatomical and physiological basis. The skin is a selective barrier that serves the function of preventing entry of foreign matter into the body and selectively facilitating passage of materials from the bloodstream to the exterior of the body. It aids in the maintenance of water balance and of constant core body temperature, functions accomplished primarily through vasoconstriction/dilation and through variation in the production of sweat. As pointed out by Edelberg (1972a), it is not surprising that an organ with such vital and dynamic functions constantly receives signals from control centers in the brain, and he suggests that "we can listen in on such signals by taking advantage of the fact that their arrival at the skin is heralded by measurable electrical changes that we call electrodermal activity" (p. 368).

There are two forms of sweat glands in the human body: the apocrine, which have been less studied, and the eccrine, which have been of primary interest to psychophysologists. The primary function of most eccrine sweat glands is thermoregulation. However, those located on the palmar and plantar surfaces are thought to be more related to grasping behavior than to evaporative cooling (Edelberg, 1972a) and they have been suggested to be more responsive to psychologically significant stimuli than to thermal stimuli. Although all eccrine glands are believed to be involved in psychological sweating, such sweating is usually most evident in these areas primarily because of the high gland density (Shields et al., 1987). The measurement of EDA by psychophysologists is primarily concerned with psychologically induced sweat gland activity.

Figure 7.1 shows the basic peripheral mechanisms involved in the production of EDA. The extreme outer layer

of the skin, the stratum corneum or horny layer, consists of a layer of dead cells that serves to protect the internal organs. Below the stratum corneum lies the stratum lucidum, and just below that is the stratum Malpighii. The eccrine sweat gland itself consists of a coiled compact body that is the secretory portion of the gland, and the sweat duct, the long tube which is the excretory portion of the gland. The sweat duct remains relatively straight in its path through the stratum Malpighii and stratum lucidum, it then spirals through the stratum corneum and opens on the surface of the skin as a small pore (Edelberg, 1972a).

Many models have been suggested to explain how these peripheral mechanisms relate to the electrical activity of the skin and to the transient increases in skin conductance elicited by stimuli. Edelberg (1993) concluded that one can account for the variety of electrodermal phenomena, including changes in tonic SCL and phasic SCR amplitude, with a model based entirely on the sweat glands.

To understand how electrodermal activity is related to the sweat glands, it is useful to think of the sweat ducts (the long tubular portion of the gland that opens onto the skin surface) as a set of variable resistors wired in parallel. Columns of sweat will rise in the ducts in varying amounts and in varying numbers of sweat glands, depending on the degree of activation of the sympathetic nervous system. As sweat fills the ducts, there is a more conductive path through the relatively resistant corneum. The higher the sweat rises, the lower the resistance in that variable resistor. Changes in the level of sweat in the ducts change the values of the variable resistors, and yield observable changes in EDA.

Historically, both the sympathetic and parasympathetic divisions of the autonomic nervous system (ANS) were considered possible mediators of EDA. This is partially because the neurotransmitter involved in the mediation of eccrine sweat gland activity is acetylcholine, which is generally a parasympathetic neurotransmitter, rather than norepinephrine, the neurotransmitter typically associated with peripheral sympathetic activation (Venables & Christie, 1980). It is now generally agreed that human sweat glands have predominantly sympathetic cholinergic innervation from sudomotor fibers originating in the sympathetic chain, although some adrenergic fibers also exist in close proximity (Shields et al., 1987). Convincing evidence for the sympathetic control of EDA has been provided by studies that have measured sympathetic action potentials in peripheral nerves while simultaneously recording EDA. The results have shown that within normal ranges of ambient room temperature and thermoregulatory states of subjects, there is a high correlation between bursts of sympathetic nerve activity and SCRs (Wallin, 1981).

Excitatory and inhibitory influences on the sympathetic nervous system are distributed in various parts of the brain and therefore the neural mechanisms and pathways involved in the central control of EDA are numerous and

complex. Boucsein (1992, pp. 30–36) followed the suggestions of Edelberg (1972a) in describing at least two and possibly three relatively independent pathways that lead to the production of SCRs (see Figure 7.2). The first and highest level of central EDA control involves contralateral cortical and basal ganglion influences (Sequeira & Roy, 1993). One cortical pathway involves excitatory control by the premotor cortex (Brodmann area 6) descending through the pyramidal tract, and another involves both excitatory and inhibitory influences originating in the frontal cortex. The second level of EDA control involves ipsilateral influences from the hypothalamus and limbic system (Sequeira & Roy, 1993). There is considerable evidence of an excitatory hypothalamic descending control of EDA. Limbic influences are complicated, but there is evidence of excitatory influences from the amygdala and inhibitory effects originating from the hippocampus. The third and lowest level mechanism is in the reticular formation in the brainstem (see Roy, Sequeira, & Delerm, 1993). Activation of the reticular formation by direct electrical stimulation or sensory stimulation evokes skin potential responses in cats, and presumably skin conductance responses in humans. An inhibitory EDA system has also been located in the bulbar level of the reticular formation.

Most of the evidence regarding the central pathways that control EDA described above was derived from animal studies, usually cats (e.g., Wang, 1964; Roy et al., 1993). More recently however, knowledge of the central control of human EDA, particularly EDA associated with attention and emotional processes, has increased dramatically with advances in neuroimaging technology. Using this technology, two strategies have been used to investigate the neural substrates of EDA: examination of EDA patterns in patients with delineated focal brain lesions (e.g., Asahina et al., 2003; Bechara et al., 1999; Tranel & Damasio, 1994; see review by Tranel, 2000), and examination of the relationship between patterns of brain activation and simultaneously recorded EDA (e.g., Critchley et al., 2000; Fredriksson et al., 1998; Nagai et al., 2004; Patterson, Ungerleider, & Bandettini, 2002; Williams et al., 2000).

Although there is not perfect overlap in the brain areas implicated across these studies, some consistent patterns have emerged. For example, activation of brain areas involved in evaluating stimulus significance, particularly the ventromedial prefrontal cortex, right inferior parietal region, and anterior cingulate, has been found to be associated with elicitation of SCRs. In addition, when the stimulus has emotional significance, the amygdala and orbitofrontal cortex, in addition to the areas mentioned above, are involved. Thermoregulatory sweating is controlled by the hypothalamus, which also integrates patterns of sympathetic activity in emotion, in conjunction with limbic structures.

Physical recording basis. As briefly described earlier, EDA is measured by passing a small current through a pair of

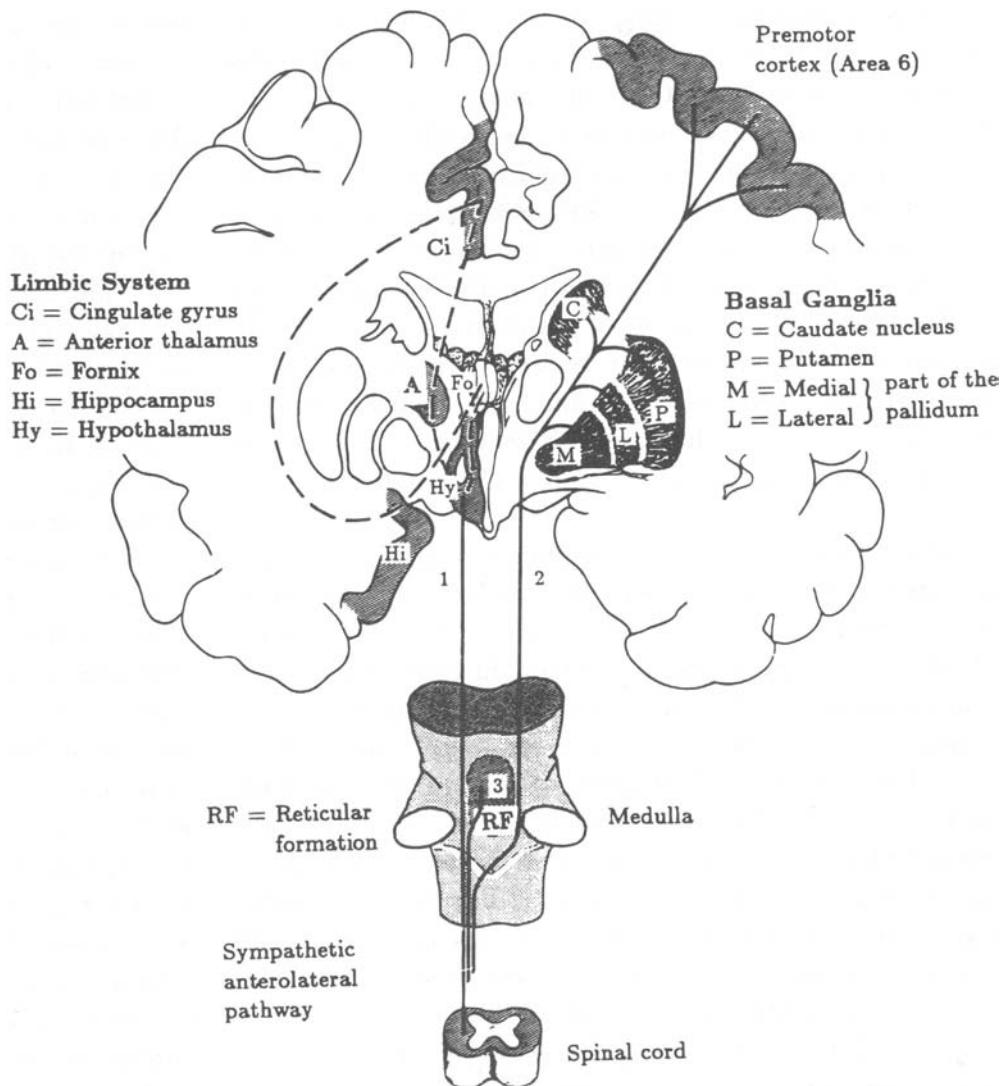

Figure 7.2. Central nervous system determiners of EDA in humans (From Boucsein, 1992).

electrodes placed on the surface of the skin. The principle invoked in the measurement of skin resistance or conductance is that of Ohm's law, which states that skin resistance (R) is equal to the voltage (V) applied between two electrodes placed on the skin surface, divided by the current (I) being passed through the skin. This law can be expressed as $R = V/I$. If the current is held constant then one can measure the voltage between the electrodes, which will vary directly with *skin resistance*. Alternatively, if the voltage is held constant, then one can measure the current flow, which will vary directly with the reciprocal of skin resistance, *skin conductance*. Conductance is expressed in units of Siemens and measures of skin conductance are expressed in units of microSiemens (μS).

Lykken and Venables (1971) argued strongly for the direct measurement of skin conductance with a constant-voltage system rather than measuring skin resistance with a constant current system. A description of constant voltage circuits that allow the direct measurement of skin conductance can be found in Lykken and Venables as well

as in Fowles et al. (1981), and most of the physiological recording systems currently on the market include constant voltage systems for the direct recording of skin conductance.

EDA recording systems. Older recording systems, in operation 10 or more years ago, output EDA to a paper record in analog form. Most recording systems today are computer-based systems in which the analog skin conductance signal is digitized and stored on a computer. With such systems, a researcher must select which time points the computer will sample the EDA. Historically, this sampling window has been a few seconds following each presentation of an experimental stimulus. In these cases, EDA at all other time points is lost. Fortunately, with expanding computing capability, it is now generally feasible to sample EDA continuously, to allow an experimenter to flag critical events with a keypress or programmed signal, and to provide a continuous printout of an experimental session. In choosing an EDA recording system one must consider

computing capabilities and software issues. For example, some manufacturers offer software packages for the acquisition of EDA, some offer software for the quantification of EDA, and some offer both (a listing of major commercial systems available for the recording and quantification of EDA is available at: <http://www.psychophys.com/company.html>).

In addition to selecting an EDA recording system, special consideration must be given to the choice of recording electrodes, electrode paste, electrode placement, and general environmental considerations. Silver-silver chloride cup electrodes are the type most typically used in skin conductance recording because they minimize the development of bias potentials and polarization. These electrodes can be easily attached to the recording site through the use of double-sided adhesive collars which also serve the purpose of helping to control the size of the skin area that comes in contact with the electrode paste, an important parameter because it is the contact area, not the size of the electrode, that affects the conductance values.

The electrode paste is the conductive medium between the electrodes and the skin. Probably the most important concern in choosing an electrode paste is that it preserve the electrical properties of the response system of interest. Because the measurement of EDA involves a small current passed through the skin, the electrode paste interacts with the tissue over which it is placed. For this reason, the use of a paste which closely resembles sweat in its salinity is recommended (Venables & Christie, 1980). Instructions for making such paste are given in Fowles et al. (1981, p. 235) and Grey and Smith (1984, p. 553). Satisfactory paste is also available commercially. Commercial EKG or EEG gels should not be used because they usually contain near saturation levels of NaCl and have been shown to significantly inflate measures of skin conductance level (Grey & Smith, 1984).

Skin conductance is recorded using two electrodes, both placed on active sites (bipolar recording); hence it does not matter in which direction the current flows between the two electrodes. Skin conductance recordings are typically taken from locations on the palms of the hands, with several acceptable placements. The most common electrode placements are the thenar eminences of the palms, and the volar surface of the medial or distal phalanges of the fingers (see Figure 7.3). It should be noted that although electrodermal activity can be measured from any of these sites, the values obtained are not necessarily comparable. Scerbo et al. (1992) made a direct comparison of EDA recorded from the distal and medial phalange sites simultaneously and found that both the elicited SCR amplitude and SCL were significantly higher from the distal recording site. The greater level of reactivity at the distal site was found to be directly related to a larger number of active sweat glands at that location (Freedman et al., 1994). Therefore, the distal phalange site is recommended unless there are specific reasons for not using the distal site (e.g., recording from children whose fingertips may be too small

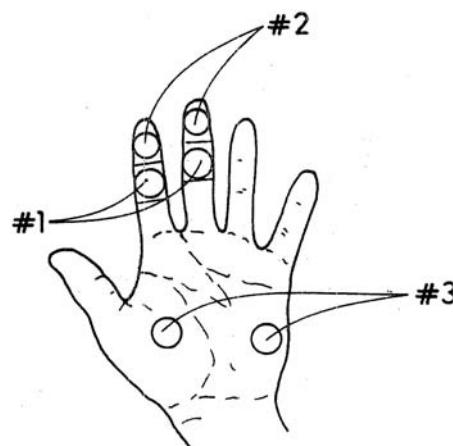

Figure 7.3. Three electrode placements for recording electrodermal activity. Placement #1 involves volar surfaces on medial phalanges, placement #2 involves volar surfaces of distal phalanges, and placement #3 involves thenar and hypothenar eminences of palms.

for stable electrode attachment, presence of cuts or heavy calluses on the fingertips, etc.).

Another recording issue concerns the hand from which to record. Many laboratories use the nondominant hand because it is less likely to have cuts or calluses, and because it leaves the dominant hand free to perform a manual task. However, this begs the question of whether there are significant laterality differences in EDA. Although differences between left and right hand EDA recordings have been reported, the differences reported across studies are often in opposite directions and the interpretations have been ambiguous (see review of early literature by Hugdahl, 1984). It is tempting to speculate that the prior conflicting findings may be because of lack of clear distinctions between emotional and nonemotional tasks (Hugdahl, 1995). EDA in emotional tasks is presumably controlled primarily by the ipsilateral limbic system, whereas EDA in non-emotional tasks may be controlled by the contralateral system (see Figure 7.2). Although research in this area continues (e.g., Brand et al., 2002; 2004; Esen & Esen, 2002; Navetuer et al., 1998; Polagaeva, Egorov, & Pirogov, 1997; Schulter & Papousek, 1998), evidence linking EDA asymmetries to specific patterns of lateralized brain activation is still inconclusive. Taken together, the current literature suggests that sensitive indices of handedness should be included in any study examining bilateral EDA (Schulter & Papousek, 1998), but provides no definitive evidence that EDA recorded from one hand gives consistently different results with respect to the effects of experimental variables than that recorded from the other hand.

Because it is critical in EDA recording that the electrical properties of the response system be preserved, the electrode sites should not receive any special preparation such as cleaning with alcohol or abrasion, which might reduce the natural resistive/conductive properties of the skin. However, because a fall in conductance has been

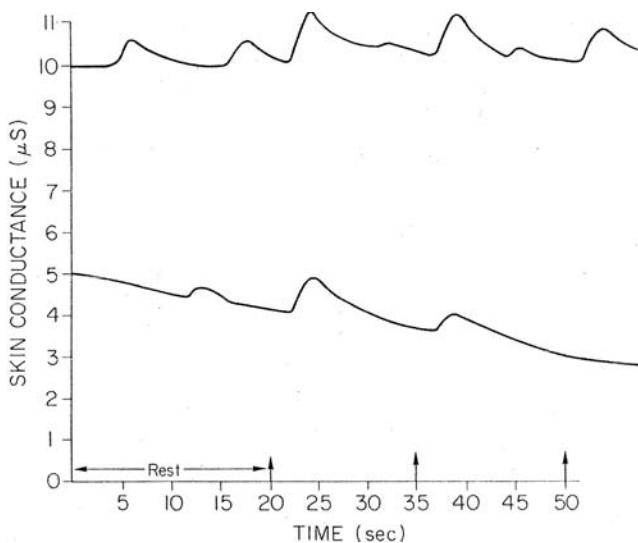

Figure 7.4. Two hypothetical skin conductance recordings during 20 s of rest followed by three repetitions of a simple discrete stimulus. Arrows represent the presentation of a stimulus (From Dawson & Nuechterlein, 1984).

noted following the use of soap and water (Venables & Christie, 1973), and because the length of time since the last wash will be variable across subjects when they arrive at the laboratory, these authors recommended that subjects be asked to wash their hands with a nonabrasive soap prior to having the electrodes attached and that the skin be kept clean and dry.

Ambient temperature and time of day are two environmental factors that should be controlled (e.g., Hot et al., 1999; Venables & Mitchell, 1996). Because EDA is influenced by hydration of the corneum, SCL tends to rise with increases in ambient temperature in the normal room temperature range. Boucsein (1992) recommends a room temperature of 23°C. Likewise, room humidity should be kept as constant as possible. Because diurnal effects may influence EDA, this variable also should be controlled across experimental conditions.

INFERENTIAL CONTEXT

Quantification procedures. Figure 7.4 shows tracings of two hypothetical skin conductance recordings during a 20 s rest period followed by three presentations of a simple discrete stimulus (e.g., a mild tone). Several important aspects of EDA can be seen in Figure 7.4. First, it can be seen that tonic SCL begins at 10 µS in the upper tracing and at 5 µS in the lower tracing. Although tonic SCL can vary widely between different subjects and within the same subject in different psychological states, the typical range is between 2 µS and 20 µS with the types of apparatus and procedures described here. Computing the log of SCL can significantly reduce skew and kurtosis in the SCL data and is recommended by Venables and Christie (1980).

It can also be seen in the lower tracing of Figure 7.4 that the SCL drifts downward from 5 µS to nearly 4 µS

during the rest period. It is common for SCL to gradually decrease while subjects are at rest, rapidly increase when novel stimulation is introduced, and then gradually decrease again after the stimulus is repeated.

Phasic SCRs are only a small fraction of the SCL and have been likened to small waves superimposed on the tidal drifts in SCL (Lykken & Venables, 1971). If the SCR occurs in the absence of an identifiable stimulus, as shown during the rest phase of Figure 7.4, it is referred to as a "spontaneous" or "nonspecific" SCR (NS-SCR). The most widely used measure of NS-SCR activity is their rate per minute, which typically is between 1 and 3/min while the subject is at rest. However, responses can be elicited by deep breaths and bodily movements, so unless these also are recorded, it is impossible to say which responses are truly NS-SCRs.

Presentation of a novel, unexpected, significant, or aversive stimulus will likely elicit an SCR referred to as a "specific" SCR. With the exception of responses elicited by aversive stimuli, these SCRs are generally considered components of the orienting response (OR). As is also the case with NS-SCRs, one must decide on a minimum amplitude change in conductance to count as an elicited SCR. Minimum values between .01 and .05 µS are generally used. Another decision regarding scoring of specific SCRs concerns the latency window during which time a response will be assumed to be elicited by the stimulus. Based on frequency distributions of response latencies to simple stimuli, it is common to use a 1–3 s or 1–4 s latency window. Hence, any SCR that begins between 1 and 3, or between 1 and 4 s, following stimulus onset is considered to be elicited by that stimulus. It is important to select reasonably short latency windows, perhaps even shorter than 1–3 s, so as to reduce the likelihood that NS-SCRs will be counted as elicited SCRs (Levinson, Edelberg, & Bridger, 1984).

An important advance in EDA research during the past decade or two is the development of computerized scoring programs. Scoring software is available from the manufacturers of several EDA recording systems, and customized software or shareware is frequently used as well. One example of shareware is SCRGauge by Peter Kohlisch, available in Boucsein (1992). Another shareware with a long history is SCORIT 1980 (Strayer & Williams, 1982), which is a revision of SCORIT (Prokasy, 1974). Interested readers can contact Dr. William C. Williams (*BWilliams@EWU.edu*) for an updated revised version of SCORIT 1980.

Having decided on a minimum response amplitude and a latency window in which a response will be considered a specific stimulus-elicited SCR, one can measure several aspects of the elicited SCR besides its mere occurrence and frequency. Definitions and typical values of the major EDA component measures are given in Table 7.1 and shown graphically in Figure 7.5. The most commonly reported measure is the size of the SCR, which is quantified as the amount of increase in conductance measured from the

Table 7.1. Electrodermal measures, definitions, and typical values

Measure	Definition	Typical Values
Skin conductance level (SCL)	Tonic level of electrical conductivity of skin	2–20 μS
Change in SCL	Gradual changes in SCL measured at two or more points in time	1–3 μS
Frequency of NS-SCRs	Number of SCR s in absence of identifiable eliciting stimulus	1–3 per min
SCR amplitude	Phasic increase in conductance shortly following stimulus onset	0.1–1.0 μS
SCR latency	Temporal interval between stimulus onset and SCR initiation	1–3 s
SCR rise time	Temporal interval between SCR initiation and SCR peak	1–3 s
SCR half recovery time	Temporal interval between SCR peak and point of 50% recovery of SCR amplitude	2–10 s
SCR habituation (trials to habituation)	Number of stimulus presentations before two or three trials with no response	2–8 stimulus presentations
SCR habituation (slope)	Rate of change of ER-SCR amplitude	0.01–0.5 μS per trial

Key: SCL, skin conductance level; SCR, skin conductance response; NS-SCR, nonspecific skin conductance response.

onset of the response to its peak. The size of an elicited SCR typically ranges between .1 and 1.0 μS . The values in Table 7.1 are representative of healthy young adults. Readers interested in the effects of individual differences in age, gender, and ethnicity should consult Boucsein (1992). Although effects of these variables on EDA have been documented and linked to differences in skin physiology, the effects appear to interact with the nature of the eliciting stimuli (e.g., emotional or neutral), recording environment (e.g., season, time of day, etc.), and recording methodology (constant current or constant voltage) (Boucsein, 1992; Venables & Mitchell, 1996). In general, we advise that these individual differences be controlled across experimental conditions.

When a stimulus is repeated several times and an average size of the SCR is to be calculated, one may choose to compute mean SCR amplitude or magnitude. *Magnitude* refers to the mean value computed across all stimulus presentations including those without a measurable response, whereas *amplitude* is the mean value computed across only those trials on which a measurable (nonzero) response

occurred (Humphreys, 1943). The magnitude measure is the most commonly used but Prokasy and Kumpfer (1973) argue against its use because it confounds frequency and amplitude, which do not always covary. A magnitude measure can create the impression that the response size is changing when, in fact, it is response frequency that is changing. Hence, these authors recommend separate assessments of frequency and amplitude rather than magnitude. However, it is important to note that a complication with the amplitude measure is that the *N* used in computing average response size can vary depending on how many measurable responses a subject gives, and the data of subjects without any measurable response must be eliminated. Thus, a subject who responds on each of ten stimulus presentations with a response of .50 μS will have the same mean SCR amplitude as a subject who responds on only the first stimulus presentation with a response of .50 μS , and does not respond thereafter. We concur with Venables and Christie (1980) that there are arguments for and against both amplitude and magnitude and that although no absolute resolution is possible, it is important to keep the difference between the two measures clearly in mind. In some situations it may be reasonable to compute and compare results obtained with SCR frequency, amplitude, and magnitude.

Like SCL, SCR amplitude and magnitude are frequently found to be positively skewed and also leptokurtotic, so a logarithmic transformation is often used to remedy these problems. If measurements are being made of SCR magnitude, so that zero responses are included, then $\log_e(SCR + 1.0)$ may be calculated, because the logarithm of zero is not defined (Venables & Christie, 1980). Another common practice is to use a square root transformation, \sqrt{SCR} , to normalize response amplitude data; this does not require the addition of a constant (Edelberg, 1972a). In some cases the choice of the square root or logarithmic

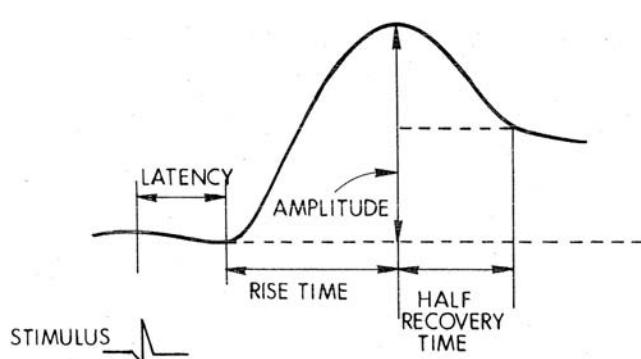

Figure 7.5. Graphical representation of principal EDA components.

transformation should be guided by considerations of achieving or maintaining the homogeneity of variance across several groups (Ferguson & Takane, 1989). If skew, kurtosis, or homogeneity of variance problems do not exist in a particular set of data, no transformations need be performed.

In addition to response size, one can also measure temporal characteristics of the SCR including onset latency, rise time, and half recovery time. These temporal characteristics of the SCR waveform are not as commonly reported as magnitude, and their relationship to psychophysiological processes is not as well understood at this time. The possibility that SCR recovery time, for example, can provide information independent of other EDA measures and is uniquely responsive to specific psychophysiological processes was suggested by Edelberg (1972b), but was questioned by Bundy and Fitzgerald (1975), and remains unsettled (Fowles, 1986, pp. 84–87; Edelberg, 1993, pp. 14–15). This is not to say that SCR recovery time is without discriminating power; rather, only that its qualitatively different informational properties relative to other EDA components is an open issue.

The usual constellation of EDA components is for high SCL, frequent NS-SCRs, large SCR amplitude, short latency, short rise time, and short recovery time to cluster together. However, the correlations among the EDA components generally are not very high, usually less than .60 (Lockhart & Lieberman, 1979; Venables & Christie, 1980; Schell, Dawson, & Filion, 1988). The size and consistency of these relationships are compatible with the hypothesis that many of the EDA components may represent partially independent sources of information although, as indicated above with SCR recovery time, this is an unsettled hypothesis. The one exception to the modest relationships among EDA components is the consistently high correlation between SCR rise time and recovery time. Based on this relationship, Venables and Christie (1980) suggest that SCR rise time and half recovery time may be essentially redundant measures and, that because recovery time is not always as available as rise time (because of subsequent responses), rise time may be the preferred measure.

A problem with quantifying the SCR components occurs when the response to be scored is elicited immediately after a preceding response that has not had time to fully recover. It is customary to measure the amplitude of each response from its own individual deflection point (Grings & Lockhart, 1965; Edelberg, 1967). However, the amplitude and the temporal characteristics of the second response are distorted by being superimposed on the recovery of the first response. For example, the measurable amplitude of the second response will be smaller given its occurrence following the first response. The amount of distortion of the second response is a function of the size of the first response and the time since the first response (Grings & Schell, 1969). Although there is no perfect solution to the response interference effect when hand-scoring EDA, it can be pointed out that response frequency may

be the least distorted component of the response in this situation. In addition, as mentioned earlier, one advantage of computerized scoring of EDA is the availability of more sophisticated scoring algorithms. In this regard, Lim et al. (1997) applied a multi-parameter curve-fitting algorithm to the scoring of overlapping skin conductance responses and they were able to decompose the overall response complex into meaningful components of the separate responses.

Another problem with quantifying the EDA components concerns the existence of large variability because of extraneous individual differences. Thus, whether an SCL of 8 μ S is considered high, moderate, or low will depend upon that specific subject's range of SCLs. For example, one can see in Figure 7.4 that an SCL of 8 μ S would be relatively low for the subject depicted in the upper tracing but would be relatively high for the subject depicted in the lower tracing. Similarly, an SCR of .5 μ S may be relatively large for one person but relatively small for another. Lykken et al. (1966) proposed an interesting method to correct for this interindividual variance called range correction. The procedure involves computing the possible range for each individual subject and then expressing the subject's momentary value in terms of this range. For example, one may compute a subject's minimum SCL during a rest period and a maximum SCL while the subject blows a balloon to bursting; the subject's present SCL can then be expressed as a proportion of his/her individualized range according to the following formula: $(SCL - SCL_{min}) / (SCL_{max} - SCL_{min})$. The rationale underlying these procedures is that an individual's range of EDA is due mainly to physiological variables unrelated to psychological processes (e.g., thickness of the corneum). It is the variation within these physiological limits that is normally of psychological interest (Lykken & Venables, 1971).

Although the range correction procedure can reduce error variance and increase the power of statistical tests in some data sets, it also can be problematic in others. For example, range correction would be inappropriate in a situation where two groups being compared had different ranges (Lykken & Venables, 1971). Taking a different approach, Ben-Shakhar (1985) has recommended using within-subject standardized scores to adjust for individual differences because this transformation relies upon the mean, a more stable and reliable statistic than the maximum response. Although these techniques may be useful under some circumstances, most investigators simply compare average values of SCL and SCR across groups, or compare difference scores within a group (e.g., SCL during a task minus SCL during rest).

Another important aspect of elicited SCRs is their decline in amplitude and eventual disappearance with repetition of the eliciting stimulus (SCR habituation). Habituation is a ubiquitous and adaptive phenomenon whereby subjects become less responsive to familiar and nonsignificant stimuli. There are several methods of quantifying

habituation of the SCR (Siddle, Stephenson, & Spinks, 1983). One simple method involves counting the number of stimulus repetitions required to reach some predetermined level of habituation (e.g., two or three consecutive trials without measurable SCRs). This “trials-to-habituation” measure is useful and has been widely employed since its use by Sokolov (1963), but it is subject to considerable distortion by the occurrence of a single response. For example, whether an isolated SCR occurs on trial 3 can make the difference between a trials-to-habituation score of “0” (indicative of an atypical nonresponder) and a “3” (indicative of a typical rate of habituation).

Another common measure of habituation is based on the rate of decline of SCR magnitude across trials as assessed by a “trials” main effect or interaction effect within an analysis of variance. However, this measure does not provide information about habituation in individual subjects and moreover can be distorted by differences in initial levels of responding.

A third measure of habituation is based on the regression of SCR magnitude on the log of the trial number (Lader & Wing, 1966; Montague, 1963). The regression approach provides a slope and an intercept score (the latter reflecting initial response amplitude), which are usually highly correlated with each other. Covariance procedures have been used to remove the dependency of slope on intercept, providing what Montague (1963) has called an “absolute rate of habituation.” However, this technique rests on the assumptions that slope and intercept reflect different underlying processes and that the treatment effects under investigation do not significantly affect the intercepts (Siddle et al., 1983). Use of the slope measure also assumes that subjects respond on a sufficient number of trials to compute a meaningful slope, which may not be the case for some types of subjects with mild innocuous stimuli. Nevertheless, to the extent that these assumptions can be justified, the slope measure is often preferable because: (1) unlike the analysis of variance approach, individual habituation scores can be derived, (2) unlike the trials-to-habituation measure, isolated SCRs have less of a contaminating effect, (3) unlike trials-to-habituation, the slope measure makes fuller use of the magnitude data, and (4) unlike trials-to-habituation, the slope measure can discriminate between subjects who show varying degrees of habituation but who fail to completely stop responding for two or three consecutive trials.

The temporal stability (test-retest reliability) of EDA measures such as the frequency of NS-SCRs, SCL, responsiveness to stimuli, and habituation have been fairly well investigated in normal healthy adults (see Freixa i Baqué, 1983 for a discussion of early studies, and Schell et al., 2002, for a more recent review). Test-retest correlations for periods extending up to one year or more have ranged from approximately .40 to .75 for NS-SCR frequencies, from .40 to .85 for SCL, and from .30 to .80 for number of SCRs elicited by a series of repeated stimuli. Stability

of temporal measures (i.e., latency, rise time, etc.) is typically lower. Schell et al. (2002) found that as measures of overall responsiveness, simple counts of the number of SCRs elicited by a series of stimuli were more reliable than trials-to-habituation measures.

ADVANTAGES AND DISADVANTAGES OF THE USE OF EDA

When one is considering use of EDA as an indicator of some psychological state or process of interest, it is well to remember that in the great majority of situations, changes in electrodermal activity do not occur in isolation. Rather, they occur as part of a complex of responses mediated by the autonomic nervous system.

Experimental treatments that have the effect of increasing SCL and/or NS-SCR rate also are expected to generally increase heart rate level and blood pressure and to produce peripheral vasoconstriction, to mention a few of the more commonly measured autonomic responses (Engel, 1960; see Grings & Dawson, 1978). The response or responses chosen for monitoring by a particular investigator should reflect considerations such as those discussed in the following section.

For some researchers, EDA may be the response system of choice because, unlike most ANS responses, it provides a relatively direct and undiluted representation of sympathetic activity. As has been pointed out above, the neural control of the eccrine sweat glands is entirely under sympathetic control. Therefore, increases in SCL or the SCR are due to increased tonic or phasic sympathetic activation. In contrast, with heart rate as with most ANS functions (pupil diameter, gastric motility, and blood pressure), a change in activity in response to stimuli of psychological significance cannot be unambiguously laid to either sympathetic or parasympathetic activity; it may be due to either one or to a combination of both. Thus, the researcher who wishes an unalloyed measure of sympathetic activity may prefer to monitor EDA, whereas the experimenter who wishes a broader picture of both sympathetic and parasympathetic activity may prefer heart rate, if constraints of instrumentation will allow only one to be recorded. Similarly, if for some reason (perhaps the use of medication with side effects on cholinergic or adrenergic systems) one wishes to monitor a response which is predominately cholinergically mediated at the periphery but which is also influenced by sympathetic activity, then EDA would be the choice.

Another advantage of measuring SCR is that its occurrence is generally quite discriminable. Thus, on a single presentation of a stimulus, one can determine by quick inspection whether or not an SCR has occurred. In contrast, the presence of a heart rate response on single stimulus presentation may be difficult to distinguish from ongoing variability in heart rate that reflects changes in muscle tonus or respiratory sinus arrhythmia.

In addition to decisions made based on neuroanatomical control and basic response characteristics, an investigator

may prefer EDA to other response systems because of the nature of the situation in which the subject is assessed. Fowles (1988) argued convincingly that heart rate is influenced primarily by activation of a neurophysiological behavioral activation system that is involved in responding during *appetitive* reward-seeking, to conditioned stimuli associated with reward, and during active avoidance. On the other hand, EDA is influenced primarily by activation of a neurophysiological behavioral *inhibition* system that is involved in responding to punishment, to passive avoidance, or to frustrative nonreward. This latter system is viewed as an anxiety system. Thus, if an investigator is studying the reaction of subjects to a situation or to discrete stimuli that elicit anxiety, but in which no active avoidance response can be made, the electrodermal system should be the physiological system that is most responsive.

For many investigators, an additional advantage of the use of EDA relative to other response systems is that of all forms of ANS activity, individual differences in EDA appear to be most reliably associated with psychopathological states. The correlates of some of these stable EDA differences between individuals are discussed in the [following section](#).

Finally, it is important to note that, in comparison to many other psychophysiological measures, EDA is relatively inexpensive to record. After initial purchase of the recording system, expenses for each subject are trivial, involving electrode collars and paste and the occasional replacement of electrodes. Electrical shielding of the room in which the subject sits which is generally needed for noise-free recording of EEG or event related potentials is unnecessary, and the costs of using EDA as a response measure are minuscule compared to those of hemodynamic techniques such as PET scans or functional MRI. Furthermore, the techniques used to record EDA are completely harmless and risk-free, and thus they can be used with young children and in research designs that require repeated testing at short intervals of time.

There are also potential disadvantages to the use of EDA as a dependent measure. First, EDA is a relatively slow-moving response system. As mentioned previously, the latency of the elicited SCR is between 1.0 and 3.0 s, and tonic shifts in SCL produced by changes in arousal and alertness require approximately the same time to occur. Thus, an investigator who is interested in tracking very rapidly occurring processes, or stages within a complex process, may not find EDA useful. Although the SCR cannot index such rapidly occurring processes as sensory gating or stages of stimulus analysis on a real-time basis, it has been found to be correlated with real-time measures of these processes. For example, Lyytinen, Blomberg, and Näätänen (1992) observed that the parietal P3a was larger when an SCR was elicited by a novel tone than when no SCR was elicited.

Another potential disadvantage is that EDA has multiple causes; the elicited SCR is not specific to a single type of event or situation (as, for instance, the N400 ERP com-

ponent appears to be specifically influenced by semantic expectancy, Kutas, 1997). However, the multiple influences on EDA may actually be as much an advantage as a disadvantage. As described throughout this chapter, EDA can be used to index a number of processes: activation, attention, and significance or affective intensity of a stimulus. In using EDA as a response measure, one must take care to control experimental conditions – that is, be sure that one is varying only one process that may influence EDA at a time. Such experimental control is essential for all attempts to draw clear inferences from results, whether one is recording EDA, electrocortical activity, or a hemodynamic measure, given the number of processes that may influence these measures as well.

Thus, like any single response system, EDA has distinct advantages and disadvantages. The ideal situation, of course, is one in which the researcher can record more than one response measure. When ANS activity is of primary interest, EDA and heart rate are probably the two most common choices: EDA for its neuroanatomical simplicity, trial-by-trial visibility, and utility as a general arousal/attention indicator and heart rate for its potential differentiation of other psychological and physiological states of interest to the researcher.

PSYCHOLOGICAL AND SOCIAL CONTEXT

In this section, we review the psychological and social factors that have been shown to influence EDA in three types of paradigm: (1) those that involve the presentation of discrete stimuli, (2) those that involve the presentation of continuous stimuli, and (3) those that involve examining the correlates of individual differences in EDA.

Effects of discrete stimuli. Properties of stimuli to which the SCR is sensitive are wide and varied: they include stimulus novelty, surprise, intensity, arousal content, and significance. It might be argued that, because EDA is sensitive to such a wide variety of stimuli, it is not a clearly interpretable measure of any particular psychological process (Landis, 1930). This view is certainly correct in the sense that it is impossible to identify an isolated SCR as an “anxiety” response, or an “anger” response, or an “attentional” response. However, the psychological meaning of an SCR becomes interpretable by taking into account the stimulus condition or experimental paradigm in which the SCR occurred. The better controlled the experimental paradigm, the more conclusive the interpretation. That is, by having only one aspect of the stimulus change across conditions (e.g., task significance) while eliminating other differences (e.g., stimulus novelty, intensity, etc.), then one can more accurately infer the psychological processes mediating the resultant SCR. As we will illustrate in the following discussion, the inference of a specific psychophysiological process requires knowledge of both a well controlled stimulus situation and a carefully measured response.

One discrete stimulus paradigm that relies on the SCR's sensitivity to stimulus significance is the so-called Guilty Knowledge Test (GKT), which is a type of detection of deception test ("lie detection"). The GKT, also sometimes referred to as a "Concealed Knowledge Test," involves recording SCRs (as well as other physiological responses) while presenting subjects with a series of multiple-choice questions (Lykken, 1959). For example, a suspect in a burglary case might be asked to answer "no" to each of the alternatives given for a question concerning details about the burglary. For each question, the correct alternative would be intermixed among other plausible alternatives. The theory behind the technique is that the correct answer to each question will be more psychologically significant to a guilty subject than will the other alternatives, whereas for the innocent subject all of the alternatives would be of equal significance. Therefore, the guilty subject is expected to respond electrodermally more to the correct alternatives, whereas the innocent subject is expected to respond randomly (Lykken, 1959). Lykken (1981) suggested that guilty subjects can be detected nearly 90% of the time and that innocent subjects can be correctly classified nearly 100% of the time with a properly constructed GKT. For a discussion of the differing views of psychophysiological techniques of detecting deception, see Iacono (Chapter 29 in this volume).

Tranel, Fowles, and Damasio (1985) developed another type of discrete stimulus paradigm with which to study the effects of significant stimuli. SCRs were recorded from normal college students while being presented a set of slides depicting faces of famous people (e.g., Ronald Reagan, Bob Hope, etc.) interspersed among a larger number of faces of unfamiliar people. Subjects were instructed simply to sit quietly and look at each slide. The results revealed that the average SCR was much larger to slides of significant faces ($M = 1.26 \mu\text{S}$) than to the nonsignificant faces ($M = .19 \mu\text{S}$).

Although the GKT of Lykken (1959) appears to be quite adequate to detect concealed information (and hence the guilty person), and the paradigm of Tranel et al. (1985) appears adequate to test for recognition of famous faces, one may question whether either paradigm is sufficient to demonstrate the effect of stimulus significance per se on the SCR. It may be argued that both paradigms confounded relative novelty with relative stimulus significance. If guilty subjects dichotomize items into relevant and irrelevant categories in the GKT (Ben-Shakhar, 1977), then the relevant category is presented less often than the irrelevant category and this relative novelty may contribute to the differential SCRs. Likewise, in the studies using slides of famous faces, the significant category of stimuli was presented less often than the nonsignificant category and this difference in relative novelty may have contributed to the differential SCRs. The number of presentations of relevant/significant stimuli should have been equal to that of irrelevant/nonsignificant stimuli in order to unambiguously demonstrate the effect of stimulus signifi-

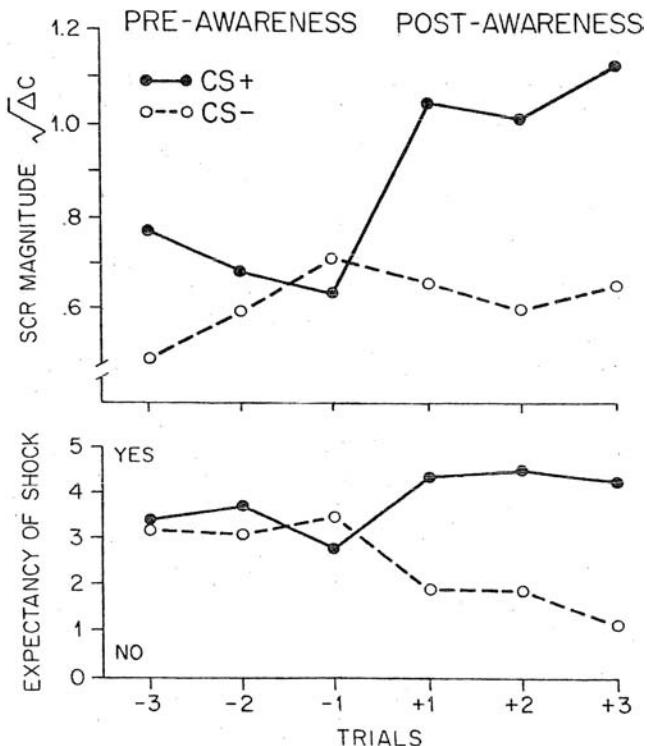

Figure 7.6. Mean SCR magnitude (top) and mean expectancy of shock (bottom) to the reinforced conditioned stimulus (CS+) and the nonreinforced conditioned stimulus (CS-) on three pre-aware and three post-aware trials (Adapted from Dawson & Biferno, 1973).

cance on SCRs. As mentioned earlier in this section, close control over stimulus properties (in this case, novelty and significance) is necessary in order to infer the psychological processes eliciting the SCR. Interestingly, using a modification of the GKT in which relevant and irrelevant items were presented equally often, Verschueren et al. (2004) have found evidence that responses to relevant items remain greater than to irrelevant items. These findings demonstrate the importance of stimulus significance in eliciting SCRs above and beyond novelty.

Another discrete stimulus paradigm in which EDA is commonly measured that highlights the influence of stimulus significance while controlling for stimulus novelty involves discrimination classical conditioning (Grings & Dawson, 1973). For example, Dawson and Biferno (1973) employed a discrimination classical conditioning paradigm in which college student subjects were asked to rate their expectancy of a brief electric shock (unconditioned stimulus, UCS) following each presentation of a CS+ (a conditioned stimulus regularly followed by the shock) and a CS- (a control stimulus never followed by shock). Tones of 800 Hz and 1200 Hz were presented equally often and served as the reinforced CS+ and the nonreinforced CS-, counterbalanced across subjects. Thus, on each conditioning trial, the subject's expectancy of shock and the associated SCR were recorded. The results, shown in Figure 7.6, revealed that subjects tended

to respond equally to the reinforced CS+ and to the nonreinforced CS- until they became aware of the contingency between the conditioned stimuli and the shock. There was no evidence of SCR discrimination conditioning prior to the development of awareness; however, once the subject became aware, the CS+ became more significant than the CS-, and there was an abrupt increase in the magnitude of the SCRs elicited by the CS+. Moreover, SCR discrimination conditioning fails to occur when CS-UCS pairings are embedded in distracting tasks that effectively prevent subjects from becoming aware of the critical stimulus relations (see reviews by Dawson & Schell, 1985; Lovibond & Shanks, 2001). These results suggest that awareness of the CS-UCS relation is necessary for human discrimination SCR conditioning.

The conditions under which subjects must be consciously aware of the stimulus significance in order to elicit SCR ORs is a topic of considerable research. For example, SCR discrimination conditioning has been reported to occur without subjects becoming aware of the CS-UCS relationship under special circumstances when "prepared" stimulus relationships are conditioned. The concept of "preparedness" is that certain stimulus associations (e.g., taste with nausea and snakes with pain) are more quickly, easily, and automatically learned than are others (e.g., an arbitrary tone and a shock) and are more resistant to extinction because they have been correlated in our evolutionary past (Seligman, 1970).

Öhman and his colleagues, in an interesting series of studies beginning in the 1970s, extended Seligman's concept to human autonomic conditioning, using types of CSs that have been termed biologically prepared, potentially phobic, or fear-relevant: pictures of spiders, snakes, and angry faces (see Öhman, 1992 for reviews). In the early studies of this series, Öhman and his colleagues demonstrated that SCRs conditioned with fear-relevant CSs and a shock UCS were more resistant to extinction than were SCRs conditioned with neutral CS-UCS relations (pictures of flowers or happy faces as CSs associated with shock). Such SCRs also were more resistant to cognitive manipulations such as extinction instructions informing subjects that the UCS would no longer be delivered (Hugdahl & Öhman, 1977) and were retained past the point of cognitive extinction (no greater expectancy of the UCS after the CS+ than after the CS-) following the presentation of many nonreinforced trials (Schell, Dawson, & Marinkovic, 1991).

In later studies of this series, backward masking was used to prevent awareness of the CS-UCS relation by preventing conscious recognition of the fear-relevant CSs. In this paradigm, visual CSs are presented very briefly (30 ms) and immediately followed by a masking stimulus. These procedures prevent recognition of the CSs in the vast majority of subjects on the vast majority of trials (Öhman, Dimberg, & Esteves, 1989a).

Backwardly masked angry and happy faces have been used as CSs during acquisition (Esteves et al., 1994). In

one group, a masked angry face (CS+) was paired with shock, whereas in another group a masked happy face (CS+) was paired with shock. During subsequent extinction, unmasked CSs were presented and conditioned SCRs were elicited to the previously masked angry face CS+, but not to the happy face CS+. Thus, electrodermal conditioning was established "nonconsciously" to a threatening angry face, but not to a friendly smiling face. Conditioning to other masked biologically fear-relevant CSs was replicated in subsequent experiments by Öhman and Soares (1998) using pictures of snakes and spiders rather than angry faces. Studies using functional brain imaging techniques have replicated these SCR results and demonstrated the importance of the amygdala, extended regions of the amygdala complex, and sensory cortex in such conditioning (Morris, Buchel, & Dolan, 2001).

Studies of brain damaged patients also indicate that the amygdala is critical for SCR classical conditioning. For example, Bechara et al. (1995) found that a patient with selective bilateral destruction of the amygdala did show unconditioned SCRs to the unconditioned stimulus but did not show SCR conditioning to the CS, although this patient was aware of the CS-UCS relation. A different patient with bilateral hippocampi damage (but intact amygdala) showed both conditioned and unconditioned SCRs but could not describe the CS-UCS relation. All in all, contrary to the results shown in Figure 7.6, these findings indicate that SCR conditioned responses may be acquired without the subjects' awareness of the CS-UCS relation in some circumstances. The nature of these circumstances (only with biologically prepared fear-relevant stimuli or with certain types of brain damage?) is a topic of ongoing research.

SCRs elicited by discrete nonaversive stimuli are generally considered to be part of the orienting response to novel or significant stimuli. We believe that the data reviewed in this section can be interpreted within this theoretical setting. The task of subjects exposed to the GKT is to deceive or conceal knowledge, and the correct item is more relevant to this task than are incorrect alternative items. Thus, subjects orient more to the task-significant items than the task-nonsignificant items. Verschueren et al. (2004) found greater heart rate deceleration following relevant items than irrelevant items in a GKT which is consistent with the orienting hypothesis. Likewise, faces of famous people may be perceived as more significant than the faces of unfamiliar people, and the signal of an impending shock (CS+) is more significant than the signal of no shock (CS-). Thus, the results observed here are consistent with the notion that the SCR is highly sensitive to stimulus significance, even under certain conditions where the reasons for that significance may not be consciously processed.

There have been several models proposed to account for the elicitation of autonomic ORs such as the SCR (see Siddle et al., 1983, for a review). For example, an influential information processing model has been proposed by

Öhman (1979). This model distinguishes between automatic preattentive processing and controlled capacity-limited processing. Autonomic orienting is elicited when the preattentive mechanisms call for additional controlled processing. According to this model, there are two conditions under which this call is made. First, the call is made and the OR is elicited when the preattentive mechanisms fail to identify the incoming stimulus because there is no matching representation in short-term memory. Thus, the OR is sensitive to stimulus novelty. Second, the call is made and the OR is elicited when the preattentive mechanisms recognize the stimulus as significant. Thus, the OR represents a transition from automatic to controlled processing based on preliminary preattentive analysis of stimulus novelty and stimulus significance. This model allows for the possibility that the OR may be elicited without conscious awareness. Others, however, have suggested that the OR occurs when controlled processing resources are actually allocated to the processing of the stimulus, at least where fear-irrelevant stimuli are concerned (Dawson, Filion, & Schell, 1989; Öhman, 1992).

Other discrete stimuli capable of eliciting SCRs are those with either strong positive or negative affective valence. We orient to stimuli that are significant because they are either very positive or very negative in terms of the emotional response that they elicit. However, unlike responses such as the startle eyeblink, the SCR does not distinguish arousing positive stimuli from equally arousing negative stimuli. Lang, Bradley, Cuthbert, and their colleagues have developed a set of widely used pictures (the International Affective Picture System, IAPS, Lang, Bradley, & Cuthbert, 1998; see Chapter 25, this volume) that are rated for both their arousal-producing quality and valence on a strongly positive to strongly negative scale. SCRs elicited by these pictures have reliably been found to be related to the arousal dimension, with responses increasing in magnitude as arousal rating increased for both positively valenced pictures (greater for erotic pictures than for beautiful flowers) and negatively valenced pictures (greater for striking snakes than for tombstones in a cemetery) (Lang et al., 1993; Cuthbert, Bradley, & Lang, 1996).

Other affective stimuli hypothesized to evoke SCRs are those associated with internal processes involved in making decisions. Damasio (1994) proposed a "somatic marker" hypothesis, the main point of which is that decision-making is influenced by emotional somatic responses. The somatic marker hypothesis has been tested by measuring SCRs during a gambling task (Bechara et al., 1997). In this task subjects select cards from "bad" decks that can yield high immediate financial gain but large long-term losses, or from "good" decks that yield lower immediate gain but a larger long-term gain. After encountering a few losses, normal subjects, as opposed to brain-damaged patients, generate SCRs in anticipation of selecting cards from the "bad" deck and begin to avoid selecting cards from that deck. These results were originally interpreted as indicating that SCRs in response to decision-

making processes reflect somatic markers that help the person make advantageous decisions even before conscious knowledge of the rules of the game was available. However, more recent research suggests that, in fact, subjects may have considerable conscious understanding of the game (Maia & McClelland, 2004) and this suggests that the SCR may only indicate when a person has consciously decided to make a risky decision.

In conclusion, in this section we have described some of the discrete stimulus paradigms in which EDA is most often measured and has proven to be most useful. We have emphasized that determining the psychological meaning of any particular SCR is dependent on a well-controlled stimulus situation. In addition, we have described a theoretical model that may be used to account for the SCRs elicited in the paradigms described. Finally, these areas of research examining the SCR to discrete stimuli underscore the point made previously that one advantage of the SCR is that the response can easily be measured on individual presentations of a stimulus. Thus, one may determine whether the response to a "guilty" relevant stimulus in a group of stimuli is greater than that to "innocent" irrelevant stimuli, whether the SCR elicited by a CS+ is greater on the first trial after awareness of the CS-UCS relationship occurs than on the last trial before that awareness occurs, whether the SCR elicited by a fear-relevant CS+ is greater than the SCR elicited by a CS- on the first trial pair following extinction instructions, whether the eliciting stimulus is highly arousing due to affective valence of either a positive or negative nature, and whether arousal states that occur during decision-making guide decisions when risk is involved.

Effects of continuous stimuli. We turn now to an examination of the effects of more chronic, long-lasting stimuli or situations as opposed to the brief, discrete stimuli reviewed above. Chronic stimuli might best be thought of as modulating increases and decreases in tonic arousal. Hence, the most useful electrodermal measures in the context of continuous stimuli are SCL and frequency of NS-SCRs, because they can be measured on an ongoing basis over relatively long periods of time.

One type of continuous stimulus situation that will reliably produce increases in electrodermal activity involves the necessity of performing a task. The anticipation and performance of practically any task will increase both SCL and the frequency of NS-SCRs, at least initially. For example, Lacey et al. (1963) recorded palmar SCL during rest and during the anticipation and performance of eight different tasks. The tasks ranged from those requiring close attention to *external* stimuli, such as listening to an irregularly fluctuating loud white noise, to those requiring close attention to *internal* information processing, such as solving mental arithmetic problems. The impressive finding for present purposes was that SCL increased in each and every one of the task situations. Typically, SCL increased about one μ S above resting level during anticipation and then

increased another one or two μ S during performance of the task. Heart rate, unlike SCL, discriminated between tasks involving attention to external stimuli and tasks requiring attention to internal information processing.

Munro et al. (1988) observed that large increases in SCL and NS-SCR frequency were induced by a different task-significant situation. In this case, college student subjects were tested during a five-minute rest period and then during performance of a continuous vigilance task. The task stimuli consisted of a series of digits presented visually at a rapid rate of one-per-s with exposure duration of 48 ms; the subject's task was to press a button whenever the digit "0" was presented. Both the number of NS-SCRs and SCL initially increased sharply from the resting levels during this demanding task and then gradually declined as the task continued.

The finding that electrodermal activity is reliably elevated during task performance suggests that tonic EDA can be a useful index of a process related to "energy regulation" or "energy mobilization." An information processing interpretation of this finding might be that tasks require an effortful allocation of attentional resources and that this is associated with heightened autonomic activation (Jennings, 1986). A different, but not necessarily mutually exclusive, explanation would invoke the concepts of stress and affect rather than attention and effortful allocation of resources. According to this view, laboratory tasks are challenging stressors, and a reliable physiological response to stressors is increased sympathetic activation, particularly EDA arousal.

Situations in which strong emotions are elicited also increase tonic EDA arousal, as would be expected from the finding discussed above that SCR magnitude is affected by the arousal value of discrete stimuli with emotional valence. In a classic experiment, Ax (1953) created genuine states of fear and anger in his subjects by causing them to feel in danger of a high-voltage shock due to equipment malfunction or by treating them in a rude and inconsiderate fashion. SCL, number of NS-SCRs, and several other measures of sympathetic nervous system activity rose during both the fear and the anger conditions, with the patterns for fear and anger differing to some degree (SCL rose more in fear than in anger, while NS-SCRs and diastolic blood pressure rose more in anger than in fear.) More recently, Levenson, Gross, and their colleagues have used films in a number of studies to elicit emotional states, primarily disgust, lasting for a minute or more (Gross & Levenson, 1993; Gross, 1998). SCL and other measures of sympathetic activation in these studies were higher during the films than during a baseline period, and the rise in SCL was influenced by the emotional regulation strategy that subjects were instructed to use. Subjects instructed to suppress their facial display of emotion, to try to behave as though anyone observing them would not know what they were feeling, showed greater increases in SCL than subjects who simply watched the films or who were instructed to reappraise what they were seeing, to

watch the film with a detached, objective, and unemotional attitude.

Social stimulation constitutes another class of continuous stimuli that generally produces increases in EDA arousal. Social situations are ones in which the concepts of stress and affect are most often invoked. For example, early research related EDA recorded during psychotherapeutic interviews to concepts such as "tension" and "anxiety" on the part of both patient and therapist (Boyd & DiMascio, 1954; Dittes, 1957). In one such study, Dittes (1957) measured the frequency of NS-SCRs of a patient during 42 hours of psychotherapy. The results of this study indicated that the frequency of NS-SCRs was inversely related to the judged permissiveness of the therapist, and Dittes concluded that EDA reflects "the anxiety of the patient, or his 'mobilization' against any cue threatening punishment by the therapist" (p. 303).

Schwartz and Shapiro (1973) reviewed several areas of social psychophysiology up to 1970, including those in which EDA was measured during social interactions. These are situations in which intense cognitive and affective reaction may occur, precipitating large changes in EDA and other physiological responses. In a series of social psychophysiological studies conducted since the Schwartz and Shapiro review, EDA was recorded during marital social interactions (Levenson & Gottman, 1983; 1985). The researchers measured SCL (in addition to heart rate, pulse transmission time, and somatic activity) from married couples while they discussed conflict-laden problem areas. It was found that couples from distressed marriages had high "physiological linkage"; that is, there were greater correlations between husbands' and wives' physiological reactions in distressed marriages than those in satisfying marriages during the discussions of problem areas. Moreover, greater physiological arousal, including higher SCL, during the interactions and during baselines was associated with a decline in marital satisfaction over the ensuing three years.

Another series of studies related the effects of stressful social interactions on EDA to relapse among schizophrenia patients. It has been well documented that patients are at increased risk for relapse if their relatives are critical, hostile, or emotionally overinvolved with them at the time of their illness (Brown, Birley, & Wing, 1972; Vaughn & Leff, 1976; Vaughn et al., 1984). The term *expressed emotion* (EE) is used to designate this continuum of affective attitudes ranging from low-EE (less critical) to high-EE (more critical) on the part of the relative.

It has been hypothesized that heightened autonomic arousal may be a mediating factor between the continued exposure to a high-EE relative and the increased risk of symptomatic relapse (Turpin, 1983). According to this notion, living with a high-EE family member produces excessive stress and autonomic hyper-arousal. Autonomic hyper-arousal has been characterized as one of several transient intermediate states that can produce deterioration in the patient's behavior, which in turn can negatively

affect people around the patient. Hence, a vicious cycle can be created whereby the increased arousal causes changes in the patient's behavior that have an aggravating effect on the social environment, which then serves to further increase autonomic arousal. Unless such a cycle is broken, (e.g., by removal from that social environment), it can lead to the return of schizophrenia symptoms and a clinical relapse (Dawson, Nuechterlein, & Liberman, 1983; Nuechterlein & Dawson, 1984).

One prediction derived from this model is that patients exposed to high-EE relatives should show heightened sympathetic arousal compared to patients exposed to low-EE relatives. The first study to test this prediction obtained rather clear confirmatory results (Tarrier et al., 1979). These investigators measured the EDA of remitted patients living in the community whose relatives' level of EE had been determined by Vaughn and Leff (1976). Patients were tested for 15 minutes without the key relative and for 15 minutes with the key relative present. The frequency of NS-SCR activity of the patients with high-EE relatives and low-EE relatives did not differ when the relative was absent from the testing room, but if the key relative was present then patients with high-EE relatives exhibited higher rates of NS-SCRs than did patients with low-EE relatives. These results indicate that the presence of high-EE and low-EE relatives have differential effects on EDA which are consistent with the hypothesis that differential autonomic arousal plays a mediating role in the differential relapse rates of the two patient groups. More complete reviews of these studies and their implications can be found in Turpin, Tarrier, and Sturgeon (1988).

Individual differences in EDA. We have discussed the utility of EDA as a dependent variable reflecting situational levels of arousal/activation or attentiveness/respondiveness to individual stimuli. In this section we consider EDA as a relatively stable trait of the individual, as an individual difference variable. Individual differences in EDA are reliably associated with behavioral differences and psychopathological states of some importance, and we will examine some of these.

Individual differences in the rate of NS-SCRs and the rate of SCR habituation have been used to define a trait called "electrodermal lability" (Mundy-Castle & McKiever, 1953; Lacey & Lacey, 1958; Crider, 1993). Electrodermal "labiles" are subjects who show high rates of NS-SCRs and/or slow SCR habituation, whereas electrodermal "stabiles" are those who show few NS-SCRs and/or fast SCR habituation. Electrodermal lability is an individual trait that has been found to be relatively reliable over time, and labiles differ from stabiles with respect to a number of psychophysiological variables, including measures of both electrodermal and cardiovascular responsiveness (Kelsey, 1991; Schell, Dawson, & Filion, 1988). In this section, we review behavioral and psychological differences associated with this individual difference in both normal and abnormal populations.

Electrodermal lability is a trait of interest in psychological research in part because many investigators have reported that labiles outperform stabiles on tasks which require sustained vigilance. When individuals perform a signal detection task that is sustained over time, deterioration across time in the accurate detection of targets is frequently observed, a phenomenon referred to as vigilance decrement (Davies & Parasuraman, 1982). Several experimenters have reported that when vigilance decrement occurs, it is more pronounced among electrodermal stabiles than among labiles. This appears to be particularly true when EDA lability is defined by differences in SCR OR habituation rate (Koelega, 1990). As time on the task goes by, labiles are apparently better able to keep attention focused on the task and to avoid a decline in performance (Crider & Augenbraun, 1975; Hastrup, 1979; Munro et al., 1987; Vossel & Rossman, 1984). With a difficult continuous performance task, Munro et al., for instance, whose study was mentioned above, found that stabiles showed a significant decrement over time in performance, whereas labiles did not. The degree of task-induced sympathetic arousal as measured by increases in NS-SCR rate was negatively correlated across subjects with performance decrement.

Researchers investigating these sorts of behavioral differences between electrodermal stabiles and labiles have concluded that lability reflects the ability to allocate information processing capacity to stimuli that are to be attended (Lacey & Lacey, 1958; Katkin, 1975; Schell et al., 1988). As Katkin (1975, p. 172) concluded, "electrodermal activity is a personality variable that reflects individual differences in higher central processes involved in attending to and processing information." Viewing electrodermal lability in this way suggests that labiles should differ from stabiles in a variety of information processing tasks. Consistent with this view, EDA labile children have been found to generally outperform stabiles on a variety of tasks that require perceptual speed and vigilance (Sakai, Baker, & Dawson, 1992).

In addition to the differences between stabiles and labiles in the normal population, reliable abnormalities in electrodermal lability are associated with diagnosable psychopathology. We will next summarize EDA abnormalities reported in schizophrenia and psychopathy. A more general discussion of psychophysiological abnormalities in these and other psychopathologies can be found in Hicks, Keller, and Miller (Chapter 28, this volume).

In general two types of electrodermal abnormalities have been reported in different subgroups of patients with schizophrenia. First, between 40% and 50% of schizophrenia patients fail to show any SCR orienting responses to mild innocuous tones (termed "nonresponders"), compared to approximately 10% nonresponders in the normal population (see reviews by Bernstein et al., 1982; Dawson & Nuechterlein, 1984; Iacono, Ficken, & Beiser, 1993; Öhman, 1981). The high proportion of electrodermal non-responders in schizophrenia has been a reliable

finding across studies. For example, Bernstein et al. (1982) examined a series of 14 related studies in which samples of American, British, and German schizophrenia patients and normal controls were tested using a common methodology and response scoring criteria. The consistent finding was that approximately 50% of the patients were non-responders, compared to only 5 to 10% of controls. (More recent data reported and reviewed by Venables and Mitchell (1996) suggest the percentage of SCR non-responders in normal groups may be closer to 25%).

The second electrodermal abnormality, found in the "responder" subgroup of patients, is the presence of higher than normal levels of tonic arousal, indicated by high SCLs and a high frequency of NS-SCRS (Dawson & Nuechterlein, 1984; Dawson, Nuechterlein, & Schell 1992a; Öhman, 1981). In effect, the nonresponder group is characterized by hyporesponsivity to stimuli whereas the responder group is characterized by tonic hyperarousal. Both types of abnormalities have been found to be reliable across time. For example, in a group of 56 chronic schizophrenia patients classified as nonresponders on an initial test, 87% remained nonresponders two weeks later and 91% were nonresponders four weeks later (Spohn et al., 1989). In a group of 29 schizophrenia nonresponder outpatients, 62% remained nonresponders one year later (Schell et al., 2002). The tonic measures of SCL and NS-SCRs also remained relatively stable over a one-year period in the schizophrenia outpatients (test-retest $r_s = .43$ and .53 respectively). The latter test-retest correlations, although significant, are in the lower end of the range of correlations found over similar time intervals with normal subjects that were reviewed earlier, possibly because of fluctuating symptoms among the patients.

The hope associated with the identification of responder and nonresponder EDA subgroups is that it will identify meaningful subgroups in terms of different symptomatic types of schizophrenia or different prognoses, or that one or both abnormalities might constitute a vulnerability marker for schizophrenia. Unfortunately, the results relating EDA abnormalities with current symptoms, future prognosis, and vulnerability have not always been consistent. As we point out later, the reasons for these inconsistencies may have to do with different populations of patients and control comparison groups.

Nonresponder and responder subgroups of patients have been reported by some investigators to show different symptomatology at the time of testing, with responders generally displaying more symptoms of excitement, anxiety, manic behavior, and belligerence, whereas nonresponders tend to show more emotional withdrawal, conceptual disorganization, and negative symptoms (e.g., Bernstein et al., 1981; Straube, 1979; Fuentes et al., 1993). Furthermore, SCR hypo-responsivity has been related to a more severe form of illness (Katsanis & Iacono, 1994), poor premorbid adjustment (Öhman et al., 1989), and more psychiatric symptoms overall (positive and negative) (Green, Nuechterlein, & Satz, 1989; Kim et al., 1993). Other inves-

tigators, however, have found the hyper-aroused responders to display the greater level of overall symptomatology (Brekke et al., 1997; Dawson et al., 1992b).

Abnormally elevated EDA arousal also has been found particularly during periods of psychotic symptomatology, compared to the same patients during periods of remission (Dawson et al., 1994) (see Figure 7.7). Moreover, heightened EDA arousal has been found to occur within a few weeks prior to an impending psychotic relapse, compared to control periods of stable remission within the same patients (Hazlett et al., 1997). This finding is consistent with a theoretical model that hypothesizes that heightened sympathetic activation is associated with a "transient intermediate state" that precedes psychotic episodes in vulnerable individuals (Nuechterlein & Dawson, 1984). According to this theoretical model, not all such intermediate states will necessarily be followed by psychotic exacerbation or relapse. Rather, these states constitute periods of heightened vulnerability with an increased risk of relapse, with the actual occurrence of relapses or exacerbation being influenced by environmental stressors.

Results regarding prediction of outcome also have been somewhat inconsistent. The predominant finding is that EDA hyperarousal is associated with poor short-term symptomatic prognosis (Brekke, Raine, & Thomson, 1995; Frith et al., 1979; Zahn, Carpenter, & McGlashan, 1981; Dawson et al., 1992b; see review by Dawson & Schell, 2002). However, a minority of studies have reported that EDA hyporesponsivity, not hyperarousal, is associated with poor prognosis. The typical procedure in these short-term studies was to relate EDA recorded during rest and simple orienting tasks from schizophrenia patients initially while in symptomatic states and then relate the EDA measures to subsequent persistence of the symptoms weeks or months later. In a longer-term study (Tarrier & Barrowclough, 1989), the number of NS-SCRs and the regression slopes of SCL measured during interactions with relatives at the time the patients were hospitalized were found to be related to symptomatic relapse over the next two years. The direction of the effect, greater frequency of NS-SCRs and greater rise in SCL among the patients who later relapsed, is consistent with the notion that high EDA arousal is predictive of prognosis. These results are consistent with the hypothesis that patients at high risk of relapse have a predisposition to autonomic hyperarousal to certain environmental or social stimuli.

The studies of prognosis reviewed above relied primarily upon measures of psychotic symptoms or hospital readmission. However, there are some studies that have measured prognosis as functional outcome, such as holding a job or having friends, instead of psychotic symptoms. Öhman et al. (1989b) reported that skin conductance non-responding and lower levels of tonic EDA activity taken at the beginning of a follow-up period predicted poor social and employment outcome over a two-year period in a subgroup of male schizophrenia patients. Their outcome criteria combined the employment and social-contact outcome

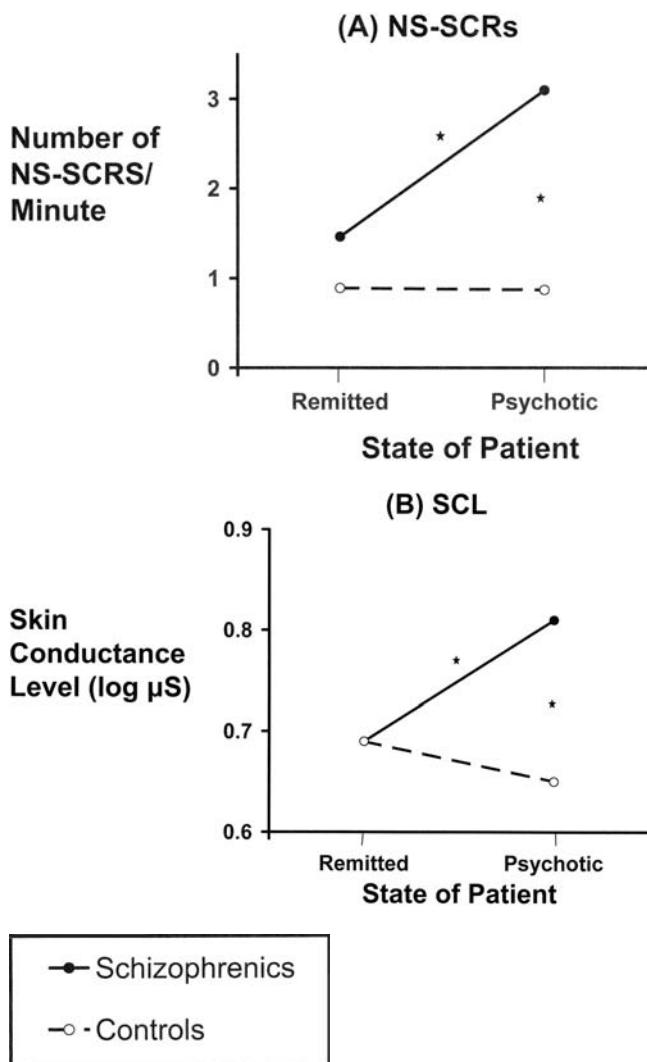

Figure 7.7. (A) Mean number of nonspecific SCR per minute and (B) mean log SCL obtained from normal controls and patients with schizophrenia when the patients were in remitted and psychotic states. Asterisks indicate significant differences (Adapted from Dawson et al., 1994).

criteria developed by Strauss and Carpenter (1974) into one outcome index. To have a “good” outcome, patients had to simultaneously have at least a minimal social life (meet with friends at least once a month) and had to be employed or enrolled in school at least on a part time basis. Conversely, Wieselgren et al. (1994), using an identical methodology to that used by Öhman et al. (1989b), reported an opposite relation for female schizophrenia patients, with high tonic electrodermal activity predicting poor social and work outcome. More recently Schell et al. (2005) used the same measure of outcome and reported results consistent with Wieselgren et al. That is, high SCL and NS-SCRs (as well as number of SCR ORs) were associated with poor social and occupational outcome and negative symptoms measured one year later. Moreover, this was true for both males and females. These results suggest that hyperarousal and autonomic hyper-reactivity to the environment may interfere with fragile cognitive process-

ing mechanisms in ways that exacerbate vulnerabilities in the areas of social competence and coping. These exacerbated cognitive and social deficits may then create a vicious cycle by feedback to the social environment with eventual symptomatic relapse (Dawson, Nuechterlein, & Liberman, 1983; Nuechterlein & Dawson, 1984).

Schell et al. (2005) also raised the possibility that both EDA abnormalities in patients with schizophrenia (non-responsiveness and hyperarousal) may predict poor outcome. Whether a particular study finds nonresponders or responders to have the poorer outcome may depend upon whether the sample as a whole is more or less responsive or aroused than normal. Many of the studies reviewed above did not include comparison of patients to normal controls, instead selecting their EDA subgroups based solely on the distribution within the patient group. However, interesting differences are present among those that did report comparisons to normal. For example, Öhman et al. (1989), who reported poorer functional outcome among nonresponders, had a sample of patients who were much more likely to be nonresponders and to have lower SCL than normal controls. However, Wieselgren et al. (1994) and Schell et al. (2005), both of whom reported poor outcome associated with the hyperaroused responders, had groups of patients who did not differ from normal on SCR responsivity but did as a whole have higher than normal EDA arousal. Thus, Öhman et al.’s more abnormal non-responders had the poorer outcome, whereas Wieselgren et al.’s and Schell et al.’s more abnormal hyper-aroused responders had the poorer outcome. It may be that either abnormality, hyporesponsiveness or hyperarousal with respect to controls, is associated with poor outcome. Hyporesponsiveness may be associated with generally limited cognitive processing capacity, whereas hyperarousal may act to interfere with efficient processing as described above.

Finally, the issue of vulnerability to schizophrenia has been addressed in some EDA studies, again not always with consistent results, by examining first degree relatives of schizophrenia patients, usually the children of schizophrenia patients, who are not manifesting schizophrenic symptomatology. The most common finding in the early research using this methodology was abnormal hyperarousal and/or hyper-reactivity to aversive stimuli in the offspring of schizophrenia patients (see reviews by Dawson & Nuechterlein, 1984; Öhman, 1981). Subsequent research has generally supported this finding. For example, Hollister et al. (1994) found that the young offspring of schizophrenic patients have higher than normal frequency of NS-SCRs, and those who later developed schizophrenia tended to have the highest level of NS-SCRs. Iacono, Ficken, and Beiser (1999) also found a higher than normal rate of NS-SCRs in the responder first-degree relatives of patients with schizophrenia. However, the latter study reported the same abnormality in first degree relatives of patients with major depressive illness, a finding that suggests that electrodermal hyper-arousal may not be a vulnerability marker specific to schizophrenia.

Abnormalities in tonic EDA and SCR responsiveness have also been reported in other psychopathologies, particularly psychopathy. Psychopaths are usually characterized as low in arousal and deficient in feelings of fear and anxiety, leading to their thrill-seeking and anti-social behavior (Lykken, 1957; Quay, 1965). It would be expected that both of these abnormalities should be reflected in EDA abnormalities, in particular in lower tonic measures of arousal such as SCL and NS-SCRs, and in smaller SCR magnitudes given in response to stimuli that would be associated with fear or anxiety in normal individuals. Both such abnormalities have been reported among psychopaths.

Fowles (1993), in a review of EDA during resting conditions, concluded that lower levels of SCL were occasionally found among psychopaths, although effect sizes were small, and less evidence existed for lower NS-SCR levels. Lorber (2004), in a meta-analysis of 95 studies of EDA and HR in psychopathy, concluded that psychopaths were characterized by reduced tonic EDA at rest, although again the effect sizes were small. Clearer differences from normal controls appear in tonic EDA levels as arousal increases, as, for instance, when simple orienting stimuli are presented (Fowles, 1993). Tonic EDA differences between psychopaths and normals clearly maximize when stressful stimuli are present (Fowles, 1993).

In one very well-known study that assessed not only tonic EDA but also response to anxiety-provoking stimuli, Hare (1965) measured SCL in psychopathic and nonpsychopathic prison inmates and college student controls during rest and while they watched the numbers 1–12 presented consecutively on a memory drum at 3 s intervals. A strong electric shock was given as the number 8 was presented. Psychopathic subjects had lower SCL during rest and during the task than the other groups, and psychopathic inmates showed smaller increases in skin conductance from numbers 1 to 8 than did nonpsychopathic inmates, which was interpreted as indicating less fear elicited in the interval prior to anticipated punishment. This finding with the “count-down” procedure has been replicated several times (for reviews, see Fowles, 1993 and Lykken, 1995).

As would be expected from Hare’s findings, numerous investigators have reported that psychopaths show impaired SCR conditioning with aversive UCSs (usually electric shocks) (Lykken, 1957; Hare, 1965; for a review, see Fowles, 1993). Psychopaths also exhibit abnormal SCR magnitudes to other affective stimuli. Verona et al. (2004) presented positively and negatively affectively valenced and neutral sounds (e.g., laughing baby, crying baby, clucking chicken) from the International Affective Digitized Sounds (IADS; Bradley & Lang, 1999) system to prison inmates assessed with the Psychopathy Checklist – Revised (PCL-R; Hare, 1991). The PCL-R assesses what are generally regarded as two factors of psychopathy, emotional detachment (e.g., egocentricity, shallow affect, and absence of remorse) and antisocial behavior (e.g., frequent trouble with the law, pathological lying, and substance abuse). Inmates scoring

high on the emotional detachment factor showed smaller responses to both pleasant and unpleasant sounds than did those who scored low on the factor, indicating that abnormalities in emotional processes in psychopathy extend beyond the realm of fear and anxiety. An interesting study by Blair et al. (1997) presented psychopathic and nonpsychopathic prison inmates with IAPS slides from three categories: nonthreatening (e.g., a book), threatening (e.g., a very angry face), and distress (e.g., a crying child). The two groups did not differ in SCR magnitude to threatening and nonthreatening stimuli, but the psychopaths responded less to the distress cues than nonpsychopaths.

In addition to these abnormalities in EDA seen in adults diagnosed with psychopathy, lower levels of tonic EDA have been reported in adolescents who later exhibited antisocial behavior. Raine, Venables, and Williams (1990) recorded EDA, heart rate (HR), and EEG during rest and several tasks from a sample of unselected 15-year-old schoolboys, and at a 10-year follow-up identified those who during the follow-up period had committed serious criminal offenses. As adolescents, the offenders had a lower rate of resting NS-SCRs, indicating lower arousal levels. The lower resting HR and greater EEG power in low-frequency bands seen in the offender group also were consistent with lower arousal.

It is worth noting that studies of the psychophysiological correlates of psychopathy have typically used only male subjects. Little if anything is known about psychophysiological abnormalities among female psychopaths.

EPILOGUE

EDA is a sensitive peripheral index of sympathetic nervous system activity that has proven to be a useful psychophysiological tool with wide applicability. Social and behavioral scientists have found that tonic EDA is useful to investigate general states of arousal and/or alertness, and that the phasic SCR is useful to study multifaceted attentional processes, as well as individual differences in both the normal and abnormal spectrum. We believe that future research will continue to support the use of EDA in a variety of situations and stimulus conditions.

An important direction for future research involves sharpening the inferential tool characteristics of EDA itself. That is, basic research is needed to address the specific conditions under which specific EDA components reflect specific psychological and physiological processes and mechanisms. For example, under what stimulus conditions does the SCR amplitude component of the orienting response reflect automatic preattentive cognitive processes versus controlled cognitive processes? Likewise, under what test situations do tonic and phasic EDA components reflect different brain systems? We expect that the expanding use of neuroimaging techniques in cognitive and affective neuroscience will elucidate these issues, making EDA an even more interesting and valuable psychophysiological tool.

ACKNOWLEDGMENTS AND DEDICATION

Michael Dawson was supported by a Research Scientist Development Award (K02 MH01086) from the National Institute of Mental Health during preparation of this chapter. We thank the following students for their generous help: Wade R. Elmore, C. Beau Nelson, Albert B. Poje, Anthony Rissling, and Gary L. Thorne. We dedicate this chapter to William W. Grings, one of the pioneers in electrodermal activity who served as mentor to the first two authors, and friend to all three.

Cardiovascular Psychophysiology

GARY G. BERNSTON, KAREN S. QUIGLEY, AND DAVE LOZANO

INTRODUCTION

The cardiovascular system is essential for life and has been a central focus of psychophysiological investigation for several reasons. First, at least some its parameters, like heart rate and blood pressure, are readily observed and quantified. Second, the cardiovascular system is a rich and intricate physiological system with multiple regulatory subsystems that are subject to central and peripheral autonomic controls and humoral influences. Consequently, it is highly sensitive to neurobehavioral processes. Finally, the complexity of the cardiovascular system renders it susceptible to a variety of disorders, many of which are impacted by psychological factors such as stress, and hence it assumes special significance in psychosomatic medicine.

The present chapter will provide an overview of the physiology of the cardiovascular system and its central and peripheral autonomic and neuroendocrine controls. It will then consider common psychophysiological measures from the methodological, analytic, and interpretative perspectives. Finally, we will highlight a few current issues and themes in the contemporary literature.

ANATOMY AND PHYSIOLOGY OF THE CARDIOVASCULAR SYSTEM

Overview

The cardiovascular system consists of the heart, a pump, and the vasculature, a distribution system, that together ensure that blood reaches all tissues of the body. The heart provides for a consistent flow of oxygenated blood by sending blood into the lungs (pulmonary circulation) and then to the rest of the body (systemic circulation). Figure 8.1 shows a schematized view of the heart and vasculature to emphasize connections among all the components. Deoxygenated blood from the venous side of the systemic circulation returns via the right atrium and then to the right ventricle of the heart from which it is pumped to the lungs for re-oxygenation. Blood returns from the lungs

by way of the left atrium, then enters the left ventricle from where it is pumped into the aorta, the large vessel from which all oxygenated blood is disseminated to the rest of the body. Blood leaving the aorta passes through ever smaller blood vessels, first entering the large arteries which later branch into smaller arterioles, metarterioles and finally into capillaries. Capillaries are small, thin-walled vessels from which oxygen and other nutrients diffuse into tissues, and into which the tissues release waste products such as carbon dioxide that must eventually be secreted or excreted from the body. After the capillary system, blood passes again into somewhat larger vessels, the venules and finally, the veins that carry blood from the systemic circulation back to the heart. The major veins that drain blood back into the heart, the inferior and superior vena cavae, return blood to the right atrium of the heart, from which blood passes to the right ventricle and again begins its journey through the pulmonary and systemic circulations.

The heart

The crucial pump of the cardiovascular system, the heart, consists of special cardiac muscle with properties different from that of skeletal muscle found elsewhere in the body. Cardiac muscle comes in three forms, atrial, ventricular, and specialized conducting fibers that serve as the electrical conducting system of the heart. The pumping action of the heart is primarily served by the atrial and ventricular muscle fibers. Cardiac muscle cells form a syncytium, so called because the tissue is electrically coupled to permit rapid spread of depolarization across the heart, particularly in a rostral to caudal direction. There are both atrial and ventricular syncytiums connected by an electrical conducting system. In the syncytiums, the boundaries of adjacent muscle cells along the longitudinal axis of the cardiac muscle consist of intercalated discs. These discs are specialized, highly permeable membranes capable of extremely fast spread of depolarization from one cardiac muscle cell to another. This is crucial to the pumping action of the heart where the rostral (atrial) and caudal

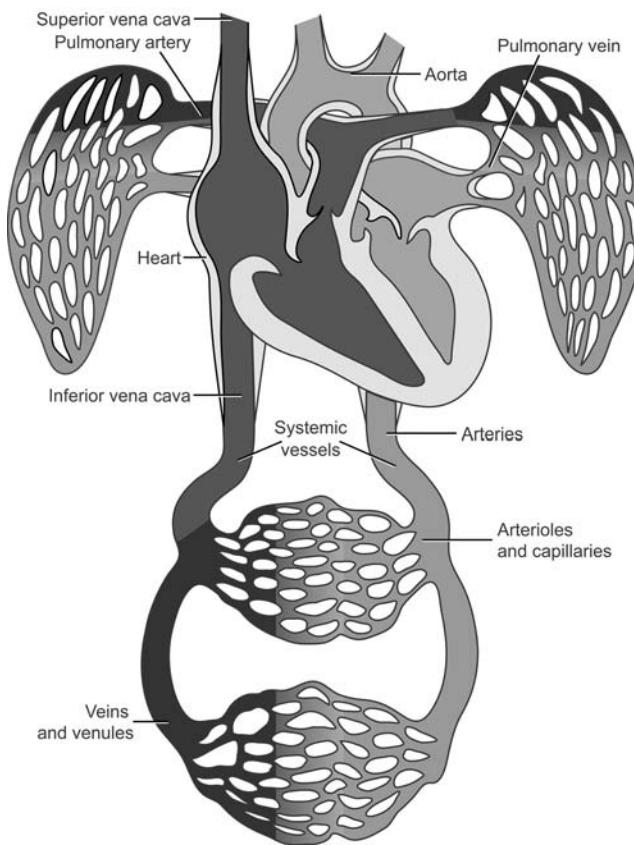

Figure 8.1. Systemic and pulmonary circulation. In keeping with usual depictions of the heart, the right side of the heart is on the left side of the picture. Lighter gray areas indicate oxygenated blood and darker gray areas indicate deoxygenated blood.

(ventricular) portions of the heart each must function as a single pumping unit, and where there must be coordinated action of each chamber.

The atrial and ventricular chambers are electrically connected by way of a conducting system that triggers ventricular contraction shortly after contraction of the atria. The specialized cardiac muscle fibers comprising the conducting system functionally couple the pumping actions of the atria and ventricles. Depolarization of two nodes of electrically active tissue, the sinoatrial (SA) and atrioventricular (AV) nodes, provides the electrical impetus that triggers contraction of the heart. The SA node in the wall of the right atrium just beneath the opening to the superior vena cava serves as the “pacemaker” of the heart. The SA node is the pacemaker because the speed of spontaneous depolarization of this node is typically faster than that of the AV node, and hence generally controls the rate of the beat. A system of internodal fibers forms a conducting system linking the SA and AV nodes. The depolarization wave is conducted away from the AV node and into the ventricles by way of the AV bundle (of His) which branches into the left and right bundles of Purkinje fibers that pass through the septum between the left and right ventricles. This system directs a wave of depolarization from the atria to the ventricles in a controlled

fashion that creates a highly coordinated pumping action with atrial contraction followed shortly by ventricular contraction.

The depolarization of cardiac muscle is different from skeletal muscle in that there is a depolarization spike followed by a sustained depolarization phase or plateau of about 0.2–0.3 seconds before the muscle repolarizes. The presence of the plateau provides a more sustained contraction in cardiac muscle than is typically observed in skeletal muscle. As a result, there is a more effective pumping action by the cardiac muscle because time is needed for blood to travel from the atria to the ventricles before the ventricles contract. The plateau in the depolarization wave of the cardiac muscle occurs because cardiac muscle depolarizes as a result of the opening of fast sodium (Na^+) channels (like those found in skeletal muscle), as well as slow calcium (Ca^{2+}) channels. The combined effect is a sustained depolarization. A similar plateau is seen in the depolarization curve of the Purkinje fibers of the conducting system. However, the velocity of conduction in atrial and ventricular muscle is on average slower (0.3–0.5 m/sec) than in the Purkinje fibers (which vary from 1.5–4.0 m/sec). This faster conduction in the Purkinje fibers permits the depolarization wave to reach all parts of the ventricular muscle quickly.

The cardiac cycle

The events that occur in the heart from one beat to the next beat are collectively referred to as the cardiac cycle (Figure 8.2). The cycle is composed of two main epochs: diastole, during which the heart does not pump and is filling with blood, and systole, during which the heart pumps. The cycle begins with depolarization of the SA node in the right atrium during the latter part of diastole. The wave of depolarization passing through the atrial muscle corresponds to the P wave in the electrical signal generated by the heart (i.e., the electrocardiogram or ECG) as recorded at the body surface (see Figure 8.3, panel A). The P wave is followed shortly thereafter by atrial contraction during which the QRS complex of the ECG appears, reflecting ventricular contraction and demarcating the onset of systole. During ventricular contraction, pressure in the ventricles is high enough to close the atrioventricular (AV) valves between the atria and ventricles. However, after ventricular contraction, as ventricular pressure falls below the atrial pressure, the AV valves open, and blood begins to rapidly fill the ventricles. Initiation of ventricular contraction leads to a large increase in ventricular pressure (more than 100 mmHg in a healthy heart). Once ventricular pressure is higher than the aortic pressure, the aortic valve opens, blood flows into the general circulation, and there is a rapid fall in ventricular volume. Late in the ventricular contraction phase, the ventricles repolarize, a phenomenon seen in the ECG as the T wave, and this initiates relaxation of the ventricles and the onset of diastole.

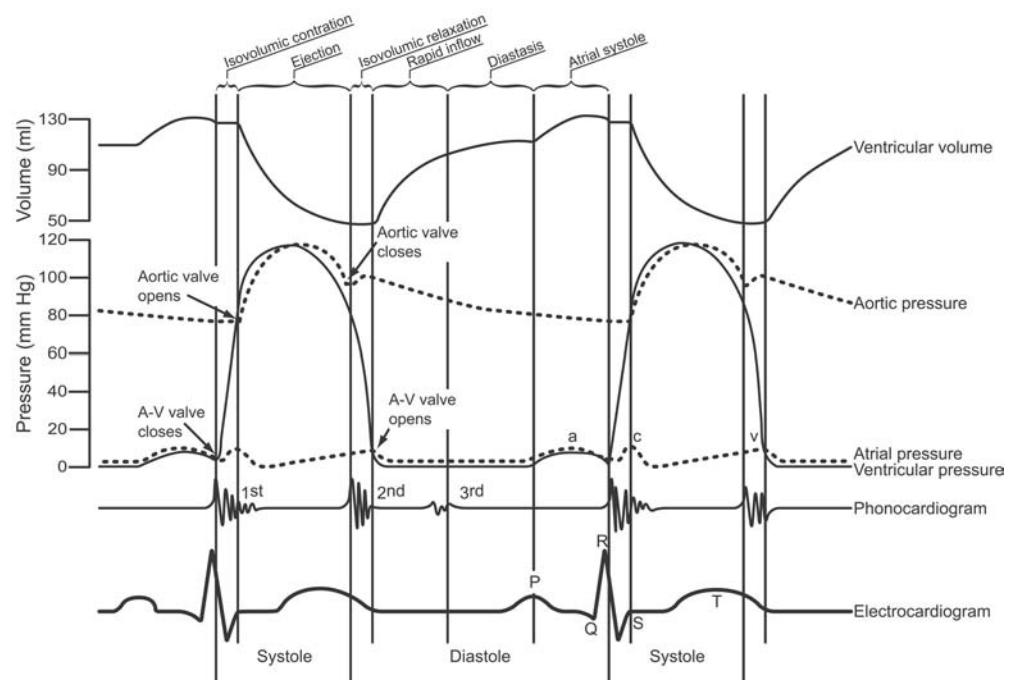

Figure 8.2. The cardiac cycle. Two cardiac cycles are shown for ventricular volume, aortic pressure, atrial pressure, ventricular pressure, the phonocardiogram, and the electrocardiogram (ECG). Phases of the cycle are indicated at the top of the figure above the brackets.

Blood flow, pressure, resistance, and cardiac output

Although Georg Ohm formulated his classic Ohm's law in the context of electrical circuits, the circulatory system adheres to the same basic relations as any other physical system where flow, pressure and resistance are operating. Ohm's Law applied to the circulation reflects the following basic relationships: (a) in order for flow in a vessel to occur, there must be a pressure gradient along the vessel (the homolog to electromotive force), and that (b) the resulting flow (the homolog of electrical current) is a function of the pressure gradient and an inverse function of the vascular resistance to that flow (the homolog of electrical resistance).

These relations are illustrated in Figure 8.4. Here, P_1 is the pressure at the initial portion of the vessel and P_2 is the pressure at the last portion of the vessel. Thus, the

gradient, or pressure differential along this vessel segment is $P_1 - P_2$. Note that as long as P_1 is larger than P_2 then blood will flow through the vessel in the direction indicated. Resistance (R), or the impediment to flow as a result of the vessel wall and the contents flowing in the vessel, occurs along the entire length of the vessel. Resistance can be increased by structural components of the vessel (e.g., bumps along the endothelial surface or bends in the vessel) or by increased viscosity (i.e., thickness) of the blood in the vessel. In this depiction, blood flow rate (Q ; usually expressed in liters/min) or the amount of blood that passes a particular point in the circulation in a given time is equal to $P_1 - P_2/R$. Thus, with a constant pressure gradient, when resistance increases, flow decreases. Alternatively, if the pressure gradient is larger, the flow increases (when resistance is the same). One commonly measured aspect of resistance is the total peripheral resistance (TPR) which

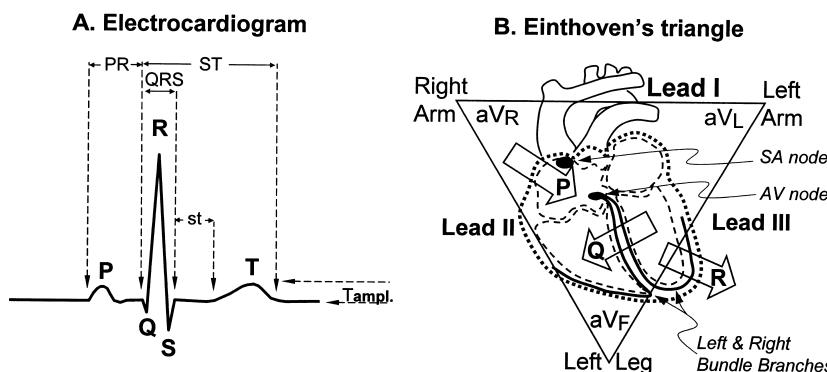

Figure 8.3. The heart and the electrocardiogram. (A) General morphology of the electrocardiographic (ECG) signal showing the P, Q, R, S, & T components, the PR, ST, and QRS intervals, the st segment, and the T wave amplitude. (B) The heart, conduction system, and Einthoven's triangle. Open arrow indicates the direction of propagation of electrical activation and the associated component of the ECG.

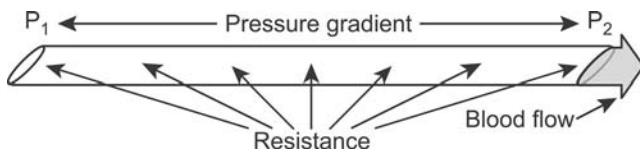

Figure 8.4. Ohm's Law applied to a blood vessel segment. This figure shows pressure differences along a vessel (difference in pressure between P_1 and P_2), resistance to flow in the vessel, and blood flow from the vessel segment. See text for relationships among these parameters.

is the resistance to flow over the entire systemic circulation (measured in dyne · seconds/centimeters⁵ or in peripheral resistance units; PRUs). This basic formulation relating resistance, pressure and flow underlies the movement of blood through the circulatory system.

Blood flow rate is also captured in Poiseuille's Law where:

$$Q = \frac{\Delta \text{ Pressure} \cdot \pi \cdot \text{Vessel radius}^4}{8 \cdot \text{Vessel length} \cdot \text{Blood viscosity}}$$

This formula illustrates an important aspect of the relationship between the factors that impact on blood flow, namely that changes in vessel diameter have a much greater influence on blood flow than any other factor. Indeed, conductance (or blood flow through a vessel for a given pressure gradient) is the reciprocal of resistance, and is proportional to the vessel diameter⁴. Thus, a very small change in vessel diameter by local, neural and hormonal control of the arterioles results in a relatively large change in blood flow.

Blood pressure is the force exerted by the blood against the vessel walls and is generally measured in units of millimeters of mercury (mmHg). Overall arterial pressure varies between the highest level of pressure seen at systole (systolic blood pressure or SBP) and the lowest level seen in diastole (the diastolic blood pressure or DBP). The difference between the systolic and diastolic pressures is called the pulse pressure (PP). Mean arterial pressure (MAP) is often calculated as: $\text{DBP} + 1/3 \text{ PP}$ (or $2\text{DBP}/3 + 1\text{SBP}/3$) because diastole is about twice as long as systole.

Blood pressure varies across different parts of the circulatory system. When measuring blood pressure, it is important to report the body location from which the pressure is measured (e.g., at the brachial or femoral artery) and for the measurement site to be located at the vertical height of the heart in order to minimize the effects of hydrostatic pressure (the pressure exerted by the fluid in the circulatory system) on the blood pressure measurement. Figure 8.5 shows how blood pressures vary throughout the circulatory system. First note that pressures are high and pulsatile near the aorta where the heart continuously pumps blood into the systemic circulation. As the pressure pulse moves further from the heart, the elastic properties of the large arteries and the control of vessel diameter by smooth muscle in the arterioles damp out much of the pulse in the pressure wave. Because the diameter of the arteriolar vessels is controlled by both intrinsic (local) and extrinsic (autonomic and hormonal) factors, these vessels function essentially as valves controlling the flow of blood into the capillary system. Arterioles are strong walled vessels and their "valvular" function is important because it prevents excessive pressures from reaching the thin walled capillaries where the vessels could be damaged. Systemic pressure falls further as the blood returns from the capillaries, through the small venules and into ever larger veins that eventually return blood to the right atrium. In the normal heart, blood pressure will be at or near zero once blood returns from the largest veins, the inferior and superior vena cavae, to the right atrium. Pressures in the pulmonary circulation are not nearly as high as the systemic circulation, in part due to the short distances the blood must travel through the lungs, relative to the distance traveled in the systemic circulation.

Based on Ohm's Law it would appear that blood pressure would cause a proportional increase in blood flow throughout the body, however, vessels can distend, a fact that complicates the prediction of blood flow with increases in blood pressure. A bolus of blood entering a vessel distends it, and thus the diameter of the vessel does not remain constant. Distensibility is an important feature of veins in particular (which are on average about 8 times more distensible than arteries) because blood is stored in the veins

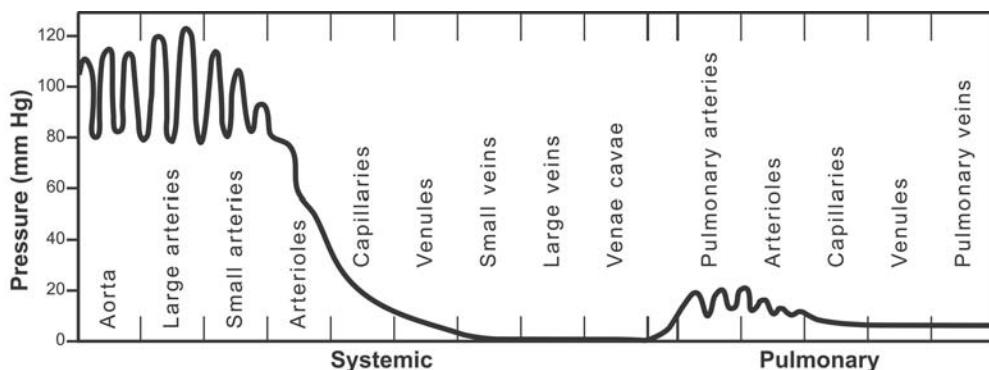

Figure 8.5. Blood pressure variations in the circulatory system. Blood pressure variations are shown for different types of vessels in the systemic and pulmonary circulation.

which form a reservoir from which blood can be marshaled when tissue needs increase. Distensibility of the vessels also helps to damp out pressure pulsations such that by the time blood reaches the capillary beds, the flow of blood is steady and provides a constant supply of nutrients and removal of wastes.

Cardiac output, another critical aspect of circulatory function, is the amount of blood pumped by the left ventricle into the aorta per unit of time (usually expressed as liters/min). Cardiac output can be expressed using another variant of Ohm's Law:

$$\text{CO} = \text{Mean arterial pressure}/\text{Total peripheral resistance.}$$

Cardiac output is directly controlled by the venous return, or the amount of blood that returns to the right atrium from the venous system each minute. Indeed the venous return and the cardiac output are usually equal (except when extra blood is stored in the heart or lungs for a few beats). Because the venous return is the sum of the local blood flows in all of the tissues of the body, the cardiac output is thus controlled by all of these local flows. Therefore, it is most appropriate to see the cardiac output as controlled by the local, neural, and hormonal controllers of these local blood flows, rather than as controlled by the heart.

Blood flow regulation

There are important local, intrinsic mechanisms for regulating blood flow to the heart and other tissues, the venous return and the cardiac output. These mechanisms work in concert with the extrinsic mechanisms (autonomic and hormonal) that are discussed in subsequent sections.

The primary intrinsic mechanism controlling blood flow to the heart is the Frank-Starling mechanism. It was observed that when there was greater venous return than was pumped out with the preceding beat, that the heart subsequently pumped more vigorously (i.e., greater contractility) and pumped a greater volume of blood (i.e., stroke volume, or the volume of blood pumped from the left ventricle with each beat of the heart). It was suggested that this phenomenon occurred due to the presence of stretch receptors in the cardiac tissue, which reacted to increased stretch by producing greater contraction of the ventricular muscle. Recent studies have suggested that a key molecular player in the Frank-Starling mechanism is a large, elastic molecule present in the sarcomeres of cardiac muscle, called titin or connectin (Fukuda, & Granzier, 2004). Not only does titin appear to have passive spring-like properties, but it may also be stretch-sensitive and thus play an active role in the Frank-Starling mechanism (Fukuda, Wu, Farman, Irving, & Granzier, 2003). Another intrinsic mechanism controlling the heart beat is that stretch of the right atrial wall produces an increase in the heart rate which in turn increases the stroke volume, although this effect plays a less important role than the Frank-Starling mechanism.

There are also local, tissue-based mechanisms that provide additional blood flow to tissues of the body when there is a local need for greater tissue oxygenation (Guyton and Hall, 2000). These mechanisms act both acutely (several seconds) and over longer periods (minutes to weeks). There are two primary theories about the acute mechanisms by which most initial changes in blood flow are locally regulated. The first is the vasodilator theory according to which blood flow is regulated by the release of vasodilator substances which increase in concentration when oxygen levels fall. Some of the possible vasodilator substances that have been proposed include adenosine (a strong contender), carbon dioxide, lactic acid, potassium ions, and hydrogen ions. The primary concern with this theory has been a problem in demonstrating that enough of these vasodilator substances are produced to account for the degree of vasodilation seen when vessels are deprived of oxygen. A second theory, called the oxygen (or nutrient) demand theory, suggests that the tissue responds to nutrient demand presumably by causing contraction of sphincters located at the entry of blood to capillary beds (i.e., precapillary sphincters) and in small arterioles (i.e., metarterioles). The theory holds that when these sphincters sense increased oxygen, they contract, thus limiting additional flow to those vascular beds with enough oxygen. This theory is based on observations of cyclical opening and closing of the precapillary and metarteriolar sphincters several times over a minute. These studies showed that the time that the sphincters are open is proportional to the amount of oxygen in the tissue. Evidence countering this theory also exists such that in some tissues, vascular smooth muscle will stay contracted even with only very small amounts of oxygen present. Guyton and Hall (2000) suggest that perhaps the mechanisms underlying acute local changes in blood flow are a combination of the mechanisms underlying these two theories.

Following acute changes in blood flow, flow tends to return to the original level through autoregulatory processes. Autoregulation is thought to occur via mechanisms that have been subsumed under one of two different theories: the metabolic theory, and the myogenic theory. The metabolic theory is based on the mechanisms just discussed, (i.e., either release of vasodilator substances or smooth muscle constriction in response to excess oxygen), but now with the effect of resetting blood flow toward the previous level. The myogenic theory, in contrast, suggests that fast stretch of vessel walls leads to smooth muscle constriction. Although this mechanism has been demonstrated in isolated vessels, it is not clear that it would be generally useful throughout the body as any stretch of the vessel wall would lead to vasoconstriction, increased pressure in the vessel, and additional stretch. This vicious cycle would not be effective for the overall functioning of the vascular system.

In combination with these local mechanisms acting predominantly in the smaller vessels (i.e., capillaries and metarterioles), are mechanisms that alter flow in larger

vessels. When increased flow enhances shear stress in arterioles and small arteries, the endothelium lining these vessels releases nitric oxide which causes local vasodilation and a concomitant reduction in the shear stress. Thus, local mechanisms are available in most of the vessels that see relatively high pressures and those critical for oxygen delivery to tissues (all arteries except the very large arteries which have little smooth muscle and capillaries). These mechanisms prevent excess pressure in delicate capillaries while maintaining a sufficient supply of nutrient to the tissues.

On a longer time scale, blood flow can increase or decrease when there is a longer term change in need by altering the vascularity of tissue. Vascularity changes are structural resulting either from changing the size and/or number of vessels. A prime example of this mechanism is the increased number of vessels that infiltrate a cancerous tumor that has an ever increasing need for additional blood flow. Together, local mechanisms provide many ways that blood flow can change both acutely and over longer periods to adapt to changing tissue demands.

AUTONOMIC AND HORMONAL CONTROL

Beyond local intrinsic autoregulatory processes are extrinsic regulatory process associated with autonomic and hormonal systems.

Autonomic nervous system

The cardiovascular system is under control of both the sympathetic and parasympathetic branches of the autonomic nervous system. A given organ system is often innervated by both autonomic branches, which typically exert opposing actions. Some organs are not dually innervated, however, and even for dually innervated organs, the autonomic branches may have synergistic rather than opposing effects or may otherwise be asymmetrical in their pattern of innervation or action. These patterns of innervation and effect are important in measuring, interpreting, and conceptualizing cardiovascular psychophysiological relations.

Historically, the peripheral components of the autonomic nervous system were the first to be described and studied, as they were the most distinct and accessible. Central neurons that give rise to the preganglionic axons of the autonomic nervous system are distributed across levels of the spinal cord and brainstem. The preganglionic fibers of the sympathetic system arise from the intermediolateral cell columns of the thoracic and upper lumbar spinal segments (thoracolumbar system). In contrast, the peripheral parasympathetic system arises from the nuclei within the brainstem, 'such as the dorsal motor nucleus and the nucleus ambiguus) and from sacral cord segments (craniosacral system).

With few exceptions, preganglionic axons terminate in peripheral autonomic ganglia, where postganglionic neurons in turn issue projections to the target organs. For

the sympathetic system, these ganglia consist of the sympathetic chain ganglia that lie along the vertebrae (also termed paravertebral ganglia) and a few more remote ganglia (e.g., the celiac ganglion). In contrast, the ganglia of the parasympathetic system are more distributed, being located in or around the organ being innervated. Consequently, the postganglionic axons of the parasympathetic system are rather short and the preganglionic fibers are long, whereas the opposite relation holds for the sympathetic system. Because of the heavy interconnections within the sympathetic chain ganglia it was believed historically that the system discharges as a whole, whereas the distinct parasympathetic ganglia allowed for a more organ specific discharge. It is now clear that even the sympathetic system is capable of targeted actions, as microneurographic recordings in conscious subjects have demonstrated a striking specificity in the pattern of sympathetic discharge across organ systems (for review see Valbo, Hagbarth, & Wallin, 2004).

In comparison to the somatic motor system, an obvious question arises as to why the peripheral autonomic nerves are interrupted by a ganglionic synapse. Minimally, this synapse would delay transmission in autonomic efferents. Although conduction velocity is crucial in the somatic motor system, it is perhaps less so for the autonomic system. The emerging picture is that autonomic ganglia may not just passively relay incoming information from preganglionic axons. Rather, autonomic ganglia may represent a first level regulatory system. Parasympathetic cardiac ganglia, for example, have been termed a "heart brain" (Randall, Wurster, Randall, & Xi-Moy, 1996), which is characterized by anatomically and neurochemically distinct sets of interacting neurons that serve to regulate aspects of cardiac function (Gray et al., 2004a,b; Randall, Wurster, Randall, & Xi-Moy, 1996; Richardson, Grkovic, & Anderson, 2003). The precise functions of these integrative networks within autonomic ganglia have not been fully elucidated and are beyond the scope of the present chapter.

Both sets of preganglionic neurons employ acetylcholine as the primary neurotransmitter, which binds to a nicotinic receptor subtype (N_N) and several muscarinic subtypes on the postganglionic neurons in the peripheral autonomic ganglia of both branches. Nicotinic receptors mediate a direct ion channel effect and muscarinic receptors can also promote activity via intracellular 2nd messenger pathways (for review and recent data see Beker, Weber, Fink, & Adams, 2003). Postganglionic parasympathetic fibers also employ acetylcholine as a primary neurotransmitter, although the receptor sub-types on the target organ are commonly muscarinic (M). In contrast, the postganglionic neurons of the sympathetic system employ norepinephrine as the primary neurotransmitter, which can act on alpha adrenergic (e.g., α_1 in arterioles) or beta adrenergic receptors (e.g., β_1 on the heart). As illustrated in Table 8.1, this pharmacological differentiation allows selective experimental manipulations of the autonomic branches. We will return to this issue later.

Table 8.1. Autonomic pharmacology

Synapse	Receptor	Agonist	Antagonist	Organ systems
<i>Acetylcholine</i>				
Autonomic Ganglia	Nicotinic (N_N)	Nicotine	Pentolinium/ Hexamethonium	broad autonomic
Postganglionic Parasympathetic	Muscarinic	Muscarine/ Pilocarpine	Atropine/ Scopolamine	heart/eccrine glands/sudomotor/ gastrointestinal/ciliary muscle
<i>Norepinephrine</i>				
Postganglionic Sympathetic	α_1	phenylephrine	prazosin	vascular vasoconstrictors
	α_2	clonidine	yohimbine	vascular vasoconstrictors (central antihypertensive actions)
	β_1	isoproterenol	atenolol	heart
	β_2	terbutaline	propranolol	bronchioles, vascular vasodilators, (nonselective) also in heart

There are additional complications and some exceptions to the above schema. Added complexity arises from the fact that many autonomic neurons, in addition to their primary neurotransmitter, express and release a variety of neuropeptides and neuromodulators such as neuropeptide Y, vasoactive intestinal peptide, enkephalins and substance P, which may impact transmitter release and/or receptor action (e.g., see Lindh & Hokfelt, 1990; Richardson, R. J., Grkovic, I., & Anderson, 2003). One rather fascinating exception to the pharmacological differentiation as summarized in Table 8.1 is the sympathetic innervation of eccrine sweat glands, which is cholinergic rather than adrenergic. The postganglionic sympathetic neurons that innervate eccrine glands initially appear to express norepinephrine but undergo a phenotypic switch to cholinergic production on interactions with the target tissue (see Landis, 1996). Subsequently, eccrine gland sweat production is controlled largely by muscarinic receptors, although other receptor types might also be involved (Kurzen, & Schallreuter, 2004; Longmore, Bradshaw, & Szabadi, 1985; see also Dawson, Chapter 7).

Another exception, more apparent than real, is the cholinergic sympathetic innervation of the adrenal medulla. In contrast to the postganglionic cholinergic innervation of eccrine glands, the cholinergic innervation of the adrenal medulla is by preganglionic fibers that bypass the ganglionic synapse. These neurons in fact show the typical cholinergic phenotype for sympathetic preganglionics. Furthermore, the direct innervation of the adrenal gland does not violate the general plan. In contrast to most visceral organs, the adrenal medulla derives embryologically from neural crest cells and is thus homologous with sympathetic ganglia. Also like ganglion cells, the adrenal medulla synthesizes and releases catecholamines – norepinephrine and epinephrine. The major difference is that

these adrenomedullary amines are released humorally into the general circulation where they can act at widespread sites. Epinephrine has a somewhat greater affinity than norepinephrine for α and β_2 receptors and an equal affinity for β_1 receptors. The effects of neural NE release and adrenomedullary NE and EPI release may be distinct, however, as diffusion barriers may reduce effects of circulating catecholamines on synaptic receptors. Of additional relevance are noninnervated α and β receptors on the heart and vasculature, which can only be activated by NE or EPI humorally or by norepinephrine spillover from adjacent synapses.

Heart. The general neuroarchitectural plan of the autonomic innervation of the heart is illustrated in Figure 8.6. Parasympathetic preganglionic projections arising from the nucleus ambiguus and the dorsal motor nucleus of the vagus project to the sinoatrial and posterior atrial ganglia, for the regulation of heart rate (chronotropic control), to the atrioventricular ganglia for the control of conduction (dromotropic control), and to the interventriculo-septal-ganglia for the regulation of myocardial contractility (inotropic control, although this is minimal for the parasympathetic system) (Gray et al., 2004a,b; Johnson et al., 2004; Pirola, & Potter, 1990; Richardson et al., 2003; Sampaio, Mauad, Spyer, & Ford, 2003). The lower central motor neurons that give rise to preganglionic sympathetic cardiac projections reside in the intermediolateral cell columns, mostly in the upper thoracic segments (Ter Horst, Hautvast, De Jongste, & Korf, 1996). These preganglionic neurons project to the stellate and cervical sympathetic ganglia, which in turn issue postganglionic projections to the heart (Anderson, 1998).

The parasympathetic system has a much wider dynamic range of control over cardiac chronotropy than does

Autonomic Innervation

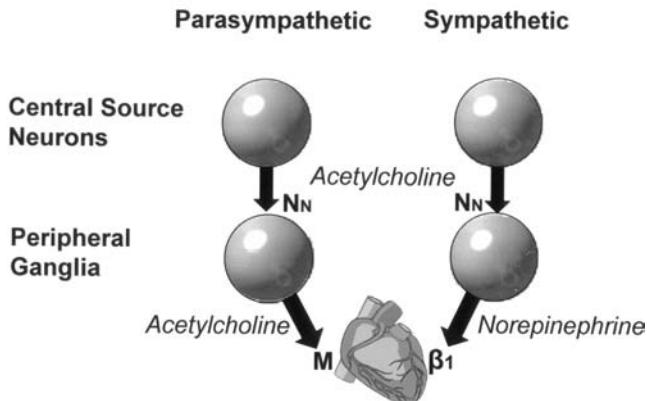

Figure 8.6. General pattern of pharmacology of the autonomic innervations. Abbreviations refer to the relevant postsynaptic receptor populations: N_N – nicotinic cholinergic; M – muscarinic cholinergic; β_1 – beta1 adrenergic.

the sympathetic system, whereas the sympathetic system has a more predominant effect on the inotropic state. In humans, the dynamic range of sympathetic chronotropic control has been estimated to be about 230 msec, whereas that of the parasympathetic system is about 1710 msec (Berntson, Cacioppo, & Quigley, 1993a). Chronotropic control of heart period is rather linearly related to parasympathetic activity, whereas there is some nonlinearity in the sympathetic branch. When expressed as heart rate, the dynamic range is highly dependent on baseline heart rate, because heart rate is a nonlinear transform of heart period. The typical dynamic range of control of the sympathetic branch, in heart rate over a wide range of baseline values is ~3–55 beats/min and that for the parasympathetic system is ~71–125 beats/min). An additional complexity is that there are interactions between the branches at the level of the sinoatrial node, and these appear to be much greater when the chronotropic state is expressed in heart rate (Berntson, Cacioppo, & Quigley, 1995). Another difference between the sympathetic and parasympathetic innervations of cardiac pacemaker tissue lies in their temporal dynamics. The parasympathetic cholinergic receptor at the sinoatrial node is directly coupled by a G-protein link to a potassium channel through which a hyperpolarizing K⁺ flux slows the spontaneous depolarization of the pacemaker potential. In contrast, sympathetic noradrenergic receptor action is mediated by a more indirect and slower 2nd messenger signaling pathway. Consequently, the parasympathetic system has a shorter latency of action, a more rapid rise time, and a higher frequency capacity – which is the basis for the selective contribution of vagal control to the high-frequency heart rate variability of respiratory sinus arrhythmia (Berntson, Cacioppo, & Quigley, 1993b; Somsen, Jennings, & Van der Molen, 2004). Vagal activation to a behaviorally relevant event, for example, can alter the

interbeat interval of the very beat within which the event occurs (see Somsen et al., 2004).

In contrast to parasympathetic dominance over heart rate, the sympathetic system dominates the control of cardiac contractility. Although there is parasympathetic innervation of the ventricles (Johnson et al., 2004), stimulation of the parasympathetic system in the absence of sympathetic activation may have relatively little direct effect on contractility beyond a secondary effect of heart rate slowing (Levy, 1984; Takahashi, 2003). Much of the parasympathetic innervation of the ventricles may represent presynaptic terminations on sympathetic synapses, which permits a vagal inhibition of sympathetic inotropic control (Levy, 1984; Takahashi, 2003). Interactions among the sympathetic and parasympathetic cardiac innervations are multiple and complex, and include a nitric oxide mediated parasympathetic inhibition of sympathetic control and neuropeptide Y-mediated sympathetic inhibition of parasympathetic control (Chowdhary, Marsh, Coote, & Townend, 2004; Ren, 1991).

Control of the vasculature. Although the heart is a crucial organ in generating the pressure differentials that contribute to circulation of the blood, the vasculature plays an essential part in the maintenance of blood pressure and the arterio-venous blood pressure difference that underlies the distribution of blood. This contribution is not merely as a passive conduit, but as an active regulator of the circulation and distribution of blood across organ systems. An important aspect of this regulation entails peripheral autoregulatory processes that are sensitive to local tissue conditions.

The autonomic nervous system, especially the sympathetic division, is also an important controller of the vascular smooth muscle. Adrenergic receptors on the smooth muscle serve as vasoconstrictors that regulate vascular tone, vascular resistance, and venous compliance. From the initial distinction between alpha and beta adrenergic receptors, an increasing array of receptor subtypes has been identified (α_1 , α_{2A} , α_{2B} , β_1) that have distinct functional roles in cardiovascular control (for review see Guimaraes & Moura, 2001). In the arterial system, the α_1 subtype of adrenoceptors mediates the classical vasoconstrictor actions of both sympathetic innervations and adrenomedullary catecholamines, whereas α_2 receptors are more prevalent in veins where they regulate venous tone and compliance. Several α_2 receptor subtypes are also present as autoreceptors on sympathetic terminals where they serve an inhibitory role in the regulation of NE release (Brede et al., 2004).

In contrast to α -adrenoceptors, the β class of adrenoceptors on smooth muscle mediates adrenergic vasodilation (Guimaraes & Moura, 2001). The β_2 subtype is most common in most vascular beds and mediates, for example, the muscle vasodilation during sympathetic activation associated with exercise. These β_2 adrenoceptors

may be particularly driven by humoral adrenomedullary catecholamines. β_2 receptors have also been described as autoreceptors on adrenergic presynaptic terminals. The β_1 subtype has been increasingly recognized as a mediator of vasodilation in certain vascular beds (e.g., the coronary and pulmonary arteries) and a novel β_3 receptor subtype appears to have vasodilatory functions in the mesenteric and other arterial beds.

Water balance. Additional hormonal and organ systems contribute to body water and electrolyte balance and thus play an important role in blood volume, blood pressure, water distribution, and hence cardiovascular regulation (Guthrie & Yucha, 2004). The kidney is the primary route by which fluids are eliminated in normal organisms. The renal tubular system receives a high volume of blood ultrafiltrate (at the renal glomerulus) including water and electrolytes such as sodium and potassium, most of which is ultimately reabsorbed by the renal tubules prior to passing to the urinary bladder for excretion. The hypothalamic-posterior pituitary hormone vasopressin has two important functions in circulation (Guthrie & Yucha, 2004). First it is a potent vasoconstrictor agent, hence its pressor effect, and secondly it promotes water resorption (antidiuretic effect) in the renal tubule system. Vasopressin stimulation is triggered by either osmotic or hypovolemic body water disturbances and its pressor effect serves to compensate for low blood volume, whereas its antidiuretic effect promotes water retention. The absence of vasopressin in *diabetes insipidus* results in a chronic condition of polyuria (frequent urination of large volumes) and polydipsia (frequent drinking).

Another important player in body water balance is the renin-angiotensin system (see Fitzsimons, 1998; Grisk & Rettig, 2004). Renin is a proteolytic enzyme secreted by *juxtaglomerular* cells of the kidney under conditions of low blood pressure and controlled in part by the sympathetic system. Renin converts a blood borne precursor (*angiotensinogen*) to angiotensin I, which is in turn converted to an active peptide hormone, *angiotensin II*, by the action of another enzyme *angiotensin converting enzyme* (ACE). Angiotensin II is notable for its wide range of actions, which include vasoconstriction, stimulation of thirst, and triggering of *aldosterone* release from the adrenal cortex. Aldosterone is an adrenocortical mineralocorticoid that promotes the resorption of sodium from the renal tubules and fosters salt appetite. Collectively, these actions compensate for the loss of body water and electrolytes and expand blood volume. In fact, they are so effective that overactivity in these systems may contribute to hypertension and ACE inhibitors are effective antihypertensive agents (Grisk & Rettig, 2004).

A final humoral system to be briefly mentioned here is the cardiac natriuretic system, which is implicated in water balance, blood volume, and blood pressure regulation (Luchner & Schunkert, 2004). Cardiac natriuretic fac-

Baroreceptor Reflex

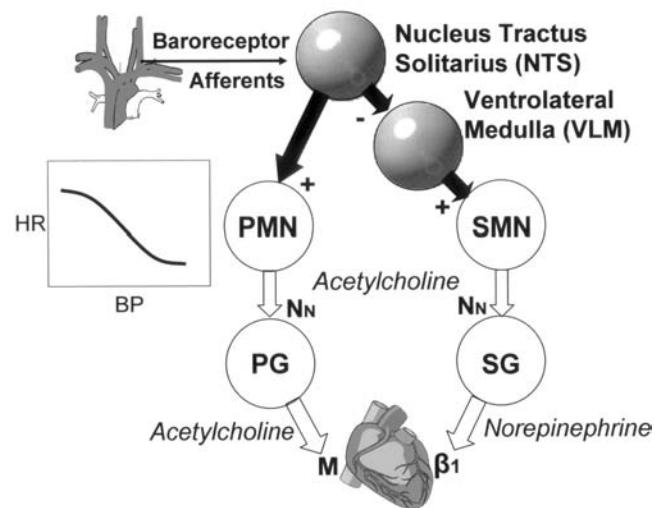

Figure 8.7. General organization of the baroreceptor heart rate reflex. Reflex originates in mechanoreceptors in the heart and the carotid and other great arteries. The NTS excites (+ symbol) the parasympathetic motor neurons (PMN) and inhibits (– symbol) relay neurons to the sympathetic motor neuron pool (SMN). Insert illustrates the relationship between blood pressure (BP) and heart rate (HR). PG and SG depict parasympathetic and sympathetic ganglia, respectively. Other abbreviations are as in Figure 8.6.

tors are released on myocardial stretch and trigger vasodilation, natriuresis (sodium excretion), and inhibition of the sympathetic nervous system and the renin-angiotensin system (Woods, 2004). This natriuretic system is suppressed by a β adrenergic mechanism and may promote vagal control, and illustrates some of the complexities in neural and humoral cardiovascular control.

Central neural control

The cardiovascular system is crucial for survival so it is not surprising that this system is regulated by complex central mechanisms, including lower-level reflex systems as well as higher neurobehavioral mechanisms.

Brainstem reflexes. Among the most well characterized of cardiovascular reflexes are the baroreceptor reflexes, including the baroreceptor heart rate reflex and the baroreceptor vascular reflex (Dampney, Polson, Potts, Hirooka, & Horiuchi, 2003; Ursino & Magosso, 2003; see also Chapter 19, this volume). The baroreceptor heart rate reflex circuit, depicted in Figure 8.7, is comprised of stretch receptor afferents from the carotid and other great arteries to the nucleus tractus solitarius (NTS), the major visceral receiving station in the brainstem. NTS projections can excite activity in parasympathetic source nuclei and via an indirect pathway can inhibit the rostral ventrolateral medulla (VLM) which is a major descending source of tonic drive on the sympathetic output neurons of the intermediolateral cell column. Through this circuit, for

example, increasing blood pressure and the associated increase in baroreceptor afferent traffic increases parasympathetic control and decreases sympathetic outflow. These reciprocal changes in the autonomic branches synergistically serve to oppose the pressure perturbation. The increase in parasympathetic and the decrease in sympathetic cardiac chronotropic control both lead to a slowing of heart rate. This, together with the reduced ventricular contractility due to withdrawal of sympathetic inotropic control, leads to a decrease in cardiac output. In addition, the withdrawal of sympathetic vasoconstrictor control results in vasodilation, which further diminishes blood pressure. Conversely, the unloading of baroreceptors during the assumption of an upright posture (orthostatic stress) yields the opposite pattern of autonomic control – an increase in sympathetic and a decrease in parasympathetic outflow, which compensates for the diminished blood pressure associated with the gravitational pooling of the blood in the lower body.

In addition to arterial baroreceptors, there are a variety of cardiopulmonary mechanoreceptors that contribute to reflex regulation of the cardiovascular system. One such reflex, which is often capitalized on in psychophysiology, has its origin in lung stretch receptors (see Berntson, Cacioppo, & Quigley, 1993b). Inspiration results in the activation of these stretch receptors and their afferents, which project to the NTS. Input from stretch receptor afferents results in a reflexive inhibition of parasympathetic cardiac outflow and an excitation of the sympathetic system. As a result, there arise respiratory rhythms in both sympathetic and parasympathetic nerves, as well as in heart rate variability. Because the sympathetic cardiac synapses can not follow the typical respiratory frequencies, however, the respiratory rhythms in heart rate are driven by the parasympathetic system. Consequently, this respiratory sinus arrhythmia is commonly employed as an index of vagal control of the heart. We will return to this issue below.

An additional class of cardiovascular reflexes are the chemoreceptor reflexes (see Ursino & Magosso, 2003). Pure hypoxia (decreased arterial O₂ pressure), for example, triggers a local vasodilation in vital organs. Although this could be considered an adaptive local regulation, if widespread, it could result in a life-threatening hypotension. Chemoreceptors in the carotid bodies and aorta detect this low oxygen pressure and convey an afferent signal to the NTS which results in a reflexive increase in respiratory minute volume. Hypoxia also yields compensatory cardiovascular reflexes, including a sympathetic vasoconstriction of arterioles throughout many organ systems (except for coronary and brain arterioles), which serve to maintain blood pressure and circulation. A concurrent parasympathetic activation results in bradycardia, which may serve to minimize cardiac work in the face of hypoxia and may also enhance cardiac output (by increasing ventricular filling time). Pure hypoxia is rare, however, as hypoxia is generally associated with changes in partial

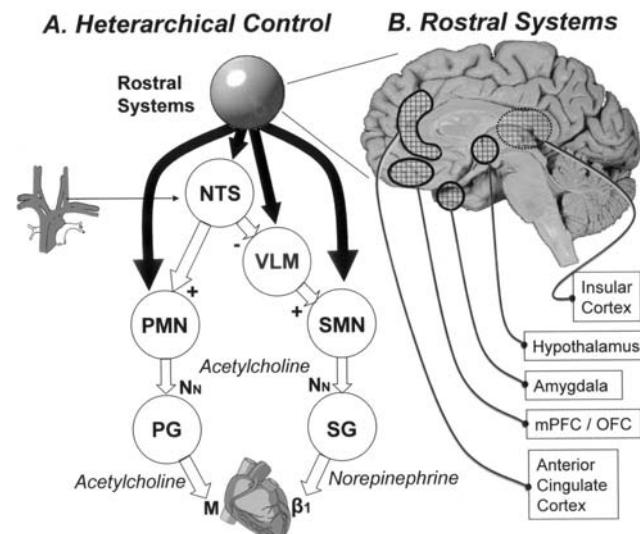

Figure 8.8. Rostral neural systems and heterarchical control. (A) Schematic representation of higher neural control of the autonomic nervous system. The figure illustrates the two general features of heterarchical control: a hierarchical structure together with long ascending (and descending) connections which bypass intermediate levels of organization. (B) Higher neural systems and areas that have been implicated in autonomic control. mPFC – medial prefrontal cortex; OFC – orbitofrontal cortex; other abbreviations are as in Figure 8.7.

pressure of CO₂, which can either increase (hypercapnia, e.g., during asphyxia) or decrease (hypocapnia, e.g., during increased respiration at high altitude). Chemoreceptors are also sensitive to CO₂ pressure (mediated by local pH), with higher levels of hypercapnia yielding progressively greater chemoreceptor activity. This signal has synergistic super-additive effects with hypoxia on chemoreceptor firing.

The cardiovascular reflexes outlined above are far from exhaustive. Rather, they are intended to be illustrative of the powerful reflex control over the cardiovascular system. In psychophysiological contexts, however, higher neuraxial levels may figure more prominently in autonomic regulation.

Higher neural controls. As illustrated in Figure 8.8, higher levels of the neuraxis, including neurobehavioral substrates of the limbic system and other forebrain areas can control, inhibit, or even bypass lower reflex mechanisms in the regulation of autonomic outflows. An example is the stress related suppression of the baroreflex which is mediated by rostral neurobehavioral systems (see Chapter 19, this volume). It is this reflex suppression that allows the concurrent increase in heart rate and blood pressure during stress, in direct conflict with baroreceptor reflexes. As is the case for the somatic nervous system, higher neural autonomic controls are far more flexible and variable than brainstem reflex substrates. Whereas brainstem reflex systems may display a rather fixed, reciprocal pattern of control over the autonomic branches, higher systems are

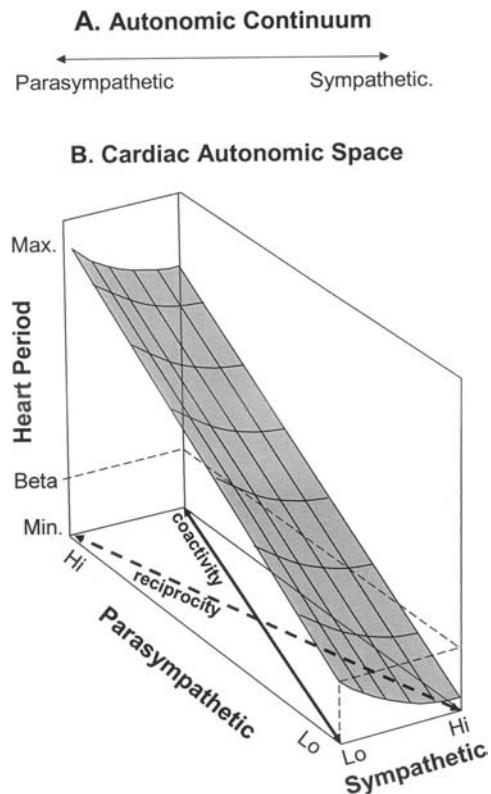

Figure 8.9. Autonomic space. (A) Continuum model of autonomic control, wherein the status of the system can be depicted along a single continuum extending from parasympathetic dominance to sympathetic dominance. (B) A more comprehensive model of autonomic control, characterized by an autonomic plane (representing the fact that parasympathetic and sympathetic systems can change reciprocally, coactively, or independently) and an overlying effector surface which illustrates the end organ state (heart period) for any location on the underlying autonomic plane. Beta illustrates the intrinsic heart period in the absence of autonomic control.

capable of reciprocal, coactive (coactivation or coinhibition) or independent changes in outflows of the two autonomic branches. This has required an expansion from the bipolar model of reciprocal autonomic control to a bivariate autonomic plane and overlying effector surface as depicted in Figure 8.9 (Berntson, Cacioppo, & Quigley, 1991, 1993a; see also Chapter 19, this volume).

There are ample routes by which higher behavioral substrates can impact autonomic cardiovascular regulation. Direct monosynaptic projections to brainstem reflex substrates and even to autonomic source nuclei have been described from rostral areas and structures that have been implicated in psychological and behavioral processes. These include the hypothalamus, amygdala, and prefrontal cortex (see Chapter 19, this volume).

A neuroanatomical tracing study illustrates the rich integration of higher neural systems in autonomic regulation. In this study, pseudorabies virus was injected into distinct areas in the rat heart (Ter Horst, Hautvast, Jongste, & Korf, 1996). Following such injections the viral infection spreads

transneuronally in autonomic nerves, in the retrograde direction back to the central nervous system, where viral labeling can reveal components of multisynaptic networks that regulate autonomic outflow. Among the areas labeled were the NTS and the ventrolateral medulla, as would be expected from Figure 8.8. Higher labeled structures included the raphe nuclei, which give rise to both ascending and descending serotonergic projections, and the A5 cell group, which gives rise to ascending and descending norepinephrine pathways. Additional structures that have been implicated in cognitive and affective processes were also labeled, including the midbrain periaqueductal gray, hypothalamus, amygdala, anterior cingulate gyrus, and the frontal and prefrontal cortex.

A combination of neuroimaging methods and autonomic measures is beginning to be applied to questions of rostral autonomic control. Although this integrative effort is in its infancy, initial findings suggest a close correspondence between neuroanatomical and neurophysiological studies on the one hand and functional neuroimaging studies of autonomic control on the other. PET and fMRI studies have reported that mental arithmetic, a Stroop-stress paradigm, or emotional contexts engage several forebrain areas that have been implicated in psychological processes and autonomic control, including the cingulate cortex, orbitofrontal cortex, insular cortex, and medial and dorsolateral prefrontal cortex, as well as related areas such as the hypothalamus, amygdala, and cerebellum (Chritchley et al., 2005a; Gianaros, May, Siegle, & Jennings, 2005; Gianaros, Van Der Veen, & Jennings, 2004; Lane, Reiman, Ahern, & Thayer, 2001; Matthews, Paulus, Simmons, Nelesen, & Dimsdale, 2004). Moreover, these studies found that the magnitude of cardiovascular responses (blood pressure, heart rate, and heart rate variability) was significantly related to the magnitude of activation in specific brain regions.

With the further development of imaging techniques, this approach will likely be of increasing importance in understanding neurobehavioral systems and their links to autonomic control. Studies using fMRI, for example, have already revealed functional subdivisions even within the anterior cingulate cortex, a complex structure that represents an important interface between cognition and emotion. These subdivisions differentially relate to behavioral inhibition (dorsal anterior cingulate) and vagal control (ventral anterior cingulate) in the Stroop task (Matthews, Paulus, Simmons, Nelesen, & Dimsdale, 2004). Brain imaging methods not only hold considerable promise for the elucidation of central autonomic and neurobehavioral systems, but also for the clarification of the links between psychological states and processes and cardiovascular health outcomes (Critchley et al., 2005b).

Figure 8.8 illustrates some brain areas that have been implicated in both cognitive and affective processes as well as autonomic cardiovascular control. The extensive overlap of these rostral systems likely reflects the close

integration between behavioral and autonomic substrates that underlies the neurobiology of psychophysiological relations.

PSYCHOPHYSIOLOGICAL MEASURES: RATIONALE AND PHYSIOLOGICAL BASES

ECG

Electrocardiography (ECG or EKG) has been well developed by the field of medical cardiology (for reviews see Berne & Levy, 2001; Goldberger, 1998). The extremity (limb) leads in clinical electrocardiology can be represented by Einthoven's triangle, as illustrated in Figure 8.3B. These leads consist of the unipolar leads of the right arm (aV_R), left arm (aV_L), and left leg (aV_F) and the bipolar leads I (left arm – right arm), II (left leg – right arm), and III (left leg – left arm), with the right leg serving as ground. These leads are often approximated by electrodes placed on the torso, rather than the limbs. In addition, a series of unipolar precordial chest leads are commonly recognized that extend from the lower peristernal region (V_1) laterally to the left (V_1 through V_5) to the midaxial line on the lateral aspect of the chest (V_6). These multiple leads are important in clinical cardiology as they offer distinct electrical perspectives on the events of the cardiac cycle. For most psychophysiological applications, however, a lead II or comparable configuration (e.g., electrodes at V_6 and the right collar bone or aV_R) work well as they yield a relatively large R-wave.

As depicted in Figure 8.3B, the P wave represents the spread of excitation from the sinoatrial (pacemaker) node through the atria, the QRS complex corresponds to the invasion of the ventricular myocardium, and the T wave reflects the repolarization of the ventricles. The arrows in Figure 8.3B illustrate the electrical vectors during selected events within the cardiac cycle. The QRS complex may manifest in just QR or RS deflections depending on the selected lead and how it “views” the electrical events. For a standard lead II configuration, the Q wave reflects the initial depolarization of the ventricular septum, which is followed by the bulk of the ventricular myocardium (R wave). Although the T wave represents the repolarization phase, it generally has the same polarity as the R wave. This is attributable to regional differences (epicardium vs. endocardium) in electrical properties of the ventricular myocytes, which results in the repolarization wave proceeding in the opposite direction to the depolarization phase (the epicardium depolarizes last, but repolarizes first).

Figure 8.3A also illustrates some time/amplitude parameters that have been employed clinically or experimentally. The PR interval (actually the PQ interval if a Q wave is present) reflects the propagation time through the atria and the atrioventricular (AV) node, by way of the conduction system to the ventricles (dromotropic function).

A PR interval longer than 200 msec suggests a conduction impairment (heart block). Within-subjects variation in the PR interval has sometimes been taken to reflect variations in vagal control of the dromotropic state (it slows conduction), although it is not a reliable measure of vagal control as the sympathetic system also influences conduction time. The QRS interval is typically 100 msec, but a prolonged interval can be seen with a block in one of the bundle branches of the conduction system (see Figure 8.3B). The ST segment corresponds to the peak of the muscle action potential and ventricular ejection, the onset of which is also reflected in the first heart sound corresponding to the opening of the aortic valve. The QT interval represents the time from ventricular excitation to the return to the resting state, it can range from 250–500 msec or so and is dependent on the heart rate (shorter at higher heart rates).

The amplitude of the T wave (see Figure 8.3A) has been proposed as a measure of sympathetic control of the heart, as it is sensitive to sympathetic activation or beta adrenergic drugs, but less so to cholinergic drugs or markers of parasympathetic activity (see Contrada, 1992; Furedy, Heslegrave, & Scher, 1992; Kline, Ginsburg, & Johnston, 1998). This measure has not received general acceptance, however, as it does show some sensitivity to cholinergic manipulations (Annala, Yli-Hankala, & Lindgren, 1994), and shows inherent rate dependent changes (Contrada, 1992; Kline et al., 1998) that are independent of, and can be as large as, autonomic effects (Rashba et al., 2002).

Heart rate/heart period

Heart period, or the time in msec between adjacent heart beats is typically measured between successive R spikes in the ECG given the larger magnitude and sharper inflection of the R spike relative to other ECG components. Traditionally, heart period (in msec) was generally converted to heart rate (in beats/min or bpm), although now both measures are used commonly. Heart period and heart rate are simple reciprocals, and one can convert from one metric to the other by dividing 60000 by the heart rate or heart period value. Heart period values become heart rate (in bpm) and heart rate becomes heart period (in msec).

Previously it was assumed that the choice of cardiac metric or measure was not important, and depending on the experimental question and the nature of the results, that may indeed be true. However, there are times where the metric does matter because heart rate and heart period are not linearly related to each other (Berntson, Cacioppo, & Quigley, 1995). Berntson and colleagues (1995) reviewed literature across several mammalian species, including humans, showing that the relationship between changes in activity of the parasympathetic and sympathetic autonomic branches and heart period are more nearly linear than the relationship between activity in either branch and heart rate. Therefore, a given change in activation

of one of the autonomic branches will result in approximately the same change in heart period regardless of the baseline heart period, whereas the same is not true of heart rate. Using data from dogs as an example (from Parker, Celler, Potter, & McCloskey, 1984), an increase in stimulation frequency of 2 Hz of the vagal nerve results in a change of 70–72 msec in heart period regardless of whether the resting (baseline) heart period is 875 msec or 350 msec. However, when the dog's basal heart period is 875 msec (or 68.6 bpm) the change in heart rate with a 2 Hz increment in parasympathetic activation is 5.1 bpm, whereas at a basal heart period of 350 msec, the same 2 Hz change in autonomic input results in a heart rate change of 29.2 bpm. Therefore, the amount of cardiac change reported as a result of an experimental manipulation can differ considerably depending upon the metric chosen to represent change in cardiac function. This is particularly true if the baselines across individuals in a sample are quite different (or different as a function of an experimental factor), or if the amount of change is relatively large. Thus, Berntson and colleagues (1995) recommended that heart period be used as the metric of choice when (a) changes in cardiac function are likely to be a result of autonomic effects (e.g., for many of the short-term cardiac responses seen in the psychophysiology laboratory), and (b) when the changes in cardiac function vary widely as a result of an experimental manipulation or between groups because here the errors due to the nonlinear relationship between autonomic inputs and heart rate can be significant and result in misleading interpretations of the data. The nonlinearity of the effects of autonomic inputs on heart rate also may impact the apparent extent of interactive effects between the two autonomic branches on the heart. The idea that the two branches affect one another and thereby alter the net change in chronotropic control of the heart is termed accentuated antagonism. Although there is no doubt that there are mechanisms by which the two branches interact (see Autonomic and Hormonal Control section), the magnitude of the effects of these interactions may be smaller than has previously been suggested. Studies showing large accentuated antagonism effects have typically used heart rate as the chronotropic metric, whereas the few studies that have used heart period have not seen such large effects. Simulated data also revealed that using the same data to demonstrate interactions between the parasympathetic and sympathetic branches showed much larger apparent interaction effects with heart rate than heart period (Quigley, & Berntson, 1996).

Once the effect of an experimental manipulation is determined using the appropriate cardiac metric, one then can represent cardiac function over a number of beats where the unit of analysis is cardiac time, or over a period of time where the unit of analysis is real time. Heart period permits cardiac function to be reported in either cardiac time or real time, whereas heart rate is represented appropriately only in real time (Berntson et al., 1995; Graham, 1978). To derive heart period or rate in real time, it is important

to use a weighted averaging procedure so that the mean reflects the proportion of time that each beat contributes to the overall average.

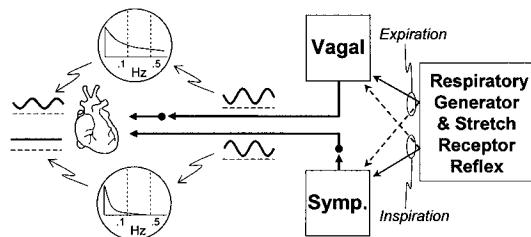

Heart rate variability

Measures of heart rate variability (HRV) have figured prominently in cardiovascular psychophysiology and there is now an extensive literature on this topic, including two international committee reports on the origins and implications of heart rate variability and methods for quantification (Berntson et al., 1997; Task Force, 1996). Of particular relevance is the fact that high-frequency heart rate variability, in the respiratory frequency range, largely reflects variations in vagal sinoatrial control and has thus been applied as a selective index of parasympathetic cardiac control (see Figure 8.10A). A wide range of measures have been used to assess heart rate variability, including time domain and frequency domain metrics.

Time domain methods include measures of the variance among heart periods, the variance of the differences among heart periods, and geometric methods based on the shape characteristics of heart period distributions (see Task Force, 1996). The simplest of the time domain metrics is the SDNN, which is the standard deviation of the normal beat to normal beat intervals (normal-to-normal or NN). Because the variance of heart periods increases over time, the SDNN is generally derived over fixed time periods, such as 5 min or 24 h. The SDNN has not seen widespread application in the psychophysiological literature, although another time domain measure that is based on the variance of beat-to-beat heart period differences has been used more frequently. This is the square root of the mean squared successive heart period differences or the RMSSD (Root Mean Square Successive Difference) statistic. As this metric is based on the differences between adjacent heart periods it is nominally independent of basal heart period, although heart period level and heart period variability are themselves physiologically correlated. Because the differences between adjacent heart periods sample heart period variability over relatively short periods of time (the duration of a heart period), the RMSSD parses the total variance by filtering out lower frequency variability. Consequently, the RMSSD has been applied as a measure of high-frequency heart period variability and respiratory sinus arrhythmia. Although the RMSSD does effectively filter out low-frequency heart period variance, the properties of this filter, including its cutoff frequency and its frequency-dependent transfer function vary as a function of basal heart period (Berntson, Lozano, & Chen, 2005). A more systematic parsing of heart period variance into specific frequency components can be achieved by frequency domain methods.

Frequency domain (spectral) methods decompose the overall heart period variance into specifiable frequency bands (see Berntson et al., 1997; Task Force, 1996). A common approach is based on the Fourier theorem which

A. Autonomic Origins of Respiratory Sinus Arrhythmia

B. Spectral Analysis of Respiratory Sinus Arrhythmia

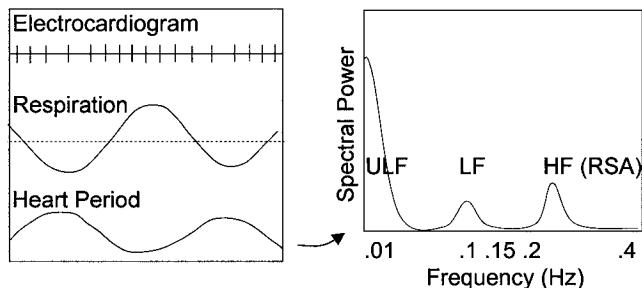

Figure 8.10. Respiratory sinus arrhythmia (RSA). (A) Neurophysiological generators of RSA. Respiratory rhythms are apparent in both sympathetic and parasympathetic nerves, but the different transfer functions (inserts) allow the parasympathetic but not the sympathetic innervations to impart a respiratory rhythm to the beat of the heart. (B) Illustrations of the relation between respiration and heart period, and its quantification by spectral analysis. ULF = ultra-low frequency; LF = low frequency, HF = high frequency.

asserts that any periodic time-varying waveform (in our case, the time varying fluctuations in heart period) can be decomposed into a set of pure sine wave components comprised of a fundamental frequency (f) and a set of harmonics ($2f, 3f, \dots, nf$). Stated conversely, any periodic time-varying waveform, however complex, can be approximated by the summation of a finite set of pure sinusoids of differing amplitudes.

Computationally, the Fourier transform decomposes the variance of a waveform into its frequency components, and “transforms” the time domain representation of the variance into a frequency domain representation or spectral density function (see Figure 8.10B for illustration). Importantly, the time and frequency domain representations are simply two complementary ways to characterize the same set of variances, with the time domain representation aggregating across frequencies and the frequency domain representation aggregating across time. The former preserves the temporal integrity of the signal at the expense of frequency resolution and the latter preserves the frequency composition of the signal at the expense of temporal resolution. If the spectral density function is integrated (summed) across frequencies, the result will equal the simple statistical variance of the signal in the time domain.

Origin and significance of heart period rhythms. As illustrated in Figure 8.10B, there are several peaks in the spec-

tral density function for heart rate variability, corresponding to one or more physiological processes (Berntson et al., 1997; Eckberg, 2000) Several general frequency bands of heart period variability have been defined in the literature. The high-frequency band (0.15 [or 0.12] to 0.4 Hz in the adult) generally corresponds to respiratory sinus arrhythmia (RSA), which reflects the respiratory gating of autonomic control by afferent input from lung stretch receptors (Berntson et al., 1993a; Eckberg, 2002). Although respiratory rhythms are apparent in the activities of both the sympathetic and parasympathetic cardiac nerves, the low-pass filter properties of the sympathetic sinoatrial synapses effectively smooth out these rhythmical fluctuations into a steady state influence on heart rate. For this reason, respiratory sinus arrhythmia is generally considered to index vagal cardiac control, although there are several caveats in its application (see Berntson et al., 1993a; Berntson et al., 1994, 1997; Cacioppo et al., 1994; Grossman, Karemaker, & Wieling, 1991; Grossman & Kollai, 1993).

Although the high-frequency band may be operationally set at 0.15 (or 0.12) to 0.4 Hz, the respiratory rate in some cases can extend below this band with slow breathing or above this band in infants or with rapid breathing in adults. For children, a commonly used respiratory band is 0.24–1.04 Hz (Quigley & Stifter, 2006). Measures of respiratory sinus arrhythmia will be biased if the breathing rate falls wholly or partially outside the selected band as the power in this frequency will not be captured within the high-frequency variability band. Consequently, it may be desirable to raise the upper band limit to 1.0 Hz with exercise, and to use a higher overall frequency band with infants (e.g., 0.20–1.20 Hz, see Bar-Haim, Marshall, & Fox, 2000). Even when respiration falls within the standard high-frequency band, the transfer function from vagal respiratory rhythms to cardiac respiratory rhythms is not flat, but decreases with increasing frequency. For these reasons it is optimal to obtain respiratory measures to insure that respiratory rates are within the high-frequency band and remain constant from condition to condition (e.g., baseline to task). If respiratory rates do change, this should be recognized and accounted for. The effects of a change in respiratory rate could be statistically controlled by adding respiratory rate as a covariate or by adjusting the estimate of vagal control by the known effects of respiratory frequency (see Berntson et al., 1997).

Respiratory depth can also alter RSA (e.g., see Grossman, Wilhelm, & Spoerle, 2004; Grossman, Karemaker, & Wieling, 1991; Grossman, & Kollai, 1993), although amplitude effects at moderate levels of variation are generally not as large as effects of rate. A paced breathing procedure could be implemented to experimentally control respiration (Grossman, Karemaker, & Wieling, 1991), although paced breathing itself may be stressful (Wilhelm, Grossman, & Coyle, 2004) and may interact with other experimental manipulations. Alternatively, if changes are observed in respiratory depth, this parameter could be entered as a covariate in statistical analyses. A more

comprehensive but more complex regression approach entails a transfer function analysis with paced breathing to define adjustment coefficients for respiratory parameters (Wilhelm, Grossman, & Coyle, 2004).

Lower frequency bands of heart period variability have also been defined in the literature. These include the low-frequency band (LF; sometimes termed the mid-frequency band) with a variable bandwidth (e.g., 0.05–0.15 or 0.8 to 0.12) centered around 0.1 Hz (sometimes referred to as the Mayer wave). Even lower frequency bands have been studied in the physiological literature (very-low .003–.05 Hz; ultra low < .003), but have not received much attention in psychophysiology. Variability within any of these bands represents a mixture of sympathetic and parasympathetic rhythms, as sympathetic rhythms can translate into cardiac rhythms at these frequencies. These lower frequency rhythms have received less attention in the psychophysiological literature, although the mid-frequency band has been of some interest and utility in the quantification of mental workload and baroreceptor function (see Boucsein & Backs, 2000; Van Roon, Mulder, Althaus, & Mulder, 2004).

An additional application of the 0.1 Hz rhythm has been in the development of an index of *autonomic balance*, which is said to characterize the relative functional point along a sympathetic-parasympathetic activation continuum (see Malliani, 1999). The index is the ratio of high-frequency variability to low-frequency variability. The general rationale is that variability in the lower band is driven by both branches of the autonomic nervous system so increases in sympathetic control will increase low-frequency variability but not high-frequency variability, and thus reduce the index value. This approach has been severely criticized on physiological grounds (Eckberg, 1997, 1998). One of the problems with this approach is that the low-frequency band is also determined by parasympathetic activity which can confound this index. In addition, the sympathovagal index assumes a reciprocally regulated autonomic continuum, wherein increases in one branch are coupled to decreases in the other. Although this may hold in some cases, such as with orthostatic stress, it does not in others, especially in psychological contexts (Berntson & Cacioppo, 1999).

Quantification. A common approach to quantification of heart period variability is by a Fast Fourier Transform (FFT), which represents a more computationally efficient approach than the full Fourier Transform. This efficiency comes with the restriction that the number of data points must be some power of 2 (e.g., 64, 128, 256, 512), but this does not generally pose a serious limitation. A more complete discussion of analytical approaches can be found in Berntson et al. (1997).

The FFT, as with other spectral methods, quantifies *periodic* components of variability and assumes at least weak stationarity of the signal (constant mean and variance over time). *Aperiodic* components or nonstationar-

ities can compromise analysis and interpretation of the data. Although moderate deviations from stationarity may not have large effects on spectral estimates, it is best to avoid these biases. One approach to enhance stationarity is to use short analytical epochs, as nonstationarities tend to increase over time. On the other hand, analytical epochs must be long enough to sample a sufficient number of respiratory cycles (a minimum of 10 cycles is recommended in the Society for Psychophysiological Research Committee Report, Berntson et al., 1997), although these could be aggregated over multiple shorter periods (e.g., 30–60 sec). A simple test is available to confirm stationarity of the data (Weber, Molenaar, & van der Molen, 1992).

Acquisition commonly entails digitization of the ECG signal at a minimum of 500–1000 Hz. Although some information may be derivable at lower frequencies, there is a progressive loss of information as digitization rate is further reduced (Riniolo & Porges, 1997). R waves must then be accurately detected, artifacts removed, and a heart period series derived. Because heart periods vary in duration, this beat series must be converted to a time series by an interpolation algorithm. The sample interval for the time series should provide 2–4 samples/beat (250 msec works with most subjects, although shorter sample times may be desirable with infants). The time series is then detrended with a first order polynomial to remove the mean and any linear trend in the data. The initial and terminal data points should be tapered by a standard hanning window, cosine window or similar function to eliminate starting and ending offsets which can introduce artifacts. The residual series is then submitted to a FFT, yielding an estimate of power (msec²/Hz) distribution across frequencies (see Figure 8.10B) and the power within the frequency bands of interest can be summed (integrated) to yield an estimate of total power (msec²) within those bands. Generally, these total power estimates are natural log transformed to normalize distributions. The power in the high-frequency band represents the quantitative estimate of vagal control of the heart.

Many other approaches to quantification have also been employed. A common alternative approach is autoregressive (AR) modeling, which is another spectral method. In contrast to the FFT, which is considered a descriptive statistic as it includes all data in the analysis, the AR approach views the signal as a combination of deterministic and stochastic components and attempts to model the salient deterministic components while eliminating "noise." In practice, with the applications of filters and other refinements in FFT (see below) these approaches generally give highly similar results. A time domain approach that approximates spectral methods has been developed by Porges and colleagues (see Porges & Bohrer, 1990). After derivation of the time series as outlined above, this approach entails the application of a polynomial filter algorithm to remove frequencies outside the band of interest, and the statistical variance of the residuals is then calculated as an index of RSA. Another time

domain approach is the peak-valley method wherein an estimate of RSA is derived from the difference between the longest beats associated with expiration and the shortest beats associated with inspiration (Grossman, van Beek, & Wientjes, 1990). Both of these time domain methods yield values similar to spectral approaches, with each having its advantages and disadvantages. A myriad of additional methods are also available including cross spectral analysis, transfer function analysis, time frequency distributions (smoothed pseudo Wigner-Ville distribution and complex demodulation), and nonlinear dynamical methods to name a few. Space precludes a meaningful coverage of these approaches here, but the interested reader is referred to Monti, Medigue, & Mangin (2002), Pumprla, Howorka, Groves, Chester, & Nolan (2002), and Wilhelm, Grossman, & Roth (1999).

Summary. Patterns of heart rate variability offer important insights into cardiovascular dynamics and their central and peripheral autonomic control. High-frequency heart rate variability is largely attributable to variations in parasympathetic control associated with respiration and is widely used as an index of vagal control of the heart. There are several important caveats in these applications, however. There are many factors that can influence basal levels of RSA, including posture, age, activity, and aerobic fitness to name a few. Consequently, the differences in the magnitude of RSA across subjects or groups may not be a valid metric for differences in vagal control of the heart unless these variables are taken into account. Although within-subjects changes in RSA may be more valid as a marker of changes in vagal control, factors such as posture and activity still need to be considered. Moreover, RSA can be influenced by respiratory rate and to a somewhat lesser extent, respiratory depth, independent of the basal level of vagal control. This has raised a question as to whether the magnitude of RSA is a valid predictor of vagal “tone,” or the average basal level of parasympathetic control. To the extent that vagal inhibition is not complete with inspiration, there may be some dissociation between respiratory vagal fluctuations and the basal level of vagal control. Minimally, respiratory parameters should be measured, and should be taken into account if they differ across critical experimental contrasts. The psychological significance of low-frequency heart rate variability is less clear, although as discussed above it may have some utility in assessment of cognitive workload. Although widely used, especially for estimating reflex regulation, the ratio of LF to HF variability as an index of autonomic balance may not have much meaning in psychological contexts unless the predominant mode of response can be shown to be reciprocal.

Blood pressure

Blood pressure can be measured in a number of ways, invasively, using intraarterial pressure transducers, or noninvasively, using auscultatory or oscillometric methods, arte-

rial tonometry, or the volume-clamp method (also called the Peñaz method). The latter two methods are especially useful when the research question calls for beat-to-beat blood pressure. The beat-to-beat methods are also more sensitive to movement, making them more difficult to record with fidelity. Because most psychophysiological laboratories are not equipped to perform invasive measures and provide the participant safeguards needed, we will focus here on the non-invasive measures. It is important to determine for any blood pressure monitoring device that it has met either or both of the Association for the Advancement of Medical Instrumentation (AAMI) or the British Hypertension Society (BHS) standards for accuracy and reproducibility (van Montfrans, 2001).

Auscultatory blood pressure measurement. The auscultatory method takes its name from the fact that auscultation or listening to bodily sounds is the basis of the technique. For arm blood pressure, a cuff is placed on the upper arm, with a stethoscope placed over the brachial artery (if done manually) or a microphone embedded in the cuff (if done with an automated device). When the cuff is inflated to a pressure sufficient to cut off all arterial blood flow (i.e., suprasystolic), no sound is heard. As the pressure in the cuff is slowly bled off, the so-called Korotkoff or K sounds appear. The cuff pressure at which the first sound is heard is taken as the systolic pressure and referred to as the start of phase I. As the pressure in the cuff decreases further, the sounds take on a murmuring quality (phase II) and then become clearer and louder (phase III). Following this, the Korotkoff sounds become muffled (phase IV) and eventually disappear altogether (phase V). In medical practice and typically in the psychophysiology laboratory, the pressure at phase V is considered the diastolic blood pressure, although sometimes Phase IV is used instead. Automated devices are particularly useful in the psychophysiological laboratory so that an experimenter need not be present in the room when a reading is taken, and also because this removes aspects of human error in reading the blood pressure (Shapiro et al., 1996).

Oscillometric blood pressure measurement. The oscillometric method utilizes oscillations in pressure in the cuff to determine systolic, diastolic and mean arterial pressure (Borow & Newberger, 1982; van Montfrans, 2001). With this method, following inflation of the cuff to a pressure above the systolic pressure where oscillations can be measured in the cuff, the cuff is slowly deflated. The systolic pressure is taken as the pressure when the oscillations in the cuff first begin to get larger, the mean arterial pressure is taken as the point when the cuff oscillations are maximal in size, and the diastolic pressure is taken as the point when the cuff pressure oscillations no longer get smaller in amplitude. As van Montfrans (2001) points out, there are issues still to be resolved with this technique, most notably, that specific algorithms used to determine systolic, diastolic, and mean arterial pressure are unlikely to

be equally accurate across all individuals thus leading to systematic errors. Especially problematic is the effect of increased arterial stiffness on oscillometric measurements which often is seen in elderly or diabetic subjects. Finally, the algorithms for each oscillometric device are different and proprietary, making it impossible for the researcher to document the algorithms used. Therefore, it is important to report the make and model of the oscillometric device used for any study.

Arterial tonometry. Blood pressure is measured using arterial tonometry (also called arterial applanation tonometry) by placing piezoelectric sensors over an artery that overlies bone (e.g., Colin 7000). Modest pressure is applied to the artery, partially flattening the artery. Multiple sensors are arrayed over the flattened artery and the device then records from the sensor reading the largest arterial pulse wave amplitude. This measure provides a pulse waveform that is calibrated against an oscillometrically derived blood pressure reading from the brachial artery. A common site for tonometric measurements is the radial artery at the wrist. Care must be taken that the sensor is placed correctly over the artery and the technique is sensitive to movement limiting the potential uses of the technique (Kemmotsu, Ueda, Otsuka, Yamamura, Winter, & Eckerle, 1991; Parati et al., 2003).

Volume-clamp or Peñaz method. The volume-clamp method typically uses a cuff on the finger to clamp the vascular volume of the finger at a specific level which is maintained from beat to beat (Parati, et al., 2003; Wesseling, 1990). A photoplethysmographic device (see section on plethysmography below) measures changes in blood volume beneath the sensor, and then using a pneumatic servo-control system, changes are made in the pressure within the finger cuff so that the artery returns to its previous volume. The amount of pressure change in the finger cuff needed to reestablish the volume in the artery is a function of the arterial pressure underlying the cuff. The device using this method that originally saw the widest use was the Finapres, which was withdrawn from the market, although it is still in use in many labs around the world. Newer devices using this technique are currently limited to the Portapres (an ambulatory monitor) and the Finometer (a stationary monitor; Parati et al., 2003).

General measurement issues for blood pressure. We outline here some general aspects of blood pressure measurement. First, because of the regional variations in blood flow, vessel diameter and blood pressure, it is important when measuring blood pressure to report the location from which pressure is measured (e.g., at the brachial or femoral artery). It's also important for the measurement site to be at the same vertical height as the heart to eliminate effects of hydrostatic pressure (i.e., the pressure exerted by the fluid in the circulatory system) on the blood pressure measurement. Another important feature is the size and placement

of the cuff. To determine the appropriate cuff size, the circumference of the upper arm is determined and the cuff width should be at least 40% of arm circumference, and the cuff length at least 80% of the circumference (Bailey & Bauer, 1993). In practice, this is usually accomplished by using standard, small, and large adult cuffs or a pediatric cuff (O'Brien, 1996). Partly because of the limitations of the instrumentation, it is uncommon for cuff occlusions to be made more frequently than once per minute. In addition, more frequent sampling than this may result in unpleasant side effects, and annoyance of the participant (Shapiro et al., 1996). Because of the variability in blood pressure that was noted previously, it is recommended that multiple blood pressure readings taken from a recording epoch be averaged to provide a more stable estimate of the blood pressure for that epoch. For specific recommendations, the reader is referred to Shapiro et al., 1996 and Llabre, Ironson, Spitzer, Gellman, Weidler, & Schneiderman, 1988.

Various participant or environmental factors can make it difficult to accurately interpret blood pressure results. These include recent eating, drinking, smoking, medications or exercise, and not controlling for phase of the menstrual cycle in women, or time of day. Blood pressure is affected by all of these factors and thus, when possible, they should be controlled within a study (Shapiro et al., 1996). Emotional factors also affect blood pressure. A well known example of this is so-called white-coat hypertension, which occurs when readings in a clinical or other evocative setting such as a lab are higher than those in a less evocative setting such as the individual's home.

Other vascular measures

Plethysmography, including venous occlusion plethysmography. Plethysmography is a technique whereby one determines the volume of a structure, either the entire structure (such as in whole body plethysmography) or part of a structure (such as determining blood volume in a body segment like the finger). Volume can be determined using a photoelectric sensor (photoplethysmography), changes in impedance (see section on impedance cardiography for a specific example of this method), or changes in circumference measured with a strain gauge.

The most common photoplethysmographic technique employs a photocell placed over an area of tissue perfused with blood. There are two variations of this method; energy emitted from an infrared source can be measured as it passes through the tissue segment (transilluminated) or as it bounces off the tissue (back-scattered). Because electromagnetic radiation in this frequency is scattered by blood, the output of a photodetector is related to the amount of blood within the segment (Jennings, Tahmoush, & Redmond, 1980). In either case, the infrared energy is measured by a photoelectric transducer and recorded as a change in voltage or current. Currently, most photoplethysmographic devices utilize a light-emitting diode (LED) as an emitter and a phototransistor as a detector,

which do not alter the underlying skin and blood vessels. If the light is transmitted through the tissue to a photodetector on the other side, only a limited number of sites are convenient (e.g., earlobe, finger), and these are not necessarily sensitive to psychological changes. However, with the back-scattered photoplethysmographic technique, the light source and the photodetector are both located on the same side of the tissue and therefore can be placed almost anywhere on the body. The back-scattered photoplethysmograph is more sensitive to vascular fluctuations occurring close to the skin surface, whereas the transilluminated photoplethysmograph is sensitive to vascular changes in both the skin and deeper tissue. Blood flow also can be measured using a transcutaneous Doppler device which detects acoustic frequency shifts caused by moving red blood cells in underlying tissue (Rose, 2000). Doppler devices share many of the same issues and limitations as photoplethysmographic devices.

Using a strain gauge, one can also measure changes in blood volume of a body segment. The strain gauge is placed around the finger, or other body segment, and changes in resistance or voltage of the strain gauge provide an indirect measurement of blood volume changes. Venous occlusion plethysmography is a special example of the use of strain gauge plethysmography to measure blood volume in limb segments (Wilkinson & Webb, 2001). This technique requires two cuffs, one placed distal to the limb segment of interest, and one placed proximal to the limb segment. The distal cuff is inflated to a pressure above the systolic pressure to prevent blood flow into and out of the distal limb segment. The proximal cuff is inflated to a pressure sufficient to eliminate venous flow from the limb segment, but not preventing arterial flow into the segment. A strain gauge is placed around the limb segment, and the change in limb circumference per unit of time is used to infer the rate of arterial blood flow into the segment. The advantage of this method is that arterial blood flow into an isolated limb segment can be measured independent of other possible sources of blood flow (e.g., venous flow). An obvious limitation of the venous occlusion technique is that measurements cannot be taken continuously, and even at very short intervals, because numbness or pain in the limb can result. Measurements also can be altered by movement of the limb.

Jennings, Tahmoush, and Redmond (1980) reviewed many of the factors that influence vasomotor changes and discussed problems of interpretation using from the indirect measures described here. For example, changes in room temperature from one day to the next during a study alter the measures for reasons unrelated to the experimental situation. Another problem is the wide variation in skin and vessel anatomy (e.g., location of vessels) which make absolute comparisons between subjects impossible. Even within the same subject, difficulty in precise placement of the transducer makes comparisons only relative, especially if the transducer is removed and replaced. Because of differential distributions of muscles and blood vessels

in different body areas, it is difficult to compare results between studies when different recording sites are used. Finally, recall that blood flow is a complex function of pressure in the vasculature, the radius of the blood vessels, and the viscosity of the blood, and flow changes may occur via arterial and/or venous flow changes either into or out of the segment of interest. Thus, one must be careful when making interpretations from indirectly measured blood flow changes.

Because of the relative nature of the vasomotor measures described here, experimenters typically examine changes for each participant from a baseline period and compare this to the experimental or task period. The change between baseline and task is generally expressed as a percentage. The magnitude of an individual pulse can be determined by measuring the difference between the lowest point and the peak or an integrating coupler can be used to perform a similar function.

Other non-invasive vascular measures. Several other non-invasive measures of vascular function have been used particularly to assess cardiovascular disease risk. Considered here are only a few of those that do not require medical facilities for their application. Measures such as brachial artery ultrasonography have been used to assess flow-mediated dilation (Corretti et al., 2002). In this technique, suprasystolic cuff pressures are used to occlude all blood flow in the arm for several minutes. Upon release of the cuff pressure, blood flow increases to the occluded limb over and above flow before occlusion (a phenomenon called reactive hyperemia). A small flow-mediated dilation response during reactive hyperemia has been shown to be related to coronary artery disease (Kuvvin et al., 2001) and cardiovascular disease risk (Kuvvin et al., 2003), the latter case being documented with both brachial artery ultrasonography and peripheral arterial tonometry over a finger. The peripheral arterial tonometry technique is very similar to arterial applanation tonometry used to measure blood pressure, although with peripheral arterial tonometry, the goal is to use the arterial waveform to derive the pulse wave amplitude. This technique has been used to measure other features of vascular physiology including pulse wave velocity and a measure of arterial stiffness called the augmentation index (e.g., Davies & Struthers, 2003; Vuurmans, Boer, & Koomans, 2003).

Pulse transit time, used in calculating pulse wave velocity, was previously used to a considerable extent in psychophysiological assessments, predominantly because it was thought to relate to blood pressure. However, pulse transit time is a function of both cardiac changes (in pre-ejection period) and the stiffness of the peripheral arterial system (Steptoe, Godaert, Ross, & Schreurs, 1983). This means that psychological antecedents which alter pre-ejection period, vascular tone or both can contribute to changes in pulse transit time, and yet the physiological source(s) of these changes will be indeterminate (Shapiro

et al., 1996). One approach that may have promise in applying pulse transit time to the measurement of blood pressure, or blood pressure change, is the concurrent monitoring of (e.g., by impedance cardiography), and adjustment for, the cardiac determinants of PTT. A more recent use of pulse transit time has been to detect brief changes in respiratory effort and “microarousals” during sleep, although the physiological basis for these pulse transit time changes remains unclear (Smith, Argod, Pépin, & Lévy, 1999).

Baroreflex measures

The baroreceptor-heart period reflex is important in the short-term control of blood pressure. Estimates of baroreflex function have been proposed using relatively invasive procedures such as pharmacologically induced changes in blood pressure or neck suction to directly activate baroreceptors (for review see Parati, di Rienzo, & Mancia, 2000). However, the focus here will be on non-invasive estimates of baroreflex function derived from spontaneous changes in blood pressure and heart period. Baroreflex sensitivity or gain can be derived using either time domain (e.g., the spontaneous sequence method; Bertinieri, di Rienzo, Cavallazzi, Ferrari, Pedotti, & Mancia, 1985) or frequency domain methods (e.g., spectral methods; DeBoer, Karemaker, & Strackee, 1987). Baroreflex sensitivity estimated from these methods is defined either as the slope of the regression of heart period on systolic blood pressure (ms/mmHg; sequence method), or the gain of the transfer function relating variations in heart period and systolic blood pressure over the frequency range of 0.04 and 0.35 Hz (spectral methods). These estimates of baroreflex sensitivity do not represent identical estimates of sensitivity (Persson et al., 2001). For one, the sequence method utilizes shorter data epochs, namely sequences of 3–6 consecutive R-R intervals where systolic blood pressure increased by more than 1 mmHg over sequential beats and heart period progressively shortened, or where systolic pressure decreased and heart period progressively lengthened. Most sequences that meet these criteria are sequences of 3 interbeat intervals, with progressively fewer sequences observed as the number of interbeat intervals in the sequence increases. Moreover, the 3 interval sequences tend to provide higher estimates of baroreflex sensitivity than the longer sequences (Reyes del Paso, Hernández, & González, 2004), although in most studies, sequences of all lengths are averaged to provide a single baroreflex sensitivity estimate. This finding of differential sensitivity with differing sequence length may be related to the fact that vagal effects on heart period occur much more quickly in response to a pressure change than do sympathetic influences (DeBoer et al., 1987). The spectral methods (using Fast Fourier Transform or autoregressive modeling techniques) are also subject to specific biases. With spectral methods, one typically reports the gain of the transfer function or the square root of the ratio of the spectral powers for the heart period and systolic blood pressure signals,

called the α coefficient, over the entire frequency range noted above. However, it has been shown that the highest coherence between heart period and blood pressure occurs in two specific frequency regions, one around 0.1 Hz and the other in the respiratory frequency range (approx. 0.15–0.35 Hz), and there is greater baroreflex influence in the respiratory frequency range than in the lower frequency range (Parati et al., 2000). Also, spectral methods typically do not take into account the phase relationship between heart period and systolic blood pressure. Thus, the estimate is less than optimal because part of the measure is not due to the baroreflex (Parati et al., 2000). Finally, the spectral methods require the use of longer data epochs for calculation than does the sequence method which can be problematic for tracking short-term changes in baroreflex sensitivity. Short-term changes will lead to nonstationarity in the signals, thereby violating a primary assumption of spectral methods. Thus, these two estimates of baroreflex sensitivity derived from spontaneous sequences have different biases, neither being a perfect reflection of the true baroreflex sensitivity, but each of which provides a useful metric under certain circumstances (Persson et al., 2001).

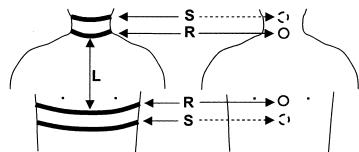

Several studies have demonstrated that psychological events can alter baroreflex sensitivity with mentally stressful events decreasing the gain of the baroreflex (e.g., Reyes del Paso, González, & Hernández, 2004; Steptoe & Sawada, 1989). In addition, respiratory biofeedback using slow paced breathing at approximately 0.1 Hz produced both within session and across session changes in baroreflex gain thereby revealing the influence of respiration on baroreflex sensitivity (Lehrer, et al., 2003).

A relatively new measure has been derived using the spontaneous sequence method called the baroreceptor effectiveness index (BEI; Di Rienzo, Parati, Castiglioni, Tordi, Mancia, & Pedotti, 2001). The BEI provides an estimate of how frequently (over a given period of time), the baroreflex is effective in altering the heart period. The data available to date on this measure show that the BEI is reflective of baroreflex function (the BEI dropped from 0.33 in intact cats to 0.04 after sino-aortic denervation), that the BEI is lower at night than during the day in humans (Di Rienzo et al., 2001), and that a visual attention task produced an increase in the BEI, whereas a mental arithmetic task did not alter BEI (Reyes del Paso, González, & Hernández, 2004). It seems clear that the BEI and baroreceptor sensitivity reflect different aspects of baroreflex function, but the usefulness of the BEI as a physiological indicator is not yet clear.

Impedance cardiography

Impedance cardiography is an important noninvasive method for obtaining more comprehensive information concerning cardiac function than can be derived from heart rate or heart rate variability alone. Impedance cardiography entails the application of a high-frequency,

A. Impedance Cardiography: Electrodes

B. Impedance Cardiography: Signals

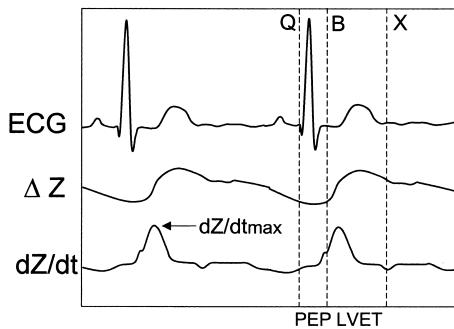

Figure 8.11. Impedance cardiography. (panel A) Typical electrode configurations. Left: standard mylar band electrodes, comprised of outer source (S) electrodes and inner recording (R) electrodes. Right: Qu et al. (1986) spot electrode configuration, consisting of two source electrodes on the dorsum (C4 and T9) and two recording electrodes on the ventrum. L = distance between the inner boundaries of the recording electrodes (for calculation of stroke volume and cardiac output). (panel B) Impedance signals, including the electrocardiogram (ECG) the basal impedance (Z) and the 1st derivative of Z . Q corresponds to the onset (or peak, see text) or the Q wave, B corresponds to the opening of the aortic valve (often indicated by a notch in the dZ/dt signal) and X (onset or peak, see text) corresponds to the closure of the aortic valve. PEP- pre-ejection period; LVET – left ventricular ejection time.

constant-current flow through a set of outer thoracic electrodes and recording of the associated voltage drop across another, inner set of electrodes. Because the current flow is held constant, based on Ohm's Law, the recorded voltage will vary inversely with the resistivity of the thoracic current path. Because the current is alternating, the resistivity to current flow is a function of both the DC resistance and the reactance of the circuit, collectively referred to as impedance. One of Kirchoff's Laws stipulates that the distribution of current through parallel resistive paths is inversely proportional to the resistances. The body components with the lowest resistivity are blood and plasma, so the measured thoracic impedance is highly sensitive to changes in the cardiac and aortic distribution and flow of blood during the cardiac cycle (Hoetink, Faes, Visser, & Heethaar, 2004). General methodological guidelines for impedance cardiography are available from a committee report of the Society for Psychophysiological Research (Sherwood et al., 1990).

Instrumentation. In measuring cardiac impedance, four electrodes are typically employed (see Figure 8.11). The outer (source) electrodes provide the constant current sig-

nal path to the subject (typically considered leads 1 and 4). Supply current parameters are not standardized across devices. Current levels generally range from 4 mA down to 0.1 mA, typically at 100 kHz, although lower frequencies have also been used. The inner two electrodes are used to measure voltage, which reflects the changes in impedance due to volumetric alterations in blood distribution and blood flow (recording electrodes, usually leads 2 and 3). The Minnesota Model 403B Impedance Cardiography device (Instrumentation for Medicine, Minneapolis) was one of the earliest and most widely used instrument, although it has now been replaced by the HIC 2000, & 3000 (Bio-Impedance Technology, Inc., Chapel Hill). More recently, impedance measures have been incorporated into ambulatory studies (Hawley, Burleson, Berntson, & Cacioppo, 2003; Sherwood, McFetridge, & Hutcheson, 1998; Willemse, De Geus, Klaver, Van Doornen, & Carroll, 1996). Several ambulatory units are now commercially available, including the VU-AMD (Vrije University, Vrije Netherlands), the AIM-8 (Bio-Impedance Technology, Chapel Hill, NC) and the recently introduced MW1000A (Mindware Technologies, Gahanna, OH) that includes a wireless network link.

There are two common electrode configurations used in recording thoracic impedance; band electrodes and spot electrodes. The band electrode consists of a thin, aluminum conductor secured to a Mylar adhesive tape that provides a means of attaching it to the subject. Spot electrodes are small, conductive disks (Ag/AgCl) with adhesive collars (same electrodes as typically used for measuring ECG). The conductive disk is generally covered with an electrode gel using a sponge-like material or imbedded in a conductive medium. Mylar band electrodes represent the standard and have been the most thoroughly validated. Spot electrodes, however, can also yield valid information and are considerably easier to use. The Qu et al. configuration entails two spot electrodes on the back and two on the front as illustrated in Figure 8.11 (Qu, Zhang, Webster, & Tompkins, 1986; see also Sherwood, Royal, Hutcheson, & Turner, 1992). Spot electrodes give generally comparable results to Mylar bands for systolic time intervals, but are less accurate for volumetric measures (stroke volume and cardiac output), especially for between-subject comparisons (Sherwood, Royal, Hutcheson, & Turner, 1992). A variety of other spot electrode placements have also been employed, which can give similar group values, but may yield variable results across individual subjects (Hoetink et al., 2002; Kauppinen, Hyttinen, & Malmivuo, 1998). A "whole-body" impedance approach has also been implemented with limb electrodes, which shows promising results, although it may be less sensitive to some cardiovascular parameters because a large proportion of the basal impedance arises from the limbs (Kauppinen, Koobi, Hyttinen, & Malmivuo, 2000).

The ECG is also required for impedance cardiography, as the Q wave serves as a landmark for the beginning of ventricular electrical activation and the R wave is employed as

the fiducial point of alignment for ensemble averaging of signals. Some devices extract the ECG from the impedance recording electrodes, although that does not always provide a very clear signal. Consequently, additional ECG electrodes are also often employed.

The primary dependent variables in impedance cardiology are ECG, Z_0 (basal impedance) and dZ/dt (first derivative of Z_0). Z_0 is a measure of thoracic impedance, in ohms, and reflects the variation in blood volume and distribution over the cardiac cycle. The variations in Z_0 over the cardiac cycle are small compared to the overall basal impedance (generally in the range of 10–40 ohms). Consequently, the dZ/dt is either derived electronically or calculated off-line to remove the baseline and to enhance the relevant components of the small variations in the signal. The recorded signal from which these parameters are extracted is a composite of the carrier frequency (100 kHz sine wave), basal impedance (Z_0), and ECG. The circuitry in instruments varies from manufacturer to manufacturer, but generally the carrier frequency is demodulated and the Z_0 and ECG are routed through low pass filters to remove any remaining high-frequency signals (>50 Hz). To achieve optimal temporal sensitivity, these signals should be digitized at 1 kHz.

Scoring. Two sets of measures are generally derived from the impedance signal: (a) systolic time intervals such as the pre-ejection period (PEP) and the left ventricular ejection time (LVET); and (b) volumetric measures such as stroke volume (SV) and cardiac output (CO). For the measurement of systolic time intervals, two landmarks are determined from dZ/dt , the B and X points. The B point is characterized by a notch or an inflection point near the onset of the rapid upstroke of the dZ/dt waveform, which serves as an index of the point in time when intraventricular pressure becomes higher than aortic pressure, the aortic valve opens, and ventricular ejection commences. The B point can be challenging to localize, especially when a distinct inflection point or notch is not apparent. It corresponds roughly with the peak of the first heart sound of the phonocardiogram, but this acoustic signal is complex and temporally distributed so that it does not serve as a viable marker of ventricular ejection time. Various methods have been used to estimate the B point from the impedance signal in the absence of a clear notch, including identification of the maximum slope or maximum slope change (2nd derivative), or the zero point crossing of the dZ/dt function (see Sherwood et al., 1990). An additional method that shows promise and may be superior to prior approaches is the use of a simple percentage or proportion (about 55%) of the time from the R peak to the peak of the dZ/dt wave (Lozano et al., in preparation).

The X wave peak is the lowest point on the dZ/dt waveform after the peak, and is taken as an index of the time when the aortic valve closes, marking the end of ventricular ejection. The peak (minimum) of the X wave is generally readily identified and has been recommended as the

X point (Sherwood et al., 1990). It has been suggested that more accurate volumetric estimates, however, may be obtained by using the X onset point which may more closely correspond to aortic valve closure (for discussion see Brownley, Hurwitz, & Schneiderman, 2000).

Four systolic time interval measures can be derived from these points and the ECG. LVET is the time from the B point to the X point. PEP is generally taken as the time between the Q wave onset and the B point inflection on the dZ/dt waveform, although the onset of the R wave (Q wave peak) has been recommended as a more consistent and identifiable fiducial point (this has been referred to as PEPr; Berntson, Lozano, Chen, & Cacioppo, 2004). PEP and PEPr are measures of contractility that are used to index of sympathetic cardiac control. Additional indices of myocardial contractility include the Heather Index (HI) which is the ratio of the dZ/dt_{max} (ejection velocity) to the Q-dZ/dt peak interval, and the Acceleration Index (ACI) which is the dZ/dt_{max} divided by the B-dZ/dt peak interval. Additional inotropic and autonomic indices have also been derived from impedance signals (Thayer & Uijtdehaage, 2001).

The ejection velocity derived from the peak value of the dZ/dt waveform is used to calculate stroke volume (SV, in milliliters) according to the Kubicek equation (Kubicek et al., 1966):

$$SV = \rho_b (L/Z_0)^2 \cdot LVET \cdot dZ/dt_{max}$$

where ρ_b is the blood resistivity (often assigned a constant value of 135 ohms/cm, although more accurate estimates may be obtainable by direct measures of this parameter); L is the distance between the recording electrodes; Z_0 is the mean thoracic impedance; LVET is as defined above; dZ/dt_{max} is the peak of the dZ/dt function (because it actually reflects a reduced impedance it is sometimes designated dZ/dt_{min}).

From stroke volume and heart rate (HR), cardiac output can be calculated as:

$$CO = SV \cdot HR$$

There have been a variety of alternative formulas offered for the calculation of impedance derived cardiac output estimates, including the Sramek equation, Bernstein's modification of this method, and a more recent proprietary modification of this method (Bernstein, 1986; see also Van De Water et al., 2003). Although some findings suggest that the latter methods may be somewhat superior to the Kubicek formula, the Kubicek equation remains the standard and is most widely used in psychophysiology.

Scoring of impedance cardiology can be accomplished on a beat by beat basis, although the method of ensemble averaging over longer epochs is more efficient and yields highly comparable results (Kelsey et al., 1998). This approach derives an average of both the ECG and dZ/dt waveforms. By ensemble averaging of the signals, random noise and movement artifact that is not synchronized with the R wave is effectively removed, which

provides for a more stable representation of cardiac activity. The ensemble method first determines the peak of the R wave of the ECG in the time series. From this point, a composite signal for both ECG and dZ/dt is calculated by averaging the signal from some fixed time before the R wave (typically 100ms) to 500–600 ms after the R peak. From these ensembled waveforms of ECG and dZ/dt , the landmarks for impedance scoring are identified as outlined above for individual cardiac cycles (see Figure 8.11). The duration of the epochs to be ensemble averaged generally ranges from 30 sec to 5 min, based in part on the experimental design and the questions to be addressed. Epochs should be short enough that cardiodynamics are relatively stable, as an average of changing values can be distorted. On the other hand, longer epochs are more efficient for scoring purposes. One minute epochs are satisfactory for most studies, and the results can be further aggregated over longer experimental periods (e.g., as five 1-min epochs over a 5-min stressor). Even longer periods extending over hours may be useable for assessing long term changes in impedance parameters (Riese et al., 2003).

Validity. Under rigorous experimental conditions, impedance-derived estimates of cardiovascular function have been reported to be highly reliable, and to correlate well with parameters determined by echocardiography or invasive techniques such as the Fick (dye dilution) method (Sherwood et al., 1990; Moshkovitz, Kaluski, Milo, Vered, & Cotter, 2004).

Generally, measures of systolic time intervals show greater correlations across methods than do the volumetric measures of stroke volume and cardiac output (Sherwood et al., 1990). Even for volumetric measures, however, a meta-analysis of three decades of validation studies revealed correlations of greater than 0.80 between impedance derived measures and those derived from reference standards, such as echocardiography and the Fick method (Raaijmakers, Faes, Scholten, Goovaerts, & Heethaar, 1999).

The accuracy of impedance estimates is enhanced by rigorous experimental control and the maintenance of constant conditions. Cardiac anomalies, for instance, may impact impedance measures of cardiovascular function. In addition, impedance-derived estimates of stroke volume and cardiac output can be biased by variations in preload or afterload associated with differences in posture or activity, and even vocalization may alter these parameters (Tomaka, Blascovich, & Swart, 1994). These considerations are especially critical for ambulatory studies. Improved volumetric estimates can also be obtained when blood resistivity is estimated from the hematocrit, rather than applying a generic constant (Demeter, Parr, Toth, & Woods, 1993).

With careful attention to experimental design and control, impedance cardiography can offer a range of non-invasive metrics of cardiac performance and autonomic control in psychophysiological contexts.

Cardiac imaging

Psychophysiolists with access to medical facilities are using cardiac imaging techniques that typically fall within the purview of the cardiologist or radiologist. We focus here on techniques that provide non-invasive images, which include echocardiography (either with or without Doppler ultrasound) and magnetic resonance imaging (cardiac MRI). Other common imaging modalities include radionuclide single photon emission computed tomography (SPECT), electron beam computed tomography (CT), and positron emission tomography (PET), which require introducing radioisotopes (Gibbons, & Araoz, 2004). Although these methods will not be considered here, their further development may allow highly specific measures of neurotransmitter release, uptake and receptor action at the level of the heart (Carrio, 2001).

Echocardiography is an ultrasound-based technique that is very commonly available in hospitals, noninvasive, relatively inexpensive, portable, and safe for the subject or patient. Echocardiography is particularly useful in providing quantitative, anatomic information about the heart (Goldin, Ratib, & Aberle, 2000). The disadvantages of echocardiography are that it requires an experienced sonographer to record the images, considerable training to read them, and typically requires breath holding so images are not obscured by lung movements. Originally, echocardiographic images were taken in 2D, and simplifying assumptions were required for calculating measures such as left ventricular volume. Failure of these assumptions introduced large measurement errors across individuals. Echocardiography can also be combined with Doppler ultrasound to determine blood flow. Doppler ultrasound techniques rely on the fact that sound waves bounced off a moving target change their frequency in direct proportion to the speed of the moving material. From this, blood flow velocities can be calculated and together with echocardiography one can obtain functional and anatomic information about heart function (Fyfe & Parks, 2002). A more recent innovation in echocardiography, known as real-time 3-D echocardiography (RT3DE) appears promising because it requires shorter scanning times (about 4 cardiac cycles) that permit recording during a single breath hold (Weyman, 2005). This technique provides left ventricular volume, mass and ejection fractions that compare well with MRI, which is quickly becoming the gold standard for anatomic measurements (Weyman, 2005). The primary downside of RT3DE is the time required for analyzing the data to make volume calculations, although automated analyses should improve this.

The other primary noninvasive cardiac imaging technique is cardiac MRI. Cardiac MRI relies on the same physical principles as any other MRI used to image the body. In simplified terms, a magnetic field applied around a body part aligns some of the protons (positive charges) on hydrogen ions that are a large component of body tissues and water. When a radio frequency pulse is applied to

the magnetic field, these protons change their alignment, and after the pulse, fall back into alignment with the magnetic field. A radio wave produced when the proton falls back into alignment is detected by the MR scanner. The number of protons depends upon the constituents of the tissue, and these different proton densities are translated into different shades of gray or color. Images are acquired in 2-D slices through the tissue and multiple slices are stacked to create a 3-D image. Like echocardiography, MRI is thought to be safe. MRI also has the advantage of not being disrupted by air in the lungs and has a broader field of view than echocardiography (Fyfe & Parks, 2002). MRI has been shown to produce even more accurate estimates of left ventricular mass and volume than echocardiography (Higgins, 2000; Myerson, Bellenger, & Pennell, 2002). Multi-slice images can be presented sequentially in a movie or cine sequence that can show functional aspects of the heart (Goldin et al., 2000). Disadvantages of MRI are that some individuals cannot tolerate the close quarters and noise of an MRI scanner, and that some individuals have internal metallic devices or implants that preclude being able to place them in a strong magnetic field. Together these techniques provide important tools for non-invasive measurements of cardiac anatomy and function.

PSYCHOPHYSIOLOGICAL CONTEXT

A Medline search on the terms “cardiovascular AND psychophysiology” yielded 15,222 hits. Obviously, space precludes a comprehensive overview of the wide range of contemporary lines of investigation in cardiovascular psychophysiology. A few general themes, however, are worth brief mention.

Psychophysiological patterns

Much of the early work in psychophysiology focused on a single response dimension, such as ECG, EMG, or SCR. When more than one measure was taken, it was often to examine replicability across measures or to draw contrasts between the measures and their sensitivity to psychological states. Although there was some early interest in patterns of activity across response domains, it was not until the mid 1900s that the Lacey (Lacey & Lacey, 1962) solidified the construct of autonomic response patterning. Since then, there has been a growing recognition that the psychological and health significance of psychophysiological states may derive more from the profile of activity across response domains, rather than from discrete responses or from simple threshold or sensitivity differences of distinct response domains.

Autonomic branches, psychological states, and cardiac risk stratification. As discussed earlier, the sympathetic and parasympathetic branches are often reciprocally controlled by reflex systems, but higher level neural systems can exert more flexible patterns of control that include

reciprocal, coactivational, or independent changes of the autonomic branches. These patterns of response may have distinct functional origins and differing consequences, but may not be apparent by measures of an end organ response (such as a change in heart rate) or by measures of either branch alone. An increase in heart rate, for example, could arise from an increase in sympathetic activity, a decrease in parasympathetic activity, a combination of both, a sympathetically dominated coactivation, or a parasympathetically dominated coinhibition.

These different patterns of autonomic response may arise from distinct neurobehavioral processes. In a conditioning study, Iwata and LeDoux (1988) found comparable heart rate increases to the conditioned stimulus in conditioned and pseudo conditioned groups. This finding raised the possibility that the psychophysiological states associated with these two conditions may not mirror the differences in the psychological significance of the CS. Selective blockades of the autonomic branches, however, revealed a distinct pattern of autonomic response despite the comparable end organ response. The pseudoconditioned CS yielded an independent sympathetic activation that drove the cardiac response. The conditioned CS, in fact, yielded a larger sympathetic activation accompanied by a parasympathetic coactivation, which yielded a comparable overall heart rate response despite different autonomic origins. This psychophysiological differentiation in the pattern of response across the autonomic branches would not have been apparent if only heart rate had been measured. A wide range of autonomic response patterns, including autonomic coactivation (e.g., Gianaros & Quigley, 2001; Bosch et al., 2001), are seen in psychological contexts in humans. An important area for future investigation is the elucidation of the specific determinants of these patterns of response.

Differential patterns of autonomic response may not only reflect distinct functional origins, they may have divergent consequences and health implications. RSA and heart rate variability have been effectively used for risk stratification in cardiac disorders, based on the fact that sympathetic activity can be deleterious, whereas parasympathetic activity may offset those deleterious effects in cardiomyopathies or myocardial infarcts (Gang & Malik, 2002; Schwartz, La Rovere, & Vanoli, 1992; Smith, Kukielka, & Billman, 2005). The importance of broader patterns of autonomic and physiological variables in health and disease is further illustrated by the ongoing development of more comprehensive cardiovascular risk factor profiles, which include multiple interacting dimensions including autonomic, neuroendocrine, and metabolic factors (Rosengren et al., 2004; Wood, 2001).

Loneliness and cardiovascular patterns. Autonomic patterns, rather than differences along single dimensions, also differentiate lonely from nonlonely individuals. Lonely individuals tend to display higher total peripheral resistance (TPR) and lower cardiac output (CO) than do

nonlonely people, and they show smaller changes in HR, cardiac contractility, and CO in response to laboratory stressors (Cacioppo et al., 2002; Hawkley, Burleson, Berntson, & Cacioppo, 2003). This pattern is reminiscent of individuals in passive coping contexts and/or making threat-related appraisals (Sherwood, Dolan, & Light, 1990; Tomaka, Blascovich, Kelsey, & Leitten, 1993). The higher TPR of the lonely likely reflect enhanced sympathetic vascular tone, whereas the lower cardiac output and smaller changes in HR and cardiac contractility suggest lower sympathetic cardiac control. These differences are not consistent with simply more or less sympathetic vs. parasympathetic activity, but with probable system-specific patterns of these activities.

The pattern of physiological states and reactivities of lonely individuals may not be limited to the autonomic domain, but may also manifest in neuroendocrine or immune processes as well. It is well established that stressors, such as medical school examinations, can compromise the immune system as evidenced by lower antibody titers to an influenza vaccination (Glaser, Kiecolt-Glaser, Malarkey, & Sheridan, 1998). This stress related deficit in vaccine-induced seroconversion, however, was positively modulated by social embeddedness, suggesting there also may be immunological correlates of loneliness. This possibility was further supported by the finding of diminished wound healing in lonely subjects (see, Cacioppo & Hawkley, 2003). Clearly, an understanding of the psychophysiology of loneliness would not be complete if attention were focused solely on the cardiovascular system or even the autonomic nervous system. Psychophysiological systems are quintessentially interacting systems. Although pragmatics may limit studies to a single or a small number of dimensions, the ultimate understanding of psychophysiological phenomena and their implications for health may require a broader perspective entailing the interactions among multiple psychophysiological systems.

Autonomic, endocrine, and immune interactions

Stressors, especially social stressors can impact immune functions, at least in part by modulating autonomic and/or neuroendocrine process. Social reorganization stress in mice, but not physical stressors such as restraint or shock, has been shown to trigger reactivation of Herpes Simplex virus (Padgett et al., 1998). In addition, introduction of an aggressive intruder, but not physical stressors, can result in notable hyper-inflammatory reactions to foreign antigens which can have lethal consequences (Sheridan, Stark, Avitsur, & Padgett, 2000). This appears to reflect alterations in glucocorticoid functions. Although social stress and physical stress yielded comparable increases in glucocorticoid levels, social stress resulted in the development of glucocorticoid resistance associated with alterations in post-receptor actions (Quan et al., 2003). This resulted in exaggerated immune responses, which were not adequately held in check by glucocorticoids. In this case, the

health consequences of social stress were related to altered immune functions, but these immune changes were secondary to an alteration in glucocorticoid processing.

In many cases, the health significance of psychophysiological states may relate to interactions among autonomic, neuroendocrine and immune systems. Exaggerated cardiovascular reactivity to stress has long been recognized as a predictor of atherosclerosis, hypertension and other cardiovascular disorders (Jennings et al., 2004; Matthews, Salomon, Brady, & Allen, 2003). More recent research suggests specific immune links in these relations. Atherosclerosis is now understood to be fundamentally an inflammatory disorder, in which exaggerated immune responses can promote plaque formation, restrict circulation, and foster emboli (see Libby, 2003; Strike & Steptoe, 2004). High heart rate reactions to stressors (especially those driven by sympathetic activation) predict greater immune consequences, and some immune responses to laboratory stressors can be reduced by sympathetic blockade (Bachen et al., 1995; Benschop et al., 1994; Bosch, Berntson, Cacioppo, Dhabhar, & Marucha, 2003; Cacioppo, 1994; Cacioppo et al., 1995). An explicit link between sympathetic reactivity to stress and cardiovascular disease is suggested by the finding that a laboratory speech stressor resulted in sympathetic activation and a correlated mobilization of a subset of T cells and monocytes that express specific cell surface markers (CXCR2, CXCR3, and CCR5; Bosch et al., 2003). The ligands for these markers are chemokines (chemical attractants) that are secreted by activated vascular endothelial cells. Consequently, stress would be expected to promote trafficking of these cells to these areas of activated endothelium and further exaggerate the inflammatory reactions associated with atherosclerosis.

This represents just one example of what are likely multiple and intricate interactions among autonomic, neuroendocrine and immune systems that contribute to health and disease. As the field of psychophysiology develops and becomes more interdisciplinary, it is likely these interactions will assume increasing importance.

Gastrointestinal Response

ROBERT M. STERN, KENNETH L. KOCH, MAX E. LEVINE, AND ERIC R. MUTH

PROLOGUE

Overview

Questions about the interaction between brain and the gastrointestinal (GI) system have interested investigators at least as far back as 1833, when Beaumont described his experiments on a fistulated patient, Alexis St. Martin. In the case of St. Martin, his fistula, or external opening into the stomach, was created by an accidental gunshot wound. Beaumont reported that upsetting emotions suppressed gastric secretion and delayed gastric emptying in his subject. Between 1840 and 1870 several physiologists created fistulas in dogs, based on Beaumont's work, and found that an intact vagus was needed for normal brain-gut interaction. This was an important finding because it indicates that one pathway by which the brain and gut communicate is via the vagus nerve or parasympathetic nervous system. Today we use the term cephalic-vagal reflex to refer to, for example, the anticipatory stomach contractions that occur when thinking about an appetizing meal. More about the cephalic-vagal reflex will follow in a later section of this chapter, but we should keep in mind that brain-gut interaction is a two-way street. That is, not only does brain activity affect GI activity, but GI activity also affects the activity in the brain. An example of the latter, which will be discussed in some detail later in this chapter, is the effect of changes in stomach activity on the sensation of nausea.

During the first half of the twentieth century, gastrointestinal scientists and clinicians were deeply committed to an interactive brain-gut view of gastrointestinal functioning and, therefore, had a lot to say to psychophysiologists. Wolf and Wolff (1943) wrote a fascinating book about their experiences over many years with their fistulated subject Tom. Their basic findings were that when Tom was fearful or depressed his gastric activity decreased, but when he was angry or hostile his gastric activity increased. During this same period, Cannon studied the effects of various emotions on GI activity and published several books on the topic including *Digestion and Health* (1936), which con-

tains chapters on the nature of appetite and hunger, and indigestion from pain, worry and excitement. Alvarez, perhaps the best-known gastroenterologist of the century, in his writings, both scientific and popular, always stressed the interaction of psychological and physiological factors in GI functioning. His book *Nervousness, Indigestion, and Pain* (1943) is highly recommended reading for psychophysiologists.

During the second half of the twentieth-century gastroenterologists developed many new techniques for measuring the activity of the GI system and adhered, in general, to a medical model. Unlike Alvarez, who said "...to understand a man's stomach, one must understand the man," gastroenterologists relied more and more on the results of laboratory tests of the GI system and ignored the "man." This meant that there was little interaction between gastroenterologists and psychophysiologists, or psychologists of any type, and because most of the new tests of GI activity were invasive, most psychophysiologists could not make use of them outside of a medical center. Fortunately, the pendulum has swung back during the past few years and as one indication, an interdisciplinary group of scientists and clinicians trained in gastroenterology, psychophysiology, epidemiology, and clinical psychology have formed an association called the Functional Brain-Gut Research Group.

As a consequence of the paucity of interaction between gastroenterologists and psychophysiologists until recently, the authors know of no psychophysiological studies of absorption, and psychophysiologists have conducted few studies of gastric acid secretion. However, several studies of motor activity, particularly in the stomach, have been conducted. In this chapter we review psychophysiological studies that have measured gastric motor activity; the major emphasis will be on the motor activity of the stomach as measured with a noninvasive technique first used by Alvarez in 1921, the electrogastrogram or EGG. Brief information about two additional noninvasive measures of motor activity appears at the end of this chapter. These measures are (1) gastric emptying time and (2) oral-cecal transit time.

Electrogastrography refers to the recording of electro-gastrograms (EGGs). Electrogastrograms reflect gastric myoelectrical activity as it is recorded from the abdominal surface with electrodes placed on the skin. EGGs are more or less sinusoidal waves recurring at a rate of 3 cycles per minute (cpm) in healthy humans. This predominant frequency is usually discernable by visual inspection of the signal, but computer analysis is essential for quantitative study of EGG recordings.

The stomach is also the source of abnormally fast or slow – usually dysrhythmic – myoelectrical signals, the tachygastrias and bradygastrias. Acute or chronic shifts from normal 3 cpm EGG signals to the gastric dysrhythmias are associated with a variety of clinical symptoms, particularly nausea. In contrast to the level of research on abnormalities in frequency, such as the gastric dysrhythmias, there has been little study about the amplitude, duration, wave form and wave propagation characteristics of the EGG.

HISTORICAL BACKGROUND

In the mid-1950s, R.C. Davis, one of the founders of the Society for Psychophysiological Research, began a series of exploratory studies with the EGG. Davis, like Alvarez, was primarily interested in the interaction of psychological and physiological factors on gastric functioning. Davis published two papers before his untimely death in 1961, papers that stimulated several other investigators to begin doing EGG research. In a 1957 paper (Davis, Garafolo, & Gault, 1957), Davis and his co-workers described their attempt to validate the EGG using simultaneous recordings from needle electrodes, a mine detector that picked up the movements of a steel ball in the subject's GI tract, and the EGG. They used needle electrodes that were insulated except at the tip so that they could rule out cutaneous tissue as the source of the EGG signal.

In a 1959 paper (Davis, Garafolo, & Kveim, 1959), Davis and his co-workers described their continuing validation of the EGG using swallowed balloons, and their studies of the effects of eating on the EGG. They reported that the activity of the stomach is at its lowest point when the stomach is empty, a controversial finding in light of the reports of so-called hunger contractions by Cannon and Carlson (Cannon & Washburn, 1912; Carlson, 1916). After recording the EGG from many fasted subjects both with and without a balloon in the stomach, Davis concluded that hunger contractions are rare and are usually stimulated by the introduction of a balloon into the stomach. This is a good example of one of the advantages of using psychophysiological methods, that is, noninvasive recording techniques that do not interfere with the behavior being studied. All other methods of recording stomach activity either require putting something inside the stomach – which stimulates it to contract – or are dangerous to use for extended periods, such as X-rays or fluoroscopy. For more information about the history of EGG see Chapter 1 in Koch and Stern (2004).

PHYSIOLOGICAL BASES OF GASTRIC MOTOR ACTIVITY AND ELECTROGASTROGRAPHY

The GI system extends from the mouth to the rectum and includes the mouth, esophagus, stomach, small intestine, large intestine, and rectum. The three functions of the GI system are movement of food through the alimentary tract, secretion of substances that aid in digestion or protect the alimentary tract, and absorption of the digestive end products. The GI tract may be considered to be a series of muscular tubes that perform region-specific digestive functions, that is, transit of food from esophagus to stomach, mixing and emptying of ingested foods from the stomach into the duodenum, and absorption of micronutrients from the small intestine. Other specialized tubes (i.e., the cecum; ascending, transverse, and descending colon; and rectum) conserve water, electrolytes, and nutrients and evacuate wastes. These functions require exquisite control and integration of relevant neural, muscular, mucosal, and hormonal systems within the GI tract.

Gastric anatomy

In most healthy humans the stomach lies in the upper quadrant of the abdomen, although there is a wide range of variability in its shape and form (see Figure 9.1). As is shown in Figure 9.1, the esophagus enters the stomach in the fundic region; the antrum is connected to the first portion of the duodenum, the duodenal bulb, via the pylorus.

As can be seen at the top of Figure 9.1, the stomach has three major regions: the fundus, body, and antrum. The middle of the figure shows the three layers of the stomach: outermost is the serosa; innermost is the mucosa, which secretes acid and pepsin; and the thickest layer is the muscular portion, which has three layers, an outer longitudinal layer, an inner circular layer, and in some areas an oblique layer. The bottom of the figure shows the relationship among the circular muscle layer, the myenteric neurons, and the interstitial cells of Cajal (ICC). The ICC are the origin of the electrical rhythmicity that is recorded as the gastric pacemaker potential. For additional information about the ICC and their relationship to gastric electrical rhythmicity see Chapter 2 in Koch and Stern (2004).

The muscular wall of the stomach contains extensive neural elements, both extrinsic and intrinsic. Extrinsic nerves are pre- and postganglionic parasympathetic fibers from the vagus nerve and postganglionic neurons from the sympathetic splanchnic nerves. These extrinsic neural circuits are closely integrated with the intrinsic nervous system of the stomach and of all regions of the GI tract, the enteric nervous system.

The enteric nervous system is a collection of nerve cell bodies in plexi located between the circular and longitudinal muscle layers, that is, the myenteric plexus (Auerbach's plexus) and submucosal plexus (see Figure 9.1). The myenteric and submucosal plexi are the largest, but

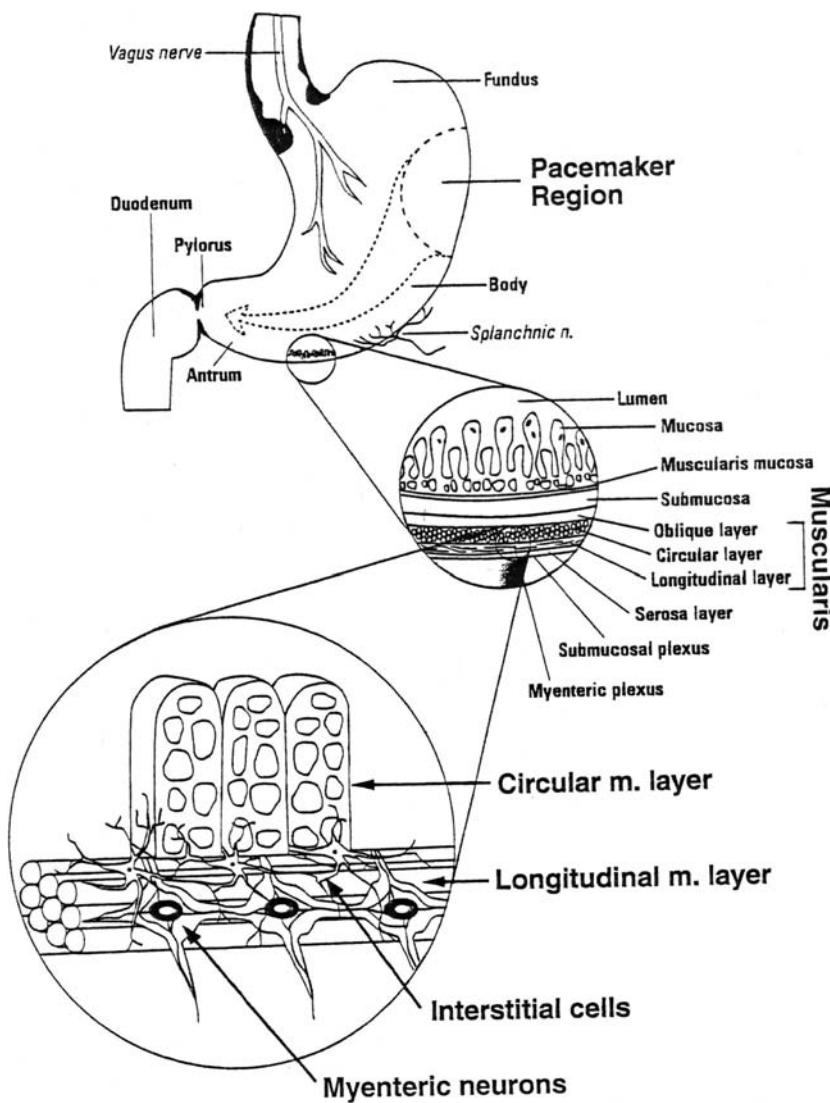

Figure 9.1. Anatomical regions of the stomach. The upper figure shows the fundus, body, and antrum of the stomach. The pacemaker region is the origin of gastric pacemaker potential activity. The cutout of the gastric wall shown in the middle portion of the figure depicts the lumen of the stomach, the mucosa, and the muscularis of the stomach wall. The main muscle layers of the stomach are the longitudinal and circular muscle layers, with some contribution by the oblique muscle layer. In the lower portion of the figure, the relationships among the circular muscle layer, the interstitial cells of Cajal, and the myenteric neurons of Auerbach's plexus are shown. The interstitial cells of Cajal synapse with the circular muscle layer as well as the myenteric neurons. The interstitial cells of Cajal are the origin of the electrical rhythmicity that is recorded as the gastric pacesetter potentials. The gastric pacesetter potentials coordinate the frequency and the propagation of the circular smooth muscle contractions. (Reprinted with permission from Koch & Stern (2004).)

seven discrete plexi have been identified. Postganglionic parasympathetic neurons, internuncial neurons, and sensory neurons are present within the plexi. Many different types of enteric neurons have been identified by immunohistochemical methods (Furness & Costa, 1980). It has been estimated that there are 10^9 neurons in the enteric nervous system, a number similar to that in the spinal cord. Fibers from the sympathetic neurons synapse on myenteric plexus neurons and innervate the circular muscle layer. Thus, the muscular layers of the stomach, particularly the circular muscle layer, have rich neural integration that allows for fine control of muscular contraction required for normal digestive function. The interested reader may refer to review articles on neural control of gastric motility (Wood, 2002).

Gastric physiology

Postprandial gastric physiology. The major physiological activities of the stomach are to receive ingested foodstuffs and to mix the foodstuffs into suspensions until they are

appropriate for emptying and further digestion in the small intestine.

Normal reception of ingested food requires the gastric fundus to relax and to accommodate the particular ingested volume. These muscular activities of the stomach are termed receptive relaxation and accommodation and are accomplished via vagal efferent activity (Roman & Gonella, 1987). Moreover, because nearly 90% of vagal fibers are sensory, it is assumed that sensory vagal traffic modulates ongoing vagal efferent activity.

After ingestion, solid foods are moved from the gastric fundus into the gastric body and antrum for mixing and emptying. This period is called the lag phase because it precedes actual emptying of the nutrient suspensions from the stomach into the duodenum (Lavigne, Wiley, Meyer, Martin, & MacGregor, 1978; Meyer, MacGregor, Gueller, Martin, & Cavalieri, 1976). In contrast to solids, non-nutrient liquids such as water have no lag phase. Before emptying, solids are normally mixed and reduced to 0.1–1 mm diameter particles and suspended in gastric juice (Meyer, Ohashi, Jehn, & Thompson, 1981).

The stomach accomplishes the work of mixing and emptying through a series of smooth rhythmic contractions at the rate of 3 cycles per minute (cpm). This phase in the digestive process, known as peristalsis, commences in the gastric body and moves through this region into the antrum where the waves dissipate in the prepyloric region. As a result of these wavelike contractions, small food particles already in suspension are carried through the open pyloric sphincter into the duodenum (Meyer et al., 1981; Meyer, Gu, Dressman, & Amidon, 1986). The pylorus and the duodenum may contract to create resistance to gastric emptying or may relax to promote gastroduodenal synchrony and enhance gastric emptying (Meyer, 1987). The hydrodynamics of the suspension itself may determine which particles are emptied and their rate of emptying (Meyer et al., 1986).

Control of the mixing and emptying of gastric content is complex. In addition to physical properties of the gastric contents and the various neural-muscular responses, the release of gastrointestinal hormones (e.g., gastrin, secretin, cholecystokinin, enteroglucagon, gastric inhibitory polypeptide, somatostatin, vasoactive intestinal polypeptide, and motilin, to name a few of the more than 20 GI hormones and candidate hormones) is believed to modulate the contractile responses of the stomach and to affect overall gastric emptying rates. However, specific actions of most GI hormones on gastric motility in humans remain to be determined.

The rate at which foodstuffs are emptied from the stomach is dependent on many factors including the volume of ingested material, caloric density (i.e., fat, protein, or carbohydrate), osmolality, temperature, acidity, and viscosity. These factors are adjusted by chemo- and mechanoreceptors in the stomach and duodenum and the variety of hormones released by the specific foodstuffs (Meyer, 1987).

Emptying of liquids is thought to be controlled by fundic tone. That is, after the ingestion of a liquid such as water, fundic pressure is greater than duodenal pressure. The pressure gradient between fundus and duodenum provides the force necessary to empty the liquid from the stomach (Meyer, 1987). Other studies indicate that the antrum has a more active role in the emptying of liquids (Camilleri, Malagelada, Brown, Becker, & Zinsmeister, 1985; Stemper, & Cooke, 1975).

Gastric physiology during fasting. During the interdigestive state (e.g., an overnight fast), the stomach completes its digestive function and participates in a stereotyped periodic sequence of contractile events termed the interdigestive complex. The complex is divided into three phases: Phase I is a period of quiescence lasting approximately 20 min; Phase II is a period of irregular contractile activity of the body and antrum lasting about 80–90 min; and Phase III is a 5–10 min period of regular and intense 3-cpm contractions of the gastric body and antrum. The antral contractions are peristaltic, moving into the duodenum and subsequently through the small bowel. Phase

III activity occurs approximately every 90–110 min in humans during prolonged fasts and has been associated with bursts of pancreatic and biliary secretions and elevations in plasma motilin levels (Code & Marlett, 1975; Lee, Chey, Tai, & Yajima, 1978; Meyer, 1987; Schlegel & Code, 1975; Vantrappen et al., 1979).

From a physiological viewpoint, Phase III contractions have been shown to empty fibrous meal residue from the stomach (Schlegel & Code, 1975). The Phase III contractions may serve a similar function in the small intestine and have been termed the “intestinal housekeeper.”

Relationship between gastric neuromuscular activity and gastric myoelectric activity

For a general discussion of myoelectrical and contractile activity of the GI system see Sarna (2002). The gastric contractions that occur at 3 cpm during the mixing and emptying of meals are the result of coordinated electromechanical coupling of circular layer smooth muscle cells. A description of the electrical and mechanical events within the smooth muscle that underlie the mechanical work performed by the stomach follows.

Gastric slow waves. Gastric slow waves are the electrical events that control gastric contractions, and recent studies have shown that the electrical slow waves are generated by the interstitial cells of Cajal (ICC). The slow waves result from spontaneous depolarization of the ICCs in the region of the juncture of the fundus and body on the greater curvature. From this region, the pacemaker area, the depolarization wave front moves circumferentially and distally toward the distal antrum. The normal slow-wave frequency in humans is 3 cpm (Abell & Malagelada, 1985; Couturier, Roze, Paologgi, & Debray, 1972; Hamilton, Bellahsene, Reichelderfer, Webster, & Bass, 1986; Hinder & Kelly, 1977; Kwong, Brown, Whittaker, & Duthie, 1970). The slow wave does not move into the fundic area, which is electrically silent. The slow wave is a spontaneous, sodium-mediated, and omnipresent event that is associated with very low-amplitude contractile activity (Morgan, Schmalz, & Szurszewski, 1978; You & Chey, 1984).

The slow wave coordinates the frequency and propagation velocity of gastric contractions in the corpus antrum. That is, the slow wave brings the circular muscle layer near the point of depolarization and, if physical, neural, and/or hormonal signals are appropriate for contraction, the depolarization threshold is reached and circular muscle contraction occurs. Because circular muscle contractions are linked with the slow wave, the circular muscle contractions occur at the slow-wave frequency (3 cpm in humans) and the contractions propagate at the slow-wave velocity (0.8–4 cm/s). For these reasons the slow waves have also been called pacemaker potentials and electrical control activity (Meyer, 1987; Roman & Gonella, 1987).

Slow waves are considered to originate in the ICCs, but extrinsic neural input may modulate the rhythmicity of

depolarization. For example, after vagotomy in dogs and humans, the slow-wave frequency may be disrupted for weeks (Kelly, Code, & Elveback, 1969; Stoddard, Smallwood, & Duthie, 1981).

Gastric spike potentials. The electrical events underlying circular smooth muscle contractions are plateau and spike potentials. Depolarizations of the circular muscle, in contrast to the longitudinal muscle, are very fast (i.e., spikes). The spikes may or may not occur on plateau potentials, which are associated with the slow wave. The spikes reflect fluxes of calcium passing through the circular muscle membrane. Contractions of the circular muscle may increase tone and/or intraluminal pressure, particularly if they form concentric ring contractions. Such strong contractions may be recorded with strain gauges, intraluminal pressure transducers, or perfused catheters. However, gastric contractions that are not concentric and lumen-occluding may not be recorded by intraluminal devices but will be recorded by strain gauges positioned on the muscle itself (You & Chey, 1984).

In summary, gastric slow waves, generated by the ICC, are present at all times and control the frequency and propagation velocity of spike potentials (i.e., circular muscle contractions) when the latter are elicited by the appropriate stimuli. Gastric slow waves and spike potentials are the myoelectric components of gastric contractions. The gastric contractions perform the work of mixing and emptying foodstuffs. Slow waves and spike potentials from the stomach may be recorded from electrodes sewn to the serosa or from electrodes applied to the gastric mucosa. Because slow waves occur within a conducting medium (i.e., the body), they are also recorded with fidelity from electrodes positioned on the skin – the EGG (Abell & Malagelada, 1985; Brown, Smallwood, Duthie, & Stoddard, 1975; Familoni, Bowes, Kingma, & Cole 1987; Hamilton et al., 1986). Figure 9.2 shows gastric myoelectric activity recorded from serosal and cutaneous electrodes during motor quiescence (A) and during gastric peristalsis (B).

Physiological basis of the EGG

Important anatomical and functional relationships exist among the circular smooth muscle layer, the myenteric neurons, and the interstitial cells of Cajal (ICC) (see Figure 9.1, bottom). As indicated above, the ICCs are the pacemaker cells, the cells that spontaneously depolarize and repolarize and set the myoelectrical rhythmicity of the stomach and other areas of the gastrointestinal tract (Thunberg, 1989; Huisings, 2001). The interstitial cells are electrically coupled with the circular muscle cells. Low amplitude rhythmic circular contractions occur at the pacemaker rhythm (Kim et al., 2002). Rhythmicity and contractility of the circular muscle layer are modulated by ongoing excitatory and inhibitory activity of myenteric neurons that synapse with the interstitial cells. The interstitial cells have a variety of other receptors. Electrocon-

tractile activities of the gastric smooth muscle are modified by neuronal and hormonal inputs appropriate for fasting and specific postprandial conditions. Control of rhythmicity may be modulated by a variety of stimuli that affect the interstitial cells and is a focus of intense investigation.

As stated earlier, human gastric slow wave or pacemaker potential activity generated by the ICCs occurs at a rate of 3 cpm (e.g., Koch, 2002). Pacesetter potential activity is illustrated in Figure 9.2. Electrodes sewn onto the serosa of the stomach record the depolarization and repolarization waves of the pacesetter potentials. The electrical wave front travels around the circumference of the stomach at a fast rate of speed and migrates slowly toward the antrum at an increasing velocity. As a slow wave disappears in the distal antrum, another slow wave originates in the pacemaker area and begins to migrate toward the antrum approximately every 20 seconds. When there is little smooth muscle contractility (Phase I or phase II of the interdigestive state, described above), these electrical events reflect depolarization and repolarization of the ICCs and some small degree of contractility of the circular muscle cells.

From an in vivo electrical viewpoint, the fasting pacesetter potential activity is relatively weak compared with the gastric myoelectrical activity during the postprandial period, when luminal contents and other stimuli augment gastric neuromuscular activity (Lin & Hasler, 1995; Lacy, Koch, & Crowell, 2002). Figure 9.3 shows a conceptualization of the human gastric pacesetter potential as an “electrical halo” migrating around the stomach very quickly and moving distally through the antrum in approximately 20 seconds resulting in the normal gastric electrical frequency of 3 cpm. It is this moving electrical wave front that is recorded in the electrogastrogram (EGG), the gastric myoelectrical activity recorded from electrodes placed onto the surface of the epigastrium.

Additional gastric myoelectrical activity occurs when stronger circular muscle contraction occurs; for example, when vagal efferent activity and release of acetylcholine from the postganglionic cholinergic neurons are elicited in response to ingestion of a meal. In this postprandial situation, plateau potentials and action potentials occur during circular muscle contraction. If more action potentials or greater amplitude and duration of the plateau potentials occur, then stronger circular muscle contractions occur. Migrating circular muscle contractions may result in gentle peristaltic waves or strong lumen-obliterating contractions. Figure 9.2B shows the relationship between the pacesetter potential that is linked to the action potential or plateau potential activity and the formation of a circular muscle contraction that migrates from proximal to distal stomach. Thus, the action potential and/or the plateau potential, linked to the migrating pacesetter potential, forms the myoelectrical basis for the gastric peristaltic contractions that ultimately mix and triturate intraluminal contents. When conditions are appropriate, peristaltic contractions empty 2- to 4-ml aliquots of chyme from the stomach into the duodenum to accomplish the

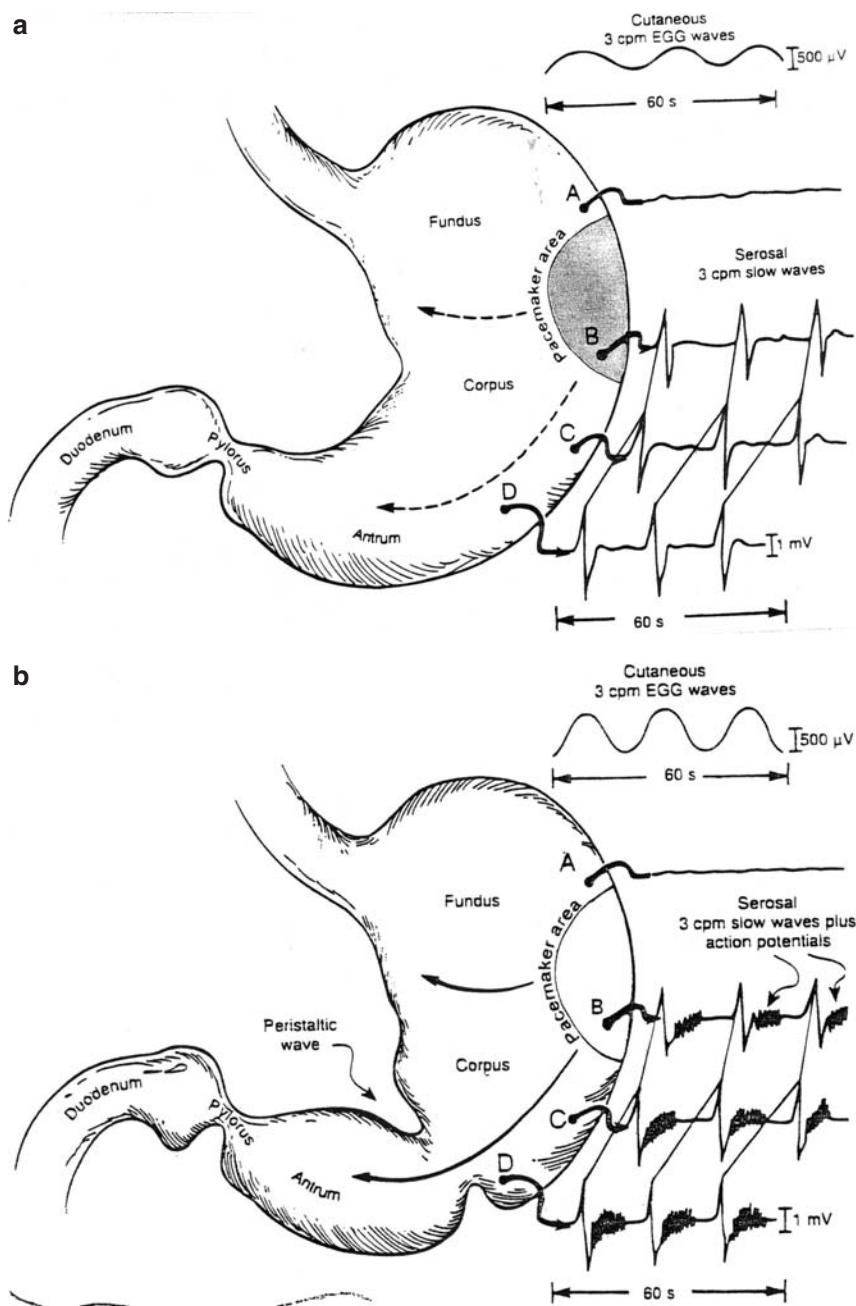

Figure 9.2. (A) Gastric myoelectrical activity during motor quiescence. The antral peristaltic contractions that produce flow of gastric content are controlled by gastric electrical slow waves. The fundus does not have pacemaker activity as shown by electrode A. Pacesetter potentials begin in the pacemaker area located in the proximal gastric body along the greater curve as shown by the gray area. Slow waves spread circumferentially and distally from the pacemaker region and migrate through the antrum (as shown by serosal electrodes, B, C, D). The slow wave migration ends at the pylorus. As the slow wave dissolves in the terminal antrum, another slow wave begins to migrate distally from the pacemaker region. Thus, as shown in the figure, three slow waves will propagate from proximal to distal stomach every 60 seconds, i.e., 3 cpm slow waves. As shown in A, the cutaneous electrogastrogram (EGG) reflects the dipole created by the migrating slow wave, which occurs every 20 seconds. **(B)** Gastric myoelectrical activity during gastric peristalsis. Action potentials occur during gastric circular muscle contraction; the action potentials are linked to the gastric slow waves or pacesetter potentials as shown in the extracellular recordings from the serosal electrodes (B, C, and D). As the slow wave linked with action potentials migrates distally along the gastric body and antrum, one gastric peristaltic wave occurs, and one EGG wave is recorded, as measured from the surface electrodes. Thus, gastric peristalses normally occur at a rate of 3 cpm. During gastric peristaltic contractions, the EGG amplitude is generally increased (compare with Figure 9.2(A)). (Reprinted with permission from Stern, Koch, and Muth (2000).)

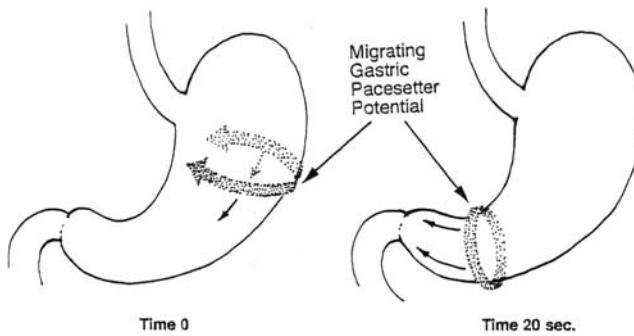

Figure 9.3. Propagation of the gastric pacesetter potential is illustrated as a faint electrical “halo.” The depolarization-repolarization electrical wavefront migrates from the pacemaker region of the corpus (time 0) through the corpus to the distal antrum (time 20 seconds). These pacesetter potentials occur at approximately 3 cpm. (Reprinted with permission from Koch and Stern (2004).)

neuromuscular work of gastric emptying. Because of the increased gastric myoelectrical activity, the EGG signal during the postprandial peristaltic contractions is generally higher in amplitude in healthy subjects compared with the fasting EGG (Figure 9.2B).

Figure 9.4 illustrates a stronger “electrical halo” formed in the postprandial period when the additional gastric myoelectrical activity of the plateau potentials or spike potentials is linked to the migrating gastric pacesetter potential. Compared with the fasted condition, shown in Figure 9.3, greater myoelectrical activity occurs at the normal 3-cpm frequency during regular peristaltic contractions. The additional intensity of gastric myoelectrical activity is present because action potentials or plateau potentials are now linked to the ongoing gastric pacesetter potential activity. Furthermore, the electrocontractile complex (the peristaltic wave) travels circumferentially as well as distally, thus forming the stronger depolarization-repolarization wave front (i.e., stronger “halo”) shown moving through the corpus to the distal antrum where the contraction dissipates. Thus, as stated above, compared with fasting, the amplitude of the EGG wave is generally greater in the postprandial condition depending on the specific meal ingested. The distance of the electrodes from the stomach may also affect amplitude of the EGG signal. These basic gastric myoelectrical activities form the physiological basis for understanding both fasting and postprandial EGG patterns recorded in healthy individuals.

RECORDING AND ANALYSIS OF THE EGG

Recording the EGG

Subjects are instructed what and when to eat prior to an EGG recording session because the contents of the stomach will affect the EGG. For most studies, subjects are instructed to fast for at least 4 hours prior to the experimental session. In other studies subjects are asked to fast overnight and consume one piece of toast and 4 ounces of

juice 2 hours prior to coming to the lab. This standard 200 Kcal meal ensures a consistent baseline EGG. An attempt should be made to reduce apprehension and to ensure the subject that he/she cannot get shocked. To reduce possible embarrassment and potential liability, female experimenters should either apply the electrodes or be present when EGG electrodes are applied to female subjects.

High-quality, fresh, disposable electrodes, such as those used for recording the EKG, are recommended for recording the EGG. Electrodes are placed on the skin surface of the epigastrium over the general area of the antrum of the stomach. EGGs are obtained with electrodes arranged for bipolar recordings. A reference electrode is positioned on the right side of the subject’s abdomen. One active electrode should be placed approximately 10 cm cephalad from the umbilicus and 6cm to the subject’s left. It is important to place this electrode below, and not on, the lowest rib to avoid respiratory signals. The second active electrode should be placed approximately 4 cm above the umbilicus (midway between the umbilicus and xiphoid) on the midline of the abdomen. The reference electrode is placed 10 to 15 cm to the right of the midline electrode, usually along the midclavicular line and 2 to 3 cm below the lowest anterior rib on the right side. The recording sites selected depend on the nature of the EGG signal desired. From our experience, the electrode locations just described provide the largest possible amplitude and least artifact in EGGs from most people. The exact placement of the electrodes is not important if the frequency of the EGG signal is what is of interest. For a discussion of the advantages and disadvantages of different electrode placements for EGG recording, see Smout et al. (1994) and Mirizzi and Scafoglieri (1983).

We have sometimes recorded from two or three abdominal sites simultaneously and chosen the more artifact-free EGG signal for analysis and interpretation (Stern et al., 1985). Chen and colleagues (Chen et al., 1996) have recorded multichannel EGGs, using four active electrodes

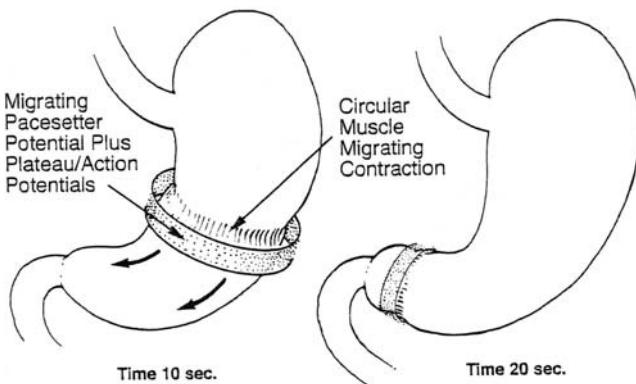

Figure 9.4. The migration of the pacesetter potential plus plateau or action potential activity is illustrated as a stronger, moving electrical “halo” compared with the noncontractile state (compare with Figure 9.3). The movement of the electrocontractile complex across the stomach is shown at 10 and 20 seconds. (Reprinted with permission from Koch and Stern (2004).)

and a common reference electrode, and reported detecting gastric slow wave propagation. They also reported quantifying the degree of slow wave coupling in normal controls and in patient groups such as individuals with systemic sclerosis (McNearney et al., 2002). In general, single-channel EGG recording is sufficient for detecting gastric dysrhythmias.

The EGG can be recorded from the wrists, but the amplitude will be low compared with recordings from the abdomen because electrodes located on wrists are far from the source of the signal, that is, the gastric pacemaker in the corpus antrum (Stern & Stacher, 1982). On the other hand, wrist electrodes are recommended when recording from obese patients, to minimize the fat layer under the electrodes, which acts as an insulator and decreases the amplitude of the EGG signal. For more details about the procedure for recording EGG, see Chapter 4 in Koch and Stern (2004).

Analyzing the EGG

Spectral analysis. Spectral analysis typically uses the Fast Fourier transform (FFT) to convert a signal in the time domain into the frequency domain. The output of a spectral analysis is the squared magnitude of the Fourier transform and is typically graphed as a curve showing the strength, or power, of the frequencies into which the original signal can be decomposed. Although power has a very specific meaning in mathematics and physics, we may think of it as an index of the amplitude of the sine waves of a particular frequency that would be required in order to recreate the EGG record. In the analysis of EGG recordings we are usually interested in the power within the following four frequency bands: 0–2.25, 2.5–3.5, 3.75–9.75, and 10.0–15.0 cpm. The exact cut-offs for these bands vary in the literature. This is due to the fact that the frequency resolution (bin-width) of the FFT is equal to the sampling rate divided by the number of samples in a window. Hence, varying sampling rates and window size will produce slightly different bandwidths based on the spectral resolution in the frequency domain. The first frequency band represents the often found but poorly understood ultra slow rhythm referred to as bradygastria. The second encompasses the normal electrical rhythm of the healthy human gastric antrum (3 cpm). The third includes frequencies commonly associated with nausea and is referred to as tachygastria. The fourth frequency may include duodenal pacemaker potentials and/or respiratory signals.

Spectral analysis is currently the most commonly used method of analyzing the EGG (see Smallwood & Brown, 1983) and the method favored by the authors. Van der Schee, Smout, and Grashuis (1982) have described an extension of this method that makes use of running spectral analysis to depict EGG data. Running spectral analysis, with overlapping power spectra displayed as a function of time, yields both frequency and time information. The more conventional spectral analysis provides

power only as a function of frequency, not time. With running spectral analysis, frequency, power, and time can be depicted two-dimensionally either with a pseudo 3-D display or with a gray-scale plot. Figures 9.5 and 9.6 show examples of pseudo 3-D displays. A description of the procedure used to go from raw EGG data to a pseudo 3-D display can be found in Chapter 5 in Koch and Stern (2004).

The first step in any quantification procedure is to insure that quality data are being analyzed (Kingma, 1989). Because of the relatively slow electrical changes that are associated with EGG, only a very electrically stable electrode can be used; silver-silver chloride (Ag/AgCl) electrodes are recommended. The optimal recording sites will depend on the nature of the signal desired: for example, the largest possible amplitude; lowest artifact from EKG, respiration and subject movement; and position of the subject's internal organs, particularly the antrum of the stomach and the diaphragm (Mirizzi & Scafoglieri, 1983). The amplifying and recording system should filter out signals below 0.5 cpm and above 15 cpm. With these filter settings one can record ultra slow rhythms (0.5–2.0) but still eliminate shifts in baseline due to DC potentials. Frequencies higher than 15 cpm are filtered out to avoid domination of the gastric signal by EKG. Respiration can also obscure the EGG, when its frequency range falls near that of tachygastria or duodenal signals. Rather than remove respiration signals with analog filters at the time of the recording, it is preferable to remove it later with more precise and flexible digital filters or by using a separate respiration tracing to visually select and exclude data that contain respiration artifact.

In order to produce a running spectral analysis, one overlaps consecutive data segments by, for example, 75%. In other words, segment one includes minutes 1–4, segment two includes minutes 2–5, and so on. Thus, one minute of new information is provided in each consecutive power spectrum. These overlapping power spectra can be plotted in a pseudo-3-D fashion to allow easy viewing of changes in power at various frequencies as a function of time (see Figures 9.5 and 9.6).

Although such running spectral analyses do provide a useful way to view frequency and power changes over time, it is important to note that transient changes in the EGG may go unnoticed if they are small. If such transient changes are large enough they will appear but only as a gradual change with the peak in spectral density appearing in the pseudo 3-D display several minutes after it occurred in real time. Thus, running spectral analysis may not be appropriate for experiments in which very short duration stimulus induced changes are expected. For such cases adaptive spectral analysis methods are recommended (Lin & Chen, 1994; Chen, Stewart, & McCallum, 1993; Chen & McCallum, 1991; and Chen, Vandewalle, Sansen, Vantrappen, & Janssens, 1990).

Similarly, spectral analysis is useful only when the EGG signal contains a significant amount of cyclical activity. This is usually the case for 3 cpm activity. However,

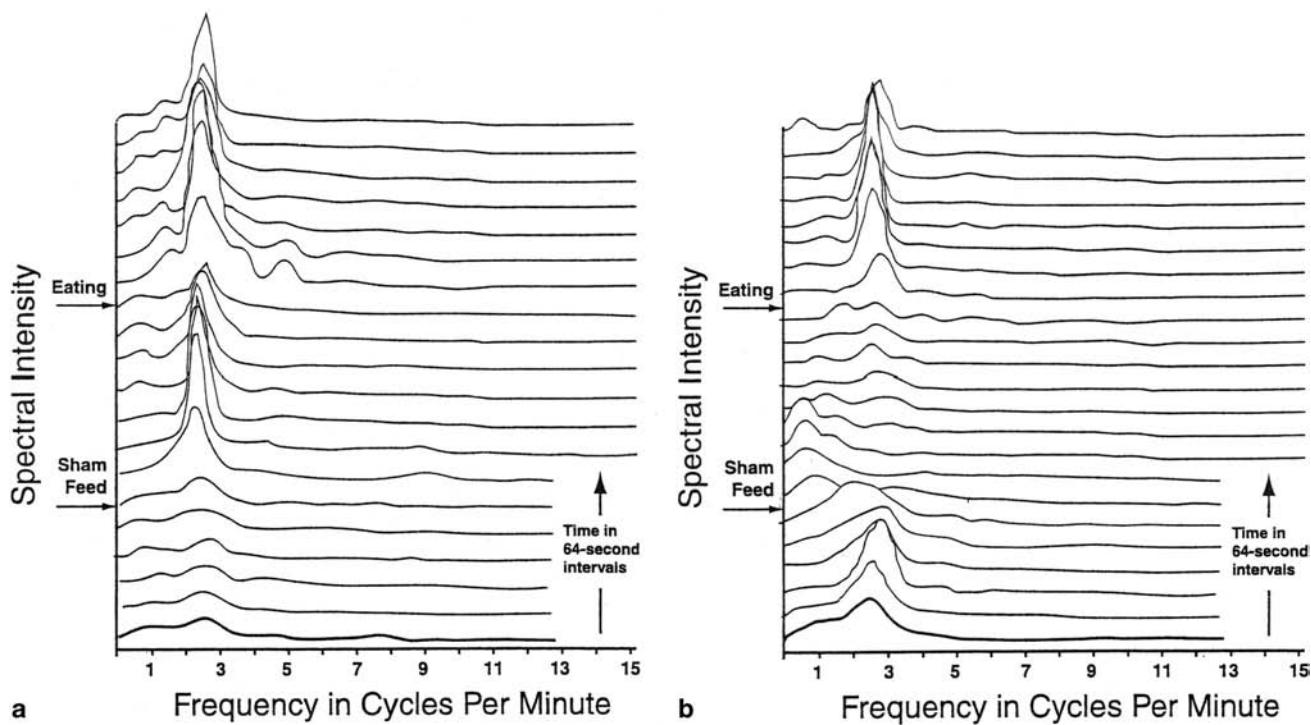

Figure 9.5. (A) Running spectral analysis of the EGG of a subject who reported that the experience of sham feeding was not disgusting. Note the low level of activity at approximately 2.5 cpm before sham feeding and the increase in power during sham feeding and during eating. (B) Running spectral analysis of the EGG from a subject who reported that the experience of sham feeding was disgusting. This subject showed power at approximately 2.8 cpm before sham feeding and a decrease during sham feed. The subject showed the typical increase in power during eating. (Reprinted with permission from Stern, Koch, and Muth (2000).)

some gastric phenomena occur intermittently and may not appear in a spectral plot. For most studies examining only the 3 cpm activity, this is not a problem because any segment of normal EGG is likely to contain a strong cyclical component. However, for phenomena such as tachygastria the issue is less clear. We have experienced no difficulty in quantifying this phenomenon through spectral analysis. When bursts of tachygastria are seen during motion sickness, they are typically one or more minutes in duration and are seen quite clearly in running spectral plots of 4-min epochs (Stern, Koch, Stewart, & Lindblad, 1987). However, there may indeed be more appropriate methods of analysis for quantification of very brief duration, intermittent phenomena lasting less than one minute (see for example, Höglz et al., 1985; Lin & Chen, 1994; and Moraes et al., 2003).

Once spectral power estimates have been calculated, data reduction is usually performed. The best method for reducing the EGG frequency and power data from an FFT is still unsettled. In most cases it will depend on the question to be answered and several methods have merit. No matter what analysis method is used, it is critical that quality raw recordings are obtained with high signal-to-noise ratio. In addition, data from healthy subjects during normal psychophysiological states should be recorded for comparison purposes.

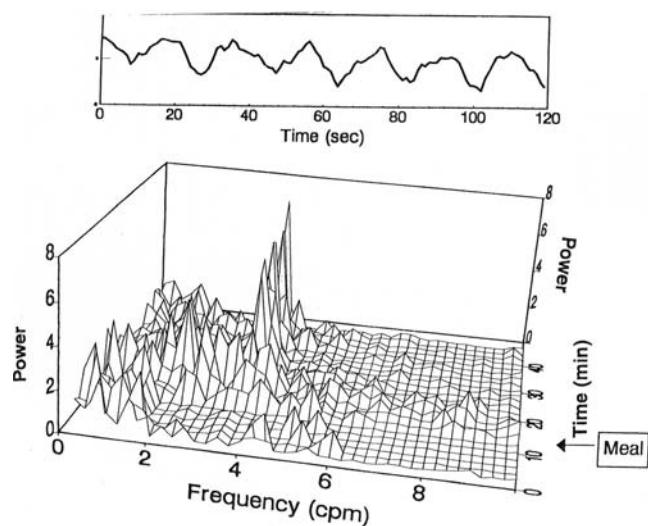

Figure 9.6. A representative raw electrogastrographic tracing (top) and spectral analysis plot (bottom) are shown for a pregnant woman with nausea before and after ingestion of a liquid protein-predominant meal. Postprandial raw signal exhibits a normal-appearing near-sinusoidal oscillation with a period of ~20 s. Spectral analysis reveals extensive dysrhythmic activity during fasting with peaks in both bradygastric and tachygastric frequency ranges. After meal ingestion, signal stabilizes with development of normal 3-cycles-per-minute (cpm) activity. (Reprinted with permission from Jednak et al. (1999).)

SPECIFIC MEASURES OF EGG ACTIVITY

1. Percentage distribution of electrogastrographic power in the four frequency bands of interest. The percentage distribution of EGG power in the four relevant frequency bands is the measure that the authors have found most useful in more than 25 years of experience in recording and analyzing EGGS in studies involving patients and healthy research participants (e.g., Stern, Koch, & Muth, 2000; Koch, 2002). The percentage distribution of total EGG power is calculated for each of the frequency bands of interest: bradygastria, normal 3 cpm, tachygastria, and duodenal/respiration. The power estimates for a given frequency range (e.g., the 1–2.5 bradygastria range) are obtained from the spectral analysis. The sum of the bradygastria power for a given time period is divided by the power for the entire frequency range (1–15 cpm) for the same time period and multiplied by 100%. Thus, the percentage distribution of all of the power from 1 to 15 cpm is determined for each of the four relevant frequency ranges: bradygastria, normal, tachygastria, and duodenal/respiration. The percentage of EGG power in the different frequency bands is altered by provocative stimuli such as the stress of doing mental arithmetic, the water load test, a caloric meal, or drug therapy. This measure should not be confused with percentage of time with the dominant frequency in the normal (or other) frequency bands, which is described next.

2. Percentage of time with the dominant frequency in the normal (or other) frequency band – This measure calculates the percentage of time (within a defined period) that the dominant EGG frequency (the specific frequency with the greatest power as determined by computer analysis) lies within a certain range of frequencies, such as 2–4 cpm (Chen & McCallum, 1994). An adaptive filter analysis of the EGG is first computed using 1 or 2 minutes of EGG data to construct each power spectrum. A spectrum is considered normal if the dominant (highest) peak lies in the 2- to 4-cpm range. The percentage of time that the highest peak is in the 2- to 4-cpm range is determined visually. Thus, if eight 1-minute spectra had the highest peak in the 2- to 4-cpm range in a 10-minute period, then the percentage of time the dominant frequency was in the normal range would be 80%. A limitation of this measure is that it ignores much of the data present in the EGG signal and focuses solely on the time that the dominant frequency is or is not within the frequency range of interest. For example, a 2-minute EGG signal with six 20-second sine waves or a 2-minute EGG signal with one large 20-second sine wave and a variety of other low amplitude waves spread out in frequencies other than 2 to 4 cpm would be labeled normal. This is why the percentage of time measure produces higher percentages of normal activity compared with the percentage distribution of EGG power, the technique described previously. Recall that the percentage distribution of EGG power compares the 3 cpm activity

present in the EGG signal with the activity in all frequencies from 1 to 15 cpm for a given period of time. Compared with that method, the percentage of time with the dominant frequency in the normal frequency band includes only a small, select portion of the total EGG data. Therefore, investigators who use this measure may arrive at erroneous conclusions about the effects of a drug or other therapy on EGG because of the selective nature of the data that are included in this measure. In addition, the percentage of time with the dominant frequency in the normal range is usually derived from an adaptative spectral analysis, not a Fourier spectral analysis, and therefore does not always accurately present the relative amplitude of the different frequencies that comprise the EGG signal.

3. Power ratio – The EGG activity in the frequency band of interest after a test or therapy is compared with EGG activity in that same frequency band during the baseline period. For example, a clinician might calculate the ratio of power in the normal range before and after treatment with a particular drug used to reduce nausea and use the ratio as a measure of improvement. However, an increase in EGG activity in all frequency bands may occur and would make interpretation of the specific ratio difficult.

4. Dominant frequency and stability of the dominant frequency – The dominant frequency is determined visually by identifying the frequency with the greatest power in the FTT or RSA during a specific time period. Frequencies can change even in healthy subjects. Note that a frequency dip to 1 to 2 cpm occurs briefly after a meal. Smout, Jebbink, and Samsom (1994) calculated various measures of stability of the dominant frequency and concluded that there is little evidence that either dominant frequency or the stability of the dominant frequency is physiologically related to gastric function.

Analysis of EGG recordings is based on the recording of high-quality EGG signals, review of the signal to identify any artifacts, and use of validated software for quantitative analysis of the EGG signal (for possible pitfalls see Ver Hagen et al., 1998. For greater details about the analysis of EGG recordings see Chapter 5 in Koch and Stern (2004).

INFERRENTIAL CONTEXT

Validation of the EGG

EGG and gastric myoelectric activity. Nelsen and Kohatsu (1968) simultaneously recorded the electrical activity from electrodes implanted on the serosal surface of the stomach and EGGS from 13 patients. They found an excellent correspondence between the frequency of the signals obtained from the EGG and the internal electrodes. They did not compare the amplitudes of the signals. A comparison of EGG and serosal recordings from dogs by Smout, van der

Schee, and Grashuis (1980b) indicated a perfect correspondence between the frequency of the signals.

In an effort to study the relationship of the EGG to internal electrical activity of the stomach without involving surgery, several investigators have compared the EGG to simultaneously recorded mucosal signals. The mucosal signals are obtained from swallowed electrodes (i.e., electrodes inside the stomach). Hamilton et al. (1986) compared EGG and mucosal signals from 20 human subjects during fasting, after ingesting milk, and in one case, during a period of spontaneous dysrhythmia. They summarized their findings as follows:

We did find that the surface recordings were of similar visual form as those obtained directly from the mucosa simultaneously. In addition, frequency analysis determined that the two simultaneously obtained signals were of the same frequency. Finally when the rare arrhythmic events occurred, they were detected in both the mucosal and cutaneous signals. Therefore, the signal obtained from the skin does seem to accurately reflect the BER as measured directly from the stomach mucosa. (p. 37)

Abell and Malagelada (1985) used magnetic force to maintain internal electrodes in opposition with the gastric wall and compared signals obtained from the mucosal electrodes with those obtained from the EGG. They also reported that frequency analysis showed very good correspondence between the internal and EGG signals. Mintchev, Otto and Bowes (1997) made simultaneous serosal and EGG recordings from dogs in whom they had created dysrhythmias by surgical means. They reported that the EGG could be used to detect severely abnormal gastric myoelectric activity 93% of the time, and mild abnormalities 74% of the time.

EGG and gastric motor activity

Until the mid-1960s investigators who used the EGG assumed that they were recording from the surface of the skin, voltage changes that were due to the contractions of the smooth muscle of the stomach; that is, they assumed a one-to-one relationship between the EGG and contractions of the stomach. However, in 1968 Nelsen and Kohatsu presented a different view of the source of the EGG signal. They stated that the EGG was a function of gastric slow-wave activity, or pacemaker potentials. Nelsen and Kohatsu and others have claimed that the surface-recorded EGG reflects the waxing and waning of pacemaker potentials of the stomach but not gastric contractions. However, they did present evidence that indicated that when contractions do occur, they are time locked to the slow wave and, therefore, to the EGG.

Beginning in 1975, Smallwood and his colleagues published a number of studies (e.g., Smallwood, 1978; Smallwood & Brown, 1983) in which they examined the frequency of the EGG and made numerous advances in techniques for analysis of the EGG signal. In some studies (e.g., Brown et al., 1975) they compared the EGG signal with

intragastric pressure recordings. Their findings were the same as those of Nelsen and Kohatsu (1968). When contractions occurred, they occurred at the same frequency as the EGG signals; and whereas the EGG showed 3 cpm almost continuously for most subjects, contractions as recorded with intragastric pressure instruments did not.

It should be noted that the simultaneous presence of 3-cpm EGG and the absence of changes in intragastric pressure does not necessarily indicate that the EGG is unrelated to contractions as Nelsen and Kohatsu (1968), Brown et al. (1975), and others have suggested. The possibility exists that the EGG is a more sensitive measure of gastric contractile activity than the pressure-sensitive probes. That is, the EGG may reflect increases in electrical activity (i.e., spike activity) during low-level contractile events that do not alter gastric intraluminal pressure. In fact, Vantrappen, Hostein, Janssens, Vanderweerd, and De Wever (1983) indicated that low-amplitude 5-cpm motor activity is always present in the dog. In addition, You and Chey (1984) have shown that in dogs the 5-cpm pacemaker potentials correlated well with low-amplitude contractions recorded by strain gauges sewn to serosa but correlated poorly with intraluminal pressure changes.

From 1980 to present, published reports have appeared that not only suggest that the EGG provides information about frequency of contractions but also, indeed, that the amplitude of the EGG is related to the degree of contractile activity (Smout, 1980; Smout, van der Schee, & Grashuis 1980a; Smout et al., 1980b). One of the major contributions of Smout and his colleagues was to point out that the amplitude of the EGG increases when a contraction occurs. They concluded that the pacemaker potential and the second potential, which is related to contractions, are reflected in the EGG. Abell, Tucker, and Malagelada (1985) conducted a study in which they compared the EGG signal from healthy human subjects with the electrical signal recorded from the mucosal surface of the stomach, and intraluminal pressure. They summarized their findings as follows: "Antral phasic pressure activity, when present, was accompanied by an increase in amplitude and/or a change in shape of both the internal and external EGG" (p. 86).

Koch and Stern (1985) reported a perfect correlation of EGG waves and peristaltic antral contractions observed during simultaneous EGG-fluoroscopy recordings in four healthy subjects. Hamilton et al. (1986) reported that fluoroscopy revealed contractions in the antrum that correlated with three- and fourfold increases in amplitude of the EGG. The relationship of the amplitude of EGG waves to contractions is complex and not totally understood at this time. However, in addition to the studies mentioned, there is considerable indirect evidence linking amplitude changes in the EGG with strength of contractile activity. For example, in situations where increased contractile activity would be expected (e.g., eating, after swallowing barium), EGG amplitude increases (Hamilton et al., 1986; Jones & Jones, 1985; Koch, Stewart, & Stern, 1987). And in patients with diabetic gastroparesis, where

one would expect weak contractile activity, Hamilton et al. (1986) found no increase in the amplitude of EGG after eating.

EGG amplitude alone cannot be used to infer reliably the presence or absence of GI contractions. It is possible that with improved methods of measuring contractile activity, we shall find that all myoelectric activity is accompanied by some contractile activity (see Morgan et al., 1978; Vantrappen et al., 1983; You & Chey, 1984) and that the amplitude of the EGG is related to its intensity or strength. A significant question then becomes: Can the amplitude of the EGG be used to determine whether the accompanying gastric contractile activity is of sufficient strength to do the motor work of the stomach (i.e., mixing and propelling)?

Several investigators (e.g., Bruley, Mizrahi, & Dubois, 1991; Dubois & Mizrahi, 1994) have examined the possibility of using the EGG as an indirect measure of gastric emptying. Chiloiro, Riezzo, Guerra, Reddy, and Giorgio (1994) simultaneously recorded gastric emptying using ultrasound and the power in the normal 3 cpm EGG from healthy subjects. The correlations ranged from 0.68 to 0.96. Other investigators (e.g., Chen, Richards, & McCallum, 1993) have demonstrated a negative relationship between the presence of dysrhythmias in the EGG and gastric emptying. And Bortolotti, Sarti, Barara, and Brunelli (1990) have demonstrated the presence of tachygastria in patients suffering from idiopathic gastroparesis, that is patients with severely delayed gastric emptying with no known cause.

In summary, the frequency of the EGG is identical to the frequency of gastric pacemaker potentials recorded from the mucosal or serosal surface of the stomach. There is, however, less general agreement as to the interpretation of the amplitude of the EGG. Indirect evidence from several studies has demonstrated that amplitude increases during an increase in contractile activity, but the amplitude of the EGG alone cannot be used to determine the presence or absence of contractions.

Applications of EGG recording

Some of the applications of EGG recording that have been described in the psychological literature that will be described below include eating, sham feeding, stress and anxiety, motion sickness and nausea, and monitoring the effects of gastric electrical stimulation.

Eating

A number of investigators have reported effects of nutrient meals on EGG patterns. Yogurt or pancake meals increase the amplitude of the 3 cpm EGG wave as one would expect, because the presence of food in the stomach is the natural stimulus for it to contract (Geldof et al., 1986). Initially, the increase in amplitude occurs at a slower frequency, 2.2–2.5 cpm, a so-called frequency dip; after approximately 10–15 minutes, the EGG frequency gradually shifts back to the

3 cpm range. Smout, van der Schee, and Grashuis (1980b) and Jones and Jones (1985) have reported finding similar increases in the amplitude of the 3 cpm EGG following eating. Ingestion of whole milk has also been shown to increase the amplitude of 3 cpm EGG waves (Hamilton et al., 1986). A technetium-labeled omelet meal evokes a complex series of events including increased 3 cpm waves in the first 15 minutes after ingestion, followed by an increase in the 1–2 cpm EGG activity during the linear phase of gastric emptying (Koch, Stern, Bingaman, & Eggli, 1991). Uijtdehaage, Stern, and Koch (1992) reported that eating a small breakfast not only increased the power of normal 3 cpm EGG, but also increased respiratory sinus arrhythmia, a measure of parasympathetic nervous system activity, and inhibited motion sickness symptoms. Non-nutrient meals such as water loads also stimulate 3 cpm waves of increased amplitude and a brief frequency dip (Koch & Stern, 1993; Koch, Hong, & Xu, 2000). Koch et al. (1993) reported successfully recording the EGG from premature and term infants. Riezzo et al. (2003) reported that breast-fed newborn healthy babies show adult-like normal 3 cpm gastric activity after nursing, but formula-fed newborns do not.

Chen, Davenport, and McCallum (1993) investigated the effect of a fat preload on gastric myoelectric activity in healthy humans using EGG. They reported that fat preload significantly decreased the postprandial 3 cpm EGG amplitude, implying a decrease in gastric contractility. In a related study, Chen, Lin, Parolisi, and McCallum (1995) looked at the effect of cholecystokinin (CCK) on postprandial gastric myoelectric activity. It is generally accepted that CCK released endogenously by a meal delays gastric emptying and inhibits additional eating. Chen et al. (1995) found that CCK given at a physiological concentration significantly decreased postprandial EGG amplitude, as did a fat preload, but did not affect the frequency or regularity of the EGG.

Do patients with anorexia nervosa or unexplained nausea and vomiting respond with an increase in the amplitude of their 3 cpm EGG following the eating of pleasant food? Abell, Lucas, Brown, and Malagelada (1985) have reported that several of their anorexic subjects failed to show an increase in amplitude of their 3 cpm EGG following eating and some showed tachygastria (4–9 cpm). Geldof, van der Schee, Blankenstein, and Grashuis (1983) found that 49% of their patients with unexplained nausea and vomiting showed tachygastria and the absence of the normal increase in amplitude of the EGG after eating. Diamanti et al. (2003) found that adolescent patients with bulimia displayed abnormal gastric activity, but patients with anorexia did not. The authors suggest that one possible explanation is the fact that the anorectic patients used in this study had a shorter disorder duration than the bulimic patients. Ogawa et al. (2004) recorded the EGG from 36 eating disorder patients following the water load test. The percentage of normal 3 cpm gastric activity was significantly less for the eating disorder patients

(44%) than controls (74%). The authors state the following pointing out the difficulty of determining which came first, the abnormal gastric activity or the eating disorder:

In conclusion it is suggested that longstanding abnormal eating in patients with eating disorders may induce disturbances to gastric motor function, resulting in abnormal, eating-related behavior, a form of a symptomatic vicious circle. The EGG may be a promising method for determining the pathophysiology of eating disorders and for developing effective therapeutic approaches. (p. 301)

Sham feeding

Stern, Crawford, Stewart, Vasey, and Koch (1989) used a sham feeding procedure to examine the cephalic-vagal reflex, a response that was mentioned in the introduction to this chapter. Previous research by several authors had shown that food or even the presence of non-nutritive substances in the stomach stimulate an increase in the amplitude of the 3 cpm EGG. The question asked by Stern et al. was whether the sight, smell, and taste of food would do the same thing to the EGG. Following a 15-min baseline period, subjects were required to chew and expectorate a hotdog and roll. After another baseline period, subjects were given a second hotdog to eat normally. The effect on the EGG of eating the hotdog was as expected, a large increase in the amplitude of the 3 cpm EGG wave that lasted several minutes. The effect on the EGG of sham feeding was an equally large but short-lasting increase in the amplitude of the EGG as can be seen in Figure 9.5A. Figure 9.5A depicts the data for one subject in the form of a running spectral analysis. EGG frequency is plotted on the X axis, time is plotted on the Y axis going from the bottom to the top of the figure, and power or spectral intensity is the third dimension. It was of interest to note that two subjects who reported after the session that the experience of chewing and expectorating the hotdog was disgusting showed a decrease rather than an increase in the amplitude of their EGG during sham feeding (see Figure 9.5B).

Following this serendipitous finding, we (Stern, Jokerst, Levine, & Koch, 2001) conducted another study in which one group of subjects was given pleasant food, a cooked hot dog, to chew and spit, and a second group was given an unpleasant food, an uncooked tofu dog, to chew and spit. The hot dog group showed a significant increase in 3 cpm activity and the tofu group did not. This result supported our initial finding that the cephalic-vagal reflex, as measured by the power in the EGG 3 cpm, depends on the subjective palatability of the food. We think that this is a good example of the sensitivity of the EGG to cognitive processing.

Stress and anxiety

The GI system may be conceptualized as a buffer between an individual and his/her environment. When extra energy

is needed for fight or flight, the GI system slows down or shuts down. Anxieties and worries also slow down the GI system. In terms of the activity of the autonomic nervous system – one of the pathways for communication between the brain and the GI system – fight, flight, anxiety, and worry are all usually associated with an increase in activity in the sympathetic branch (SNS) of the autonomic nervous system. And numerous studies have shown that an increase in activity in SNS activity decreases stomach activity. Increases in activity in the parasympathetic branch (PNS) of the autonomic nervous system increase normal stomach activity. The cephalic-vagal reflex, described above, is an example of this relationship. A complication, however, is that not a lot is known about the changes in PNS activity that are associated with different psychological states for different people, or the relationship between SNS and PNS activity. For a discussion of this most important issue see Berntson, Cacioppo, Binkley, Uchino, Quigley, and Fieldstone (1994). As can be seen in the examples that follow, in a particular stress situation, some individuals might show an increase in SNS and little change in PNS, or even an increase in PNS activity, whereas in a different stress situation some individuals might show an increase in SNS activity and a decrease in PNS activity. Note that the normal functioning of the GI system is not crucial for momentary survival, as is the case with the cardiovascular system. Wide swings in functioning of the GI system have been documented, and these extreme responses may be perceived by some individuals as GI symptoms.

As stated earlier in this chapter, the area of brain-gut interaction has a long history, going back to Beaumont (1833), but a short past in that little work has followed up on the very early studies. In the case of autonomic-GI interactions, a relatively recent study has set the stage for applying EGG findings to clinical work (Muth, Koch, & Stern, 2000). This study examined the EGG and ANS activity in people suffering from functional dyspepsia. Functional dyspepsia is a gastrointestinal disorder characterized by a symptom cluster that often includes nausea, pain, bloating and/or early satiety after eating, with no organic findings that explain the symptoms (e.g., the presence of an ulcer). A comparison of gastric emptying, gastric myoelectrical activity, symptoms, and psychological factors separated participants into two groups: SNS reactive and PNS rigid. The SNS reactive had more ANS variability, higher sympathetic activity, more cardiac reactivity, and higher scores of neuroticism. The PNS rigid group had more PNS activity, lower ANS variability, and more abnormal EGG tests that indicated gastric myoelectrical abnormalities. These findings seem to point to a brain-gut explanation to the symptoms in these patients. In one sub-group it appears that psychological causes may be at the root of the problem and the individuals are perhaps hypersensitive or vigilant to conditions when the GI system is functioning at the extreme; and these extremes may get internalized as symptoms for these patients. In the other sub-group, it appears that autonomic dysfunction may cause symptoms

by affecting the electrical activity of the stomach directly as indexed by the EGG. Research needs to be done to explore further these hypotheses, but this research is an example of the use of EGG to gain a better understanding of how stress affects the GI system.

Stressors can be classified as either primary physiological or primary psychological in nature. Changes in the EGG have been examined in relationship to both types of stressors. Physiological stressors seem to yield relatively consistent effects on the EGG, but psychological stressors sometimes do not.

Muth, Thayer, Stern, Friedman, and Drake (1998) studied the effect on the EGG of two tasks, reaction time/shock avoidance, and cold face stress. As expected, the RT task produced shorter cardiac IBIs than baseline, and placing a cool bag of water on the face produced longer IBIs than baseline. These manipulation checks supported the experimenters' assumption that the RT task would increase SNS activity whereas the cold face stress would increase PNS. Analyses of the EGG data indicated that there was significantly greater normal 3 cpm activity during the cold face stress than during the RT task. And there was greater tachygastria during RT than during the cold face stress. These findings are in agreement with the results of motion sickness studies (see below) that have shown that increased PNS activity increases 3 cpm EGG activity and decreases symptoms of motion sickness. On the other hand, subjects who experience motion sickness show an increase in SNS activity, a decrease in PNS activity, and tachygastria (e.g., Stern & Koch, 1994) as well as delays in oral-cecal transit time (Muth, Stern, & Koch, 1996).

Stern, Vasey, Hu, and Koch (1991) examined the effects of another stressor, the cold pressor test on EGG activity. The procedure used was similar to that used by Thompson, Richelson, and Malagelada (1982), who reported a significant decrease in gastric emptying as a response to cold stress. In our experiment, subjects who had recently eaten were asked to put their hand into a container of ice water (4°C) for 1 min, take it out for 15 s, put it back for 1 min, and so on, for a total of 20 min. The results were similar to those reported by Stewart (unpublished) for the effects of the Stroop stress test and are what would be predicted by the gastric emptying results of Thompson et al. (1982). There was a significant attenuation of EGG 3 cpm activity starting at the point in time when the subject put his/her hand into the ice water. Tachygastria was not seen as a response to the cold pressor test, a procedure that induces pain but not nausea.

The results of two additional studies reporting the effects of psychological stressors on the EGG have been inconsistent. Baldaro et al. (2001), who used viewing an unpleasant film as a stressor, and Riezzo et al. (1996), who used the Stroop color-word test as a stressor, failed to find a difference in EGG activity between their stressor group and a control group. In the absence of detailed information about the EGG equipment and analysis programs used in these studies, we assume that the lack of a significant dif-

ferences in the EGG was a function of the nature of the psychological stressors used in these two studies.

Gianaros et al. (2001) in a two-part study, presented subjects with two laboratory stressors: speech preparation and isometric handgrip and measured ANS and EGG responses. As expected the stressful tasks produced tachygastria, and increases in SNS activity and decreases in PNS activity. In the second part of the study, the same subjects were exposed to a rotating optokinetic drum. The results demonstrated that the extent of decrease in PNS activity to the laboratory stressors in the first part of the study predicted motion sickness susceptibility. Further these data show that both physiological and psychological stressors can affect stomach electrical activity and the EGG.

We consider the EGG to be a valuable noninvasive instrument to study the effects of stress on the GI system, especially considering the fact that the measure itself evokes no stress, and does not interfere with the activity of the stomach. A better understanding of the effects of stress on the GI system could result from the use of the EGG to study brain-stomach relationships in functional GI disorders such as functional dyspepsia, as described above.

Motion sickness and nausea

During the past 25 years, we have been using a rotating optokinetic drum to produce nausea and other symptoms of motion sickness in healthy subjects and recording EGG and other physiological measures. In the first experiment that attempted to relate changes in gastric myoelectric activity to the development of symptoms of motion sickness, Stern, Koch, Leibowitz, Lindblad, Shupert, and Stewart (1985) obtained EGGs from 21 healthy human subjects who were seated within an optokinetic drum, the rotation of which producedvection (illusory self-motion). Fourteen subjects developed symptoms of motion sickness duringvection, and in each the EGG frequency shifted from the normal 3 cpm, to 4–9 cpm, tachygastria. In six of seven asymptomatic subjects, the 3-cpm EGG pattern was unchanged duringvection. It was concluded that the sensory mismatch created by the illusory self-motion produced tachygastria and symptoms of motion sickness in susceptible subjects. In a follow-up study (Stern, Koch, Stewart, & Lindblad, 1987), 15 healthy subjects were exposed to the rotation of the same drum. Ten subjects showed a shift of the dominant frequency of their EGG from normal to tachygastria, during drum rotation and reported symptoms of motion sickness. A comparison of running spectral analyses and symptom reports revealed a close correspondence over time between tachygastria and the development of symptoms of motion sickness.

It is important to note that during tachygastria, gastric motility decreases or even completely shuts down, and one of the most common symptoms of motion sickness is nausea. It is of interest to note that Wolf (1943) showed many years ago that stressful situations, including putting cold

water in one ear, swinging, rotation of the head, situations involving fear, inhibited gastric contractile activity, and provoked nausea. The advantage of our current use of the EGG in similar studies is that it is noninvasive; Wolf's subjects had a balloon positioned in their stomach to record gastric pressure changes. Wolf grappled with a problem inherent in all studies that relate some bodily change to a sensation, in his case the relationship of inhibited gastric motor activity to the sensation of nausea. To what extent is the altered bodily change essential to the occurrence of the sensation? In a series of ingenious experiments, unfortunately with only three subjects, Wolf gave his subjects a combination of two drugs that prevented the inhibition of gastric motor activity, exposed the subjects to the stress situations that had previously provoked nausea, and found that no nausea was reported. Wolf (1943) concluded as follows: "The fact that nausea may be prevented, despite strong nauseating stimuli, by controlling with drugs the pattern of gastric motility indicates that gastric relaxation and hypomotility are essential to the occurrence of nausea" (p. 882).

In our labs, 50% percent of healthy European-American and African-American subjects and 80–90% of Asian and Asian-American subjects developed tachygastria and got motion sick while sitting inside a rotating optokinetic drum. We have been studying this differential susceptibility to motion sickness for over 25 years and published a review article summarizing our results (Stern & Koch, 1996).

In a study not of the nausea of motion sickness, but rather of the nausea of the first trimester of pregnancy, Jednak et al. (1999) reported that a high protein meal decreased nausea significantly better than a high carbohydrate meal (see Figure 9.6). Levine et al (2004) followed this study with a motion sickness study and demonstrated that a high protein meal consumed prior to exposure to a rotating drum decreased tachygastria and the symptoms of motion sickness.

To summarize our findings with regard to the relationship of EGG activity to nausea, any manipulation that increases PNS and normal 3 cpm EGG activity, such as eating, deep breathing, gastric electrical stimulation, or biofeedback, decreases nausea.

Monitoring the effects of gastric electrical stimulation (GES)

An exciting new area of GI research involves gastric electrical stimulation to either strengthen normal 3 cpm activity in, for example, gastroparetic patients refractory to medical treatment, or to disrupt normal gastric activity in an effort to reduce appetite in obese patients. In either model EGG recording is essential to determine if the stimulation is having the desired effect on the stomach. The two areas that require considerable additional research are as follows: (a) the characteristics of the electrical signal, and the time of stimulation (e.g., continuous, when fed, when the

patient shows gastric dysrhythmias); and (b) diagnostic criteria that indicate which patients will benefit from GES, and the characteristics of the electrical signal for optimal improvement of the symptoms of different patients.

The following quote from a noted gastroenterologist that appeared in the *American Journal of Gastroenterology* sums up our opinion of the status of GES in 2004:

...neural electrical gastric stimulation, consists of a microprocessor-controlled sequential activation of a series of annular electrodes which encircle the distal two thirds of the stomach and induce propagated contractions causing a forceful emptying of the gastric contents. This method is the most promising, but it has so far only been tested in animals and would need to be tested in patients with gastroparesis before it can be used as a solution for this disease. (Bortolotti, 2002, p. 1874)

OTHER NONINVASIVE GASTROINTESTINAL MEASURES OF INTEREST TO PSYCHOPHYSIOLOGISTS

The goal of this section is to introduce briefly two additional measures of GI activity, gastric emptying time and oral-cecal transit time. Both of these measures of GI motor activity can be measured noninvasively and complement the electrical-based EGG measure.

Gastric emptying

The two most common indicators of gastric emptying are the lag phase, referred to as T_{lag} , and the half emptying time, referred to as $T_{1/2}$. The lag phase of gastric emptying is the amount of time it takes for food to begin to empty from the stomach to the small intestine. The half emptying time is the amount of time it takes for half of the test meal to empty from the stomach. Both of these measures include the time it takes for the meal to get from the mouth to the stomach, which is usually considered negligible and ignored. The classic method of measuring gastric emptying involves having the subject ingest radio-isotope-labeled scrambled eggs and using a procedure called scintigraphy tracking the meal. However, a breath test method (Ghoos et al., 1993) has been developed for deriving gastric emptying data, and commercial devices are beginning to appear on the market that are relatively easy to use by a nonmedical person to derive these measures.

The breath test method of measuring gastric emptying involves having an individual ingest a test meal, such as 100 mg of sodium octanoate (also known as caprylic acid), that is not broken down and absorbed in the stomach, but rather in the small intestine (see Figure 9.7). The sodium octanoate is modified such that instead of containing carbon-12 or radio-active carbon-14, it contains carbon-13. As the labeled meal passes from the stomach into the small intestine, the sodium octanoate is broken down by the small intestine. The carbon-13 is then absorbed in the bloodstream as carbon dioxide, eventually

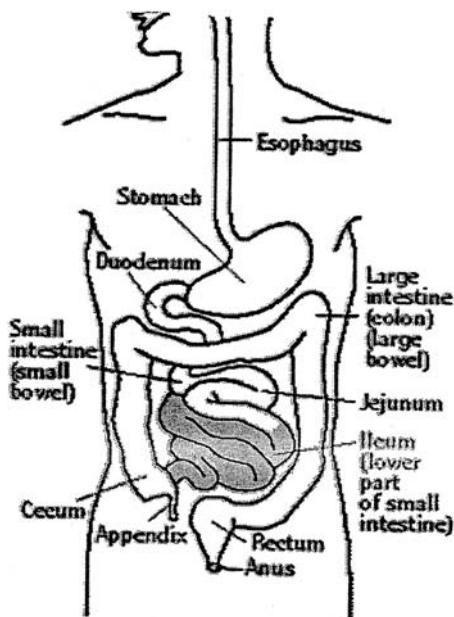

Figure 9.7. This figure shows the general anatomy of the gastrointestinal (GI) tract. The duodenum is the beginning of the small intestine where sodium-octanoate is broken down and absorbed. Oral-cecal transit time is the time it takes for a meal to pass from the mouth to the junction between the large and small intestine called the cecum.

flows to the lungs and is exhaled in the breath. An infrared spectrometer is then used to compare the ratio of carbon-12 to carbon-13 in the exhaled breath. As the ratio changes in the favor of more carbon-13 it is an indicator that the test meal is being emptied from the stomach. Procedures have been developed to derive T_{lag} and $T_{1/2}$ times from the breath samples over time (Ghoos et al., 1993). Several companies have incorporated these procedures into relatively easy to use, albeit expensive, devices. However, this procedure can be performed providing you have an adequate breath collection system and a way to sample the carbon-12/carbon-13 ratio with an infrared spectrometer which is often available in a university chemistry laboratory.

Oral-cecal transit time

Oral-cecal transit time (OCTT) refers to the time it takes for a meal to travel from the mouth to the junction between the small and large intestine called the cecum (see Figure 9.7). Breath testing procedures for deriving OCTT are well established (Sciarretta et al., 1994; Read et al., 1984). The procedure is very similar to the breath testing for gastric emptying. In the case of OCTT, a nonabsorbable carbohydrate such as 10 g lactulose is added to a test meal and ingested. The lactulose passes through the stomach and small intestine and is not broken down until it passes into the large intestine. The digestion process releases hydrogen into the blood stream that reaches and is exhaled by the lungs. By measuring breath hydrogen production using a gas chromatograph, OCTT is indicated as the time from meal ingestion to a peak in breath hydrogen. Again, sev-

eral companies produce commercial devices specifically for measuring breath hydrogen as part of breath testing procedures. However, as with the gastric emptying tests, if one has access to a gas chromatograph and adequate breath collection devices, it is possible to perform this test without further specialized equipment.

It is important to note that if both gastric emptying measures and OCTT are collected simultaneously on the same test meal, a third measure can be derived. That measure is small bowel transit time (SBTT). SBTT is the time for the meal to travel through the small intestine. It can be derived by subtracting T_{lag} from OCTT.

Research in the authors' laboratories has shown that both psychological stressors (Muth, Koch, Stern, and Thayer, 1999) and physiological stressors (Muth, Stern, and Koch, 1996) can affect these GI measures. It is currently unknown if different stressors affect the GI system differently and if different parts of the GI system (i.e., stomach and small intestine) respond to stress differently. Psychophysologists can now do research in the area of stress effects on the GI system using the noninvasive EGG method coupled with other noninvasive measures of GI neuromuscular activity.

EPILOGUE

Unanswered questions

Why do many people complain of GI symptoms when they are under stress? We take a functionalist position on this question and, as we stated earlier, think that the GI system acts as a buffer or special response system between the organism and the environment. When extra energy is needed for fighting with or fleeing from a saber-toothed tiger, for example, the GI system shuts down. In our labs and in others, the EGG has been used to document and quantify the shutting down of the stomach. Two distinct patterns of EGG activity have been identified which are associated with a decrease in normal neuromuscular activity of the stomach: a flat line (the absence of cyclic myoelectrical activity), and tachygastria. We know that tachygastria is associated with the experience of nausea, but we don't know much about the association of the absence of cyclic activity in the EGG and GI symptoms. This is an unexplored area. Perhaps symptoms are only experienced after the passage of a certain period of time. Or, perhaps unpleasant symptoms are only experienced if one eats while one's stomach is shut down.

We know that eating or thinking about eating pleasant food increases the amplitude of normal 3 cpm activity in the EGG of healthy subjects. Disgusting food does not have this effect. These studies raise important methodological questions that have not been systematically studied. For example, how fast does gastric myoelectric activity, as measured with EGG, change? That is, can we expect to see a measurable change in the EGG following the presentation of a brief discrete stimulus? Or, how long would a given

stimulus have to be presented before we would expect to see a change in the EGG? In general, we think of the GI system as being slow responding compared to other biological systems because momentary adjustments in activity are not essential to survival, but data on this issue are lacking. And how should one interpret abnormal EGGs recorded from a patient with an eating disorder? Is the abnormal EGG just a result of abnormal eating, or is it contributing to the behavior? We don't know. It is possible that in some cases abnormal gastric activity was a part of the individual's pathology, but as time passed, the abnormal eating caused the gastric activity to worsen and a vicious cycle was created.

Future directions

The EGG, because of its noninvasive nature, will continue to aid basic researchers in their quest for additional information about gastric myoelectric activity, gastric neuromuscular activity, and their relationship in normal and pathophysiological conditions.

Applied research using the EGG by gastroenterologists is increasing rapidly largely due to the ease and reliability of its use in detecting gastric dysrhythmias and the recently established relationship between gastric dysrhythmias and upper GI disorders including delayed gastric emptying, nausea, and dyspepsia. Pharmaceutical companies have supported much of this research, and we anticipate that this will continue. Many disorders, such as diabetic gastroparesis, are marked by abnormal EGG recordings, and studies of the degree to which EGG normalization accompanies improvement in symptoms are likely to provide new insights into the complex relationship between gastric myoelectric activity and the pathophysiology of these disorders.

A related exciting new area that requires EGG recording in order to assess results of therapeutic interventions is gastric electrical stimulation of the stomach (GES). As described above, studies are currently in progress using GES to both strengthen normal 3 cpm activity in patients with nausea and/or delayed gastric emptying, and to disrupt normal 3 cpm activity in obese patients in an effort to decrease appetite. Another area of research that we are engaged in is biofeedback of EGG for individuals with gastric dysrhythmias in an effort to restore normal 3 cpm activity, and thereby, relieve nausea. In a recent study (Stern et al., 2004), we demonstrated that healthy people can increase their normal 3 cpm activity with biofeedback. Future studies should explore both the sub-group(s) of nausea patients who might benefit from the procedure, and the most efficacious procedure.

EGG recording may also prove to be of value in the study of eating disorders. A potential application of our finding, described above, that sham feeding of disgusting food is not accompanied by an increase in normal 3 cpm EGG activity is to use the EGG response to the sham feeding of pleasant food to track the progress during therapy of

individuals with eating disorders. Assuming that subjects with certain types of eating disorders cognitively appraise eating as less than pleasant, we would expect them, therefore, not to show an increase in EGG 3 cpm activity during sham feeding. Quantification of the cephalic-vagal reflex, as measured by the EGG 3 cpm activity, might provide a more valid measure of recovery than weight gain or the judgment of the therapist.

The increase in the use of the EGG by gastroenterologists has brought with it refinements in both hardware and software, including ambulatory units that have flown on NASA Shuttle flights. We predict that with the availability of this new equipment additional psychophysiolists will soon be using the EGG as a noninvasive window into the complex brain-stomach relationship that was first brought to the attention of GI researchers and clinicians by Beaumont's description of changes in the stomach activity of his fistulated subject in 1833.

10 The Respiratory System

TYLER S. LORIG

1. INTRODUCTION

Often overlooked in psychophysiology, the respiratory system is remarkably complicated and sensitive to a variety of psychological variables. Scientists have examined this system since the time of Galen and even before (Sternbach et al., 2001).

Over the intervening years some have argued for what has perhaps been an overly influential role for respiration. Feleky (1916) argued that the ratio between inspiration and expiration was intimately connected to psychological state and personality. Nielsen and Roth (1929) reviewed more than 20,000 spirometry records and identified ten breathing patterns that they argued were associated with the heritability of some traits. Sutherland, Wolf, and Kennedy (1938) stated the “respiratory curve is as constant and characteristic of an individual as his handwriting” and suggest that it is closely related to personality. Although few recent studies have sought to connect personality and respiration, it is clear that some individuals possess common respiratory patterns. This has led some to establish categories for these respiratory types or the “*personalité ventalitoire*” (Shea & Guz, 1992).

More often than overestimating respiration’s role in psychophysiology, this process is often ignored. In psychophysiology, respiration has been far overshadowed by research on the heart, brain, and electrodermal activity (Harver & Lorig, 2000). Wientjes and Grossman (1998) have effectively argued that it is respiration’s susceptibility to voluntary influences that led early psychophysologists to look elsewhere for physiological phenomena to study.

When respiration has been recorded, it is most often done to account for artifacts in other measures of more interest to the investigator (Grossman, 1983). Because of the coupling between breathing and cardiac output, heart rate changes as a function of the respiratory cycle. This phenomenon is called respiratory sinus arrhythmia (RSA) and for those interested in the cardiovascular system, it makes respiration an intervening variable. In fact, the degree of dissociation between heart rate and respiration has become of great interest in recent years since the “tight-

ness” of this coupling can be viewed as an index of the vagal control of the heart (Berntson, Cacioppo, & Quigley, 1993). In addition to influencing cardiac activity, respiration can be a potent source of noise in electrodermal recordings as well (Rittweger, Lambertz, & Langhorst, 1997).

Part of the problem associated with measuring respiration in psychophysiology is that our needs are often so different from those of respiratory medicine. The past decade has provided tremendous advances in data and approaches related to respiratory health. Medical approaches to respiration are direct. They have been systematic and a number of standards exist for making lung function measurements (Evans & Scanlon, 2003). Almost all measurements of lung function in medical settings are made using spirometry. Even though this can be a very valuable technique in psychophysiology, many research questions limit the use of this approach. During a spirometric evaluation, the patient is usually nose clipped and breathes through a tube placed into the mouth. Though not invasive in the typically sense, it is psychologically invasive because it often centers the patient or subject’s attention on the process of respiration (Han et al., 1997). In a medical setting, a technician making the recording encourages the patient to exhale even after the person feels their lungs fully exhausted. Certainly, this type of subject-experimenter interaction is foreign to most psychophysiological laboratories. Research questions seeking to relate cognition or emotional change to respiration must take a somewhat different approach and often use continuous measurements such as thoracic distention, pressure, or temperature as dependent variables while the tasks of interest are performed. These measurements provide less precise information about respiratory volume than spirometric approaches and don’t often provide information about blood gasses. Even so, they may be preferred in some situations because they do not invade the psychological dimensions of the task. Carefully habituating subjects to spirographic evaluation can also be accomplished (Ritz, 2004) but requires great care and tasks that demand attention from subjects.

Few would argue that respiration’s primary function is gas exchange. Oxygen is delivered to the blood stream

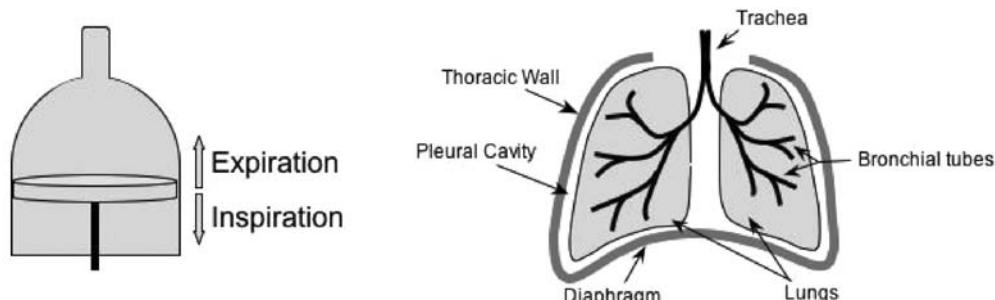

Figure 10.1. The left panel illustrates the principle by which the lungs operate. As the piston or diaphragm moves down, the pressure inside the vessel is reduced and air flows in to equalize the pressure. The right panel illustrates the placement of the lungs and diaphragm in the thoracic cavity.

and carbon dioxide is removed by the actions of this system. Certainly the literature in medicine has emphasized this role and much research has been conducted to evaluate chemosensory receptors in the wall of blood vessels, absorption of oxygen into the blood, integrity of the lungs and alveoli, and many other portions of this system (Comroe, 1974). For psychophysologists however, gas exchange is but one of several important functions. The respiratory system also acts to modulate the air necessary for speech, the pressure necessary to bring odors to the olfactory mucosa, and it anticipates the metabolic demands of cognitive and muscular activity (Collet et al., 1999). Furthermore, the interaction of this system with cardiac and other autonomic systems is a remarkable illustration of the functional complexity and cross-system integration of the nervous system.

Respiration is important in a number of illnesses of interest to psychologists such as asthma, which is widely studied for its psychological dimensions. From a respiratory perspective, it is associated with increased respiratory resistance or reduced airflow (Ritz, 2004). Persons experiencing an asthma attack must exert more effort to inhale because of narrowed air passages. This increased ventilatory effort is, in itself, a cue for breathing difficulty and may serve to provide positive feedback exacerbating respiratory difficulty (Harver & Mahler, 1998).

At its essence, the respiratory system is mechanical. Muscles control the filling of air sacks and these sacks are, in turn, connected to the outside world through air passages. Figure 10.1 illustrates the similarity of this system to a piston. The left panel of the figure shows a piston in a bottle. Movement of the piston is analogous to the contraction of the diaphragm. When the diaphragm contracts, the piston moves down, it creates an area of low pressure that causes air to flow into the bottle or lungs. The right panel of the figure illustrates the schematic nature of the mechanical system. Integrity of the air passages, sacks, and muscles all influence the system because it is controlled through multiple feedback loops. As an example, diminished air intake in one inhalation leads to subsequent increases in muscle activity producing increasing lung expansion and airflow. If resistance is increased in the system, volume will be decreased even though rate of flow

is high in just the same way that a nozzle on water hose increases the speed of the water but decreases the volume. The mechanical nature of this system belies its complexity. Because respiration is an essential component of life, it broadly influences activity in other systems. Similarly, it is mutually dependent on many other systems in the body for its regulation.

2. NEURAL CONTROL

The fact that breathing “is a truly strange phenomena of life caught midway between the conscious and unconscious” (Richards, 1953) is only suggestive of the system’s diverse sources of regulation. Clearly, breathing is under voluntary control and just as clearly, it is not. Under ideal conditions, respiratory activity is a harmonious product of both sources of control. This harmony may breakdown in cases of pathology or under periods of stress to the system.

2.1. Autonomic control of respiration

Like most muscles systems, respiration depends upon feedback loops for its regulation. This feedback arises from a large number of receptor types including mechanoreceptors and chemoreceptors. In the case of the respiratory system, receptors in the walls of the airways (slowly adapting receptors – SARs) increase their activity in response to stretch associated with the volume of inhaled air (Hlastala & Berger, 1996). SARs provide negative feedback to the system via the vagus nerve. The action of these receptors is responsible for the Hering-Breuer reflex, a lengthening of the exhalatory phase of the cycle in response to distention of the airway wall.

In addition to SARs, Rapidly Adapting Receptors also influence the system by way of the vagus. These receptors are found on the epithelium of the airways and are responsive to both mechanical and chemosensory irritation. Activity in these receptors results in reflexive coughing (Hlastala & Berger, 1996). Particulates in the air and some chemicals such as chlorine activate these receptors which are more dense in the upper airways. This system is distinct from the trigeminally based irritation sensors in the nasal cavity and mouth.

Feedback to the respiratory system is also influenced by chemoreceptors in the arterial system. These receptors are found in a variety of arteries but those most influential to regulation of the respiratory system are the carotid bodies that are found in the carotid arteries. A second and slightly less influential set of chemoreceptors, the aortic bodies, is found in the wall of the aorta. Both the carotid and aortic bodies communicate with the central nervous system by way of the glossopharyngeal nerve. Receptors in both structures are sensitive to circulating levels of blood gases including oxygen and carbon dioxide and also blood pH (Hlastala & Berger, 1996). Because of the extreme vascularity of the carotid bodies in particular, even small reductions in oxygen lead to increased activity in the receptors. Similarly, activity in the nerve is also increased when CO₂ is abundant. These changes in blood gas increase activity in the nerve and subsequently the muscles of respiration. Through this mechanism, hypoxic events lead to increased ventilatory effort often including prolonged inhalation and gasping (Fung & St. John, 1995).

The arterial system is just one source for chemosensory regulation of breathing. There are also centrally located receptors sensitive to oxygen, CO₂, and pH in cerebrospinal fluid. Research by Harada et al. (1985) has demonstrated that perfusion of a rat brain *in vitro* leads to with increased levels of CO₂ or decreased O₂ leads to increased phrenic nerve output. This nerve is responsible for the contraction of the diaphragm. Hlastala and Berger (1996) review these data and propose two distinct areas or chemoreceptive zones. Both zones are on the ventral surface of the medulla with the larger zone at the level of the VIIIth nerve and the other is more caudal and closer to the midline.

Central mechanisms coordinate the input from these mechano and chemoreceptors and generate output to control the muscle groups associated with breathing. Several different areas of the brain contribute to the automatic regulation of the system and these areas differ from those used in voluntary control. As an example of this differential regulation, individuals afflicted with Ondine-Curse syndrome selectively lose the ability to automatically regulate breathing but are able to breathe by voluntary effort. This syndrome can arise in patients who have undergone surgery to transect the ventrolateral cervical spinal cord (bilaterally). This surgery is sometimes used for regulation of intractable pain and severs ascending pain projections. Descending pathways to the phrenic nerve are also disturbed however. Persons undergoing this procedure must be artificially ventilated during sleep because conscious regulation of breathing is necessary for their survival.

The descending fibers associated with automatic respiration arise in three different areas of the brain stem (Hlastala & Berger, 1996). These three groups of nuclei are located bilaterally in the pons, ventral and dorsal medulla. All of these respiratory groups have cells that increase their responding during inhalation and provide excitatory output to muscles as well as cells that inhibit spinal areas asso-

ciated with output to respiratory muscles systems. Pathways between the respiratory groups and in the spinal cord provide internal feedback and regulation.

2.2. Voluntary regulation

Voluntary regulation of breathing ultimately uses the same muscles as automatic regulation but the pathways to those muscles differ. For instance, the spinal pathways that ultimately lead to the phrenic nerve and the nerves that control the intercostals travel through the corticospinal tract in the posterior-lateral portion of the cord. Output to those same nerves and muscles associated with automatic control travel in ventral pathways in the cord. Additionally, the nuclei that give rise to the fibers in these pathways are quite different. Because most automatic control can be associated with the brain stem (including the pons), voluntary control is much more complicated and involves cortical and diencephalic regions (Hlastala & Berger, 1996).

Much of the feedback for voluntary regulation comes from somatic receptors that relay information about the relative distention of thoracic muscles. This input comes to somatosensory areas of the thalamus and is relayed to diverse parts of the cortex and basal ganglia (Bramann, 1995). Cortical areas interact with basal ganglia and the medullary respiratory groups in coordinating output to the nerves and muscles associated with respiration. Instigation of the voluntary act of breathing, like the instigation of other voluntary acts, obviously involves multiple cortical systems but remains largely unknown. Curiously, because breathing can produce artifactual findings in fMRI research, there is great interest in the cortical components of respiration. Recent research on sniffing has indicated different mechanisms associated with voluntary sniffs versus odors arising in nonvoluntary inspirations (Sobel et al., 1998). Findings in this domain are bound to add tremendously to our knowledge of the cortical components of voluntary respiratory activity.

3. THE MECHANICAL SYSTEM

As mentioned previously, breathing is clearly a mechanical activity that is mutually dependent on vast feedback networks. This mechanical system consists of several interconnected parts that all function in unison but can have relatively independent regulation. Nasal congestion, as an example, may take place without altering patency of airways closer to the lungs (Eccles, 1996).

3.1. Functional anatomy

3.1.1. Lungs

The lungs are often characterized as air filled sacks. In fact, they are collections of much smaller sacks called alveoli that are connected to air passages. These sacks are plentiful (Comroe (1974) estimated 30 million), richly vascularized, and thin-walled. The massive surface area (approximately

140 m² (Johnson & Miller, 1968)) of these sacks and their thin walls make gas exchange fast and efficient. There are two types of cells that make up the wall of the alveoli. Type I cells form most of the volume of this wall and are the epithelial cells through which gases are exchanged. Type II cells are less plentiful but produce a surfactant-like phospholipid that reduces surface tension across the wall of the alveolar sack leading to more rapid gas exchange. The bronchial tubes that serve the lungs form three distinct regions in the right lung each with its collection of millions of alveoli. These lead to formation of three lung lobes: the lower, middle, and upper. The left lung, which is slightly smaller than the right, has only two lobes. Volume of the normal adult human lungs is approximately 5l (Hlastala & Berger, 1996).

3.1.2. Muscles

The primary muscle of external respiration (breathing) is the diaphragm. This is a large domed muscle (see Figure 10.1) that separates the thoracic cavity from the abdominal cavity. When contracted, the muscle flattens increasing the volume of the thoracic cavity. This creates an area of low pressure inside the cavity and airflows into the lungs to fill the volume. The lungs, which are highly elastic, are passive in this process. Diaphragmatic muscle spasms, also known as hiccups, are common and not necessarily indicative of other pathology.

In addition to the diaphragm, muscles of the ribs also contribute to breathing. The intercostal muscles are interconnected to the ribs. The external intercostals are the most superficial and their contraction leads to the lateral expansion of the rib cage. The contraction of these muscles and the diaphragm produce the majority of the muscular effort to inhale a bolus of air (DeTroyer, Gorman, & Gandevia, 2003). Exhalation is largely passive and is the result of gravity and the elasticity of the rib fascia and thoracic cavity. Rapid relaxation of the external intercostals and diaphragm leads to rapid exhalations. The role of the internal intercostals in this operation is controversial. A variety of reports suggest that these muscles act in opposition to the external intercostals and pull the ribs down thereby assisting in forced exhalation. In experiments with dogs, De Troyer and colleagues (1985) found that the internal intercostals function to further expand the ribs. Thus these two sets of intercostals muscles tend to both overlap in function and both act to expand the rib cage. At the margins of the ribs, the shallow insertion angle of the muscles leads to slight competition between these muscle groups for “opening” the ribs. This suggests that whereas both diaphragm and intercostals work to expand the volume of the thorax during inhalations, exhalation and even forced exhalation, are largely passive. More recent findings in humans (Wilson et al., 2001) have confirmed the effects the internal intercostals on exhalations. They found that these muscles, functioning on the lower ribs, do contract to increase expiration. Forced expirations may also involve abdominal muscles that, through their contraction, force

the diaphragm further up into the thorax pushing out additional air.

3.1.3. Airways

The trachea is the most commonly described portion of the airways but the nasal and oral cavities, larynx, and bronchial tubes are also important features of the airway. At the upper end of the airway, the nose is a remarkable air sampling system. Air is pulled through the two external openings (nares) into the nasal cavity. This cavity has three boney protuberances called turbinates that increase the turbulent airflow allowing a relatively small volume of air to reach the olfactory mucosa while the majority of airflow is pulled into the trachea. Despite the enormous volume of air that flows through this system, it is capable of resisting drying under most conditions. Muscles of the nares contract during respiration and can be used to evaluate breathing.

Breathing may also take place through the mouth in some cases. Unlike the nose, this system dries easily and is not typically the preferred route for inspiration despite having half the ventilatory resistance of the nasal channel. Expired air, which tends to have increased humidity due to gas exchange, is less problematic. Inhaled air passes into the pharynx and past the epiglottis. The epiglottis folds up during inhalation opening the airway and down during swallowing to prevent liquids from entering (Hlastala & Berger, 1996).

The next portion of the airway is the larynx. In humans, this cartilaginous enlargement of the airway includes the vocal chords and is responsible for speech. The thyroid gland also occupies space in this area. Enlargement of the thyroid or pathology of the larynx may affect the air passage and increase airway resistance.

The trachea begins immediately below the larynx and divides into the left and right bronchial tubes. Like the lungs, the right bronchus is slightly larger in diameter than the left. These bronchi divide again and again. After some 24 divisions or generations, they connect to the alveoli (Ritz et al., 2002).

The trachea and bronchial tubes are sections of U-shaped cartilage bound by muscle tissue lined with an inner layer of epithelial and support cells. These cells contain cilia and other cells that secret mucus. Inflammation of these epithelial cells is commonly known as *bronchitis* and leads to excessive mucus production. As the cilia move this mucus (and foreign objects) back toward the mouth, reflexive contraction of the internal intercostals and abdominals (coughing) pushes short bursts of air and mucus out of the mouth. Additionally, the swelling of this tissue increases ventilatory effort causing the muscles of the system to expend more energy and thus requiring more ventilation to address the energy demands of that increased load in a positive feedback loop. Obviously, this problem is exacerbated by exertion and helps explain the “exhaustion” often reported by persons recovering from bronchitis or other pulmonary obstructive diseases.

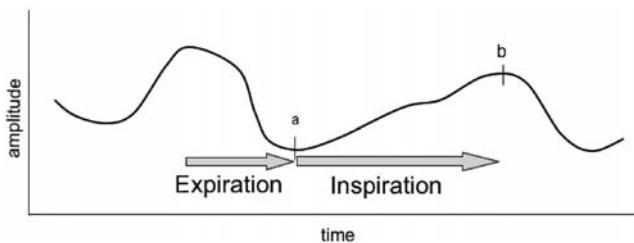

Figure 10.2. Typical output from piezoelectric belt transducer.

3.2. Measurement and quantification

Measurement and quantification of all types of pulmonary function have been aided immensely by the recent publication of guidelines for lung function measurements (Ritz et al., 2002). Readers should consult this report for specific details related to individual types of measurements. The descriptions of various techniques in this chapter are meant to help investigators make choices about which of the many respiratory parameters they may wish to evaluate.

Measurements of the mechanical aspects of respiration are straightforward and often quite simple. Most of these measurements depend upon changes in the volume of the thorax and abdomen and may be considered as a form of plethysmography. A variety of devices have been produced to make these measurements. Among the simplest is the respiratory belt (Grossman, 1967). This is a belt or tube that is affixed to the subject usually under the arms and around the chest and often a second belt is placed around the lower abdomen. The belt contains a sensor that is responsive to stretch. As the subject inhales, the volume of their upper thorax increases and stretches the device. In the past, these sensors have been, air filled bellows, strain gauges, mercury filled tubes, inductive coils and, most recently, fiber optic loops (Davis et al., 1999). The most commonly used belt method is currently a piezoelectric device. These are robust, don't leak air or mercury and provide reliable signals that can be incorporated into most electrophysiological recording systems. Pennock (1990) evaluated piezo-based respiratory belts and found that they were relatively linear compared to measurements made with a screen pneumotachometer. Figure 10.2 represents output typical of such a piezoelectric device.

The tracing in Figure 10.2 appears simple and is artifact free. Quantification of this signal is also straightforward but requires defining both the interests of the investigator and the parameters of the system. Peak exhalation is defined as the minima of the waveform between two cycles and is labeled as "a" on the graph. Peak inspiration is the maxima and is labeled as "b." It is an easy matter to evaluate the difference in these two points to find how much the chest changed during the inspiration. Counting the number of inspirations in a minute gives the rate of inspiration but the data contain far more information. Table 10.1 illustrates the variety of measurements that can be made from the simple waveform presented in Figure 10.2.

Only a few of these measurements are in common use but they serve to illustrate the complexity of the problem. Selection of the proper technique is related to the hypothesis, the way the data are acquired and the method used to reduce those data. Too often, an experimenter will seek to measure respiration then purchase the instrumentation to do so and find themselves at the end of the experiment left with still more questions about the respiration data. Perhaps worse, they will find themselves with a psychological variable that has no effect on *respiratory rate* and conclude that respiration was insensitive to their manipulation. In fact, many different parameters of respiration might have changed because *respiratory rate* is among the least sensitive (Wientjes & Grossman, 1998). This insensitivity is what led early researchers to adopt new metrics such as the inspiration/expiration ratio in the early twentieth century (Feleky, 1916).

In order to choose the proper technique, the investigator must consider, in depth, the mechanisms that lead physiological variables to change. If, for instance, one were concerned about cognitive problems related to subjects working at high altitude, the first mechanism to consider would be oxygen deprivation. Although such deprivation might lead to higher breathing rates, it will certainly lead to reduced blood levels of O₂ no matter the respiratory rate. In this example, the investigator should select a technique that, when mathematically reduced, will produce a direct measurement of the amount of oxygen in the blood over time so that it can be correlated with cognitive performance over time. It would be reasonable to add rate as a secondary measure but this would add relatively little to the findings. On the other hand, using respiratory rate exclusively would be highly problematic because rate is a very poor proxy for blood oxygen level. Respiratory patterns can be surprisingly complicated. A subject faced with a task may suspend breathing for several seconds. They may also immediately take a deep breath then suspend breathing. Breathing may become shallow or show a pattern of slow inhalations followed by brief periods of exhalations. Over minutes, one can expect that increases in metabolic demands will be equilibrated with both breathing and cardiovascular activity. Shorter epochs can be and often are much more variable and inconsistent with metabolic conditions. With respiration, just as with any psychophysiological dependent variable, the investigator must consider how the numbers that will ultimately be entered into their analysis will truly represent the psychological and physiological processes under investigation.

Although the respiratory belt has several advantages, it also suffers from several real problems. One problem is related to the transducer itself. Pulling the belt too tight leaves the transducer at the upper limit of its range and will produce "clipping" or a ceiling effect. Using a more loosely fitting belt can be equally problematic because only large inhalation may stretch the belt enough to produce a recording. Even with a properly fitting belt, individual differences in breathing lead some individuals to produce

Table 10.1. List of measurements that can be obtained from breathing transducers

Measurement	How obtained
Frequency/Rate	Mean number of peaks per minute
Inspiratory Volume (relative)	Base to peak or integration
Expiratory Volume (relative)	Base to peak or integration
Inspiration/Expiration Ratio	Computed
Inspiratory duration (absolute)	Base to peak duration
Expiratory duration (absolute)	Base to peak duration
Duration ratio	Computed
Complexity (frequency)	Spectral analysis combined with examination of the amplitudes of non-dominant frequencies

more abdominal distention making a belt placed under the arm pits insensitive to breathing. It is possible and often preferable to use a second belt placed over the abdomen (Grossman, 1967). Doing so, however, may increase subject discomfort. No matter how many belts are used, this method always provides external feedback because the belt must tighten during breathing resulting in greater constriction of the chest wall. Such feedback can make subjects far more aware of their breathing pattern and more likely to adopt response strategies that are different from less invasive procedures (Han et al., 1997). Finally, because the subject is often seated during testing, non-respiratory movements can stretch the transducer causing artifacts.

Similar to the respiratory belt is inductive plethysmography, here the subject wears a broad band and more recently, a “shirt” that contains sensors responsive to abdominal stretch and distention. The LifeShirt® (Wilhelm, Roth, & Sackner, 2003) is a new and interesting technique that may prove very helpful in the field of respiratory measurement. This is a continuous ambulatory monitoring garment for cardiovascular and respiratory measures (VivoMetrics, Ventura, CA) that collects a variety of data available for telemetry or later download and analysis. Like impedance pneumography, investigators attracted to using this device to obtain continuous cardiovascular measures will also get respiratory signals from inductance plethysmography recording devices. This technique uses changes in magnetic flux of wires embedded in the shirt to estimate thoracic volume and respiratory activity. It provides data on rib and abdominal excursions that lead to the calculation of many respiratory parameters including tidal volume, respiratory timing, and inspiratory flow. The system can also contain noninvasive blood gas monitors in addition to a variety of sensors not associated with respiration. As several reviews point out, techniques such as this offer the

opportunity to make detailed measurements of subject physiology in real-life settings and emergencies.

Another technique that makes use of the distention of the chest wall and abdomen is magnetometry. In this technique, as the subject's abdomen moves, magnet flux is sensed and the position can be plotted. This 3-D space can be differentiated into a change score that can be viewed like the output from a respiratory belt. Levine and colleagues (Levine et al., 1991) report good results using sources placed on the ventral and dorsal surfaces in predicting tidal volume. Recently, McCool, Wang, and Ebi (2002) have introduced a portable version of this device.

In some situations such as a driving simulator or cockpit, it is possible to use cramped space to the experimenter's advantage. Casali, Wierwille, and Cordes (1983) used a proximity indicator to estimate the location of the abdomen during breathing. Although certainly not applicable to all situations, this technique had the advantage of being less invasive although it may be more susceptible to movement artifacts.

Whole body plethysmography refers to using the fluctuating volume of a chamber containing the subject to determine respiratory activity (Ries, 1989). The air supply to the subject originates outside the chamber. As air is pulled into the lungs, the change in chest volume reduces the volume of the chamber. In the past, the chambers were water filled but more recent approaches use an air filled chamber and pressure transducers. This remains a widely used method in medicine and has particular advantages for measuring lung capacity in laboratory animals (Rozanski & Hoffman, 1999).

Another important measurement of thoracic volume is impedance pneumography. This technique measures the impedance of the thorax as it changes during respiration. This is a viable and interesting technique but is not often employed. Even though few investigators actively seek to measure respiration this way, it is often used to measure the heart via impedance cardiography. Recently, Ernst and colleagues (Ernst et al., 1999) have devised a way to extract impedance pneumography data from impedance cardiography recordings. This approach uses standard tetrapolar electrodes for impedance cardiography. The pneumographic signal can be derived from ΔZ (or ΔZd derived by integration of dZ/dt) by first using a digital filter to eliminate high frequency and cardiac activity and then demeaning or removing the signal offset. Ernst and colleagues (1999) compared this derived signal with both spirometry and strain gauge recordings of the chest and found high coherences for the derived measure and spirometry. In fact, the derived signal was a

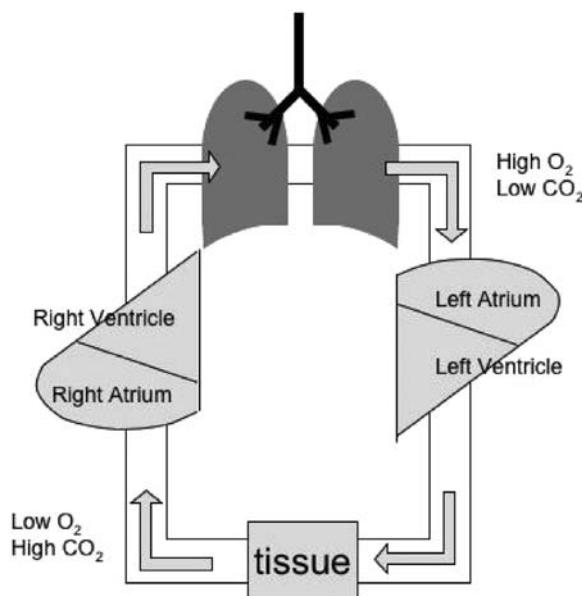

Figure 10.3. Function anatomy of gas distribution.

better predictor of the spirographic record than was the strain gauge. Because of the recent growth in impedance cardiography research, respiratory research may inadvertently gain new data and appreciation due to this analytic procedure.

Electromyography of the intercostals may also prove a useful technique under some conditions. If the investigator is measuring EKG from the chest wall in a position near the intercostals, these electrodes may also pick up activity from these respiratory muscles that, through filtering, can provide respiratory information (Pauyl, 1957). Additionally, as mentioned previously, activity in the *nares dialator* can be monitored with electromyographic techniques (Sasaki & Mann, 1976).

4. THE GAS SYSTEM

The mechanical activity of the lungs, diaphragm and airways all serve the purpose of facilitating gas exchange with the blood. Oxygen in inhaled air passes through the wall of the alveoli and carbon dioxide diffuses from the blood into the alveoli and is expelled during exhalation.

4.1. Functional anatomy

Figure 10.3 shows a diagram of the functional anatomy of the gas distribution system. Air that is rich with oxygen and low in carbon dioxide fills the lungs and specifically, the alveoli. Here passive diffusion takes place across the cell membrane and pulmonary capillaries. Oxygen, in low concentration in the blood, flows into the capillaries and carbon dioxide that is in high concentration in the blood diffuses into the alveoli. This newly oxygenated blood flows into the left atrium and ventricle then provides the rest of

the body a supply of oxygen. As cellular metabolism takes place, the amount of oxygen in the blood is reduced and the supply of carbon dioxide increased. These products flow through the blood into the right side of the heart and are pumped into the lungs where gas exchange occurs with the air (Guyton & Hall, 2000).

4.2. Measurement and quantification

There are many different approaches to measuring the gasses associated with respiration. Among the most simple and reliable is pressure (Carroll et al., 1992). Because inspired air flows into the lungs through the nose and mouth, a cannula connected to a pressure transducer can readily measure the pressure changes during breathing. Like the mechanical measurements mentioned above, the output of such a device produces a record very much like the respiratory belt. Unlike the belt, this type of measurement is far less prone to movement artifacts. Any movement of the cannula itself, however, can produce far less effective recordings. A variety of respiratory pressure devices are available that were primarily designed to monitor sleep apnea. Most use a small soft nasal cannula that fits in the nose and over the ears and is often used to deliver oxygen in home medical applications.

Similar to pressure transduction, temperature transducers may also be used to measure breathing. Because air is warmed in the lungs before being exhaled, a temperature sensor can readily detect exhalations. Inhalations can also cool the transducer if sufficiently forceful. Like the pressure transducer, this device is very sensitive to positioning and requires some means to fix its position on the face. Some transducers have a nose or mouth clip to facilitate this process. One additional caveat about this type of sensor is its response speed or time constant. Thermocouples and thermisters used in these devices tend to be rather slow and sluggish in response to rapid changes in temperature. A few devices of this type respond rapidly and investigators interested in the shape of the breathing cycle should be certain that they use a device fast enough to record the responses of interest. Although normal respiratory activity has a cycle of approximately 0.3 Hz (approximately 18 inspirations per minute), the shape of the wave will change much faster and require capturing phenomena of 2.0 Hz and possibly higher. As an example, inhalation of a malodor causes rapid cessation of the inspiration (Frank, Dulay, & Gestland, 2003). In cases such as this, a temperature transducer would be a very poor choice because it tends to be less sensitive to the inspiratory phase of the cycle and slow to react to the change in breathing.

Sound may also be an effective means of determining breathing cycle. A small microphone placed at the nares will record clearly different sounds for inhalation and exhalation allowing the investigator to make a determination of respiratory cycle. Such devices are most often used for recording snoring but can be adapted to record

normal breathing sounds by integrating the output of the microphone. As one might imagine, this technique is prone to artifacts from ambient noise. Such artifacts can easily overwhelm the small changes that are due to respiratory activity. Furthermore, should the subject speak, the output from the microphone has the potential to saturate the amplifiers and delay subsequent recordings. Que and colleagues (Que et al., 2002) recently reported on a more sophisticated approach to this problem. Using a tracheal microphone, in a technique they call phonspirometry, they analyzed sounds related to air flow in the lungs and were able to estimate a variety of respiratory parameters including tidal volume. They report that their measures corresponded well to more classic procedures and did not require subject to use mouthpiece or nose clip.

Spirometry is the most widely used technique for evaluating respiratory activity and can be accomplished with a variety of devices. The original spirometers required subjects to use a mouthpiece and nose clamp. Their exhalations were used to displace water under a bell. The volume of the displaced water was used to determine the volume of gas (under pressure) that was expired. More sophisticated devices added simple gas analysis to this operation. Modern approaches to spirometry seldom use water displacement and gas analysis is now far more specific.

Although subjects continue to use a mouthpiece and nose clip, the air they exhale now flows through a tube and fills a bellows or activates a small turbine or pressure transducer attached to a screen. In fact, portable devices now make it possible to collect data with a handheld computer and lightweight spirometry tube that produce data that are comparable to laboratory spirometers (Mortimer et al., 2003). Spirometry tends to concentrate on one phase of the breathing cycle at a time and provides the experimenter with a volume X time plot of the inhalation or, more commonly, the exhalation. Almost all specific respiratory measurements are conducted using spirometry (see Table 10.1). These will be detailed later in this chapter.

In addition to measuring the volume of air inspired or exhaled, it is also common to assess the efficiency of the gas exchange using a gas analysis system. In such a system, the analytic apparatus samples expired air. This apparatus may be a general-purpose analytic system such as a gas chromatograph or a system designed to specifically analyze a particular respiratory gas such as carbon dioxide. In fact, carbon dioxide monitoring is relatively common. Both oxygen and carbon dioxide monitoring equipment provide numeric readouts and most provide a linear analog voltage referred to that readout for connection to recording equipment producing a volume X time recording. Investigators interested in this type of analysis should be concerned about the timing of the analysis. Some devices respond relatively slowly and may not give breath-by-breath responses making the volume X time recording less valuable.

Although not specifically related to spirometry or other respiratory measurements *per se*, non-invasive measure-

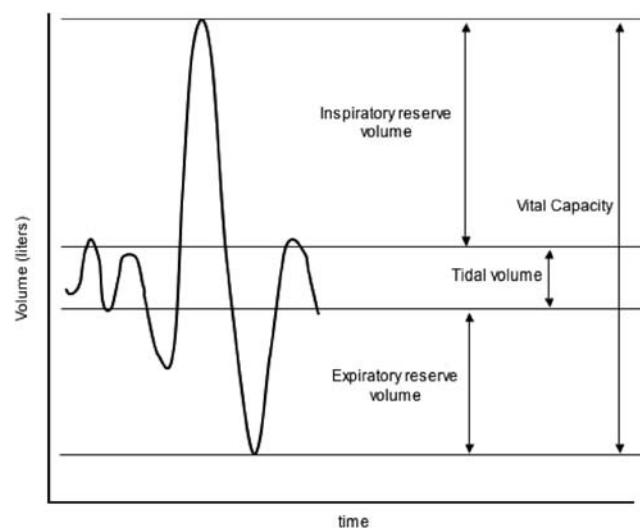

Figure 10.4. A typical spirographic record and the respiratory measurements that can be obtained from this method (adapted from Hlastala & Berger, 1996).

ment of blood gas may be an important part of understanding respiration and its psychophysiological components. Recently, pulse oximetry has become available to record parameters related to blood gases. This technique requires that a transducer, much like a photoplethysmograph be placed on the subject's skin. The pulse oximeter provides an estimate of the percentage of hemoglobin that is saturated with oxygen. This device works similarly to a photoplethysmograph except that it detects the ratio of absorbed light for two different light sources, one of which is specifically absorbed by oxygen bound hemoglobin. This technique provides a rapid readout but is very sensitive to the nature of the vascular bed over which the sensor is placed (Allen, 2004).

5. SPECIFIC RESPIRATORY MEASUREMENTS

Because of the importance of respiratory function to well-being and other physiological systems, it is extensively measured in medical settings. These measurements are standardized and can have a variety of uses for psychophysologists interested in this system. Ritz and colleagues (2002), in their guidelines for psychophysiological research on respiration, provide a full list of such measurements. Furthermore, subjects undergoing this testing follow a prescribed protocol involving several forced breathing maneuvers. Typical values for many of these measurements are presented in Hlastala and Berger (1996) and some are discussed below. Figure 10.4 shows the relationship of several of these measures to a spirographic record. Some of the more commonly used measures are presented below.

Respiratory frequency (*f*) is the number of respiratory cycles occurring in one minute. This value ranges from about 12–15 respirations per minute under resting conditions.

Tidal volume (V_T) is the normal volume of air inhaled after an exhalation. It is highly variable but averages about 0.5l.

Vital capacity (V_C) is the volume of a full expiration. This metric depends upon size of the lungs, elasticity, integrity of the airways, and other parameters therefore it is highly variable between subjects. Values may range from 2l to 7l for adults.

Residual volume (V_R) is the volume that remains in the lungs following maximum exhalation. Like other measures that depend upon the size of the chest and lungs, this tends to be highly variable ranging from 1.41 to 1.91 in larger subjects.

Compliance (C) is a measure of the elasticity of the thoracic area. It may be applied to the lungs (C_L), chest wall (C_{CW}) or thorax (C_T). Conceptually it is the resistance to change in response to pressure. Highly compliant lungs, for instance, change in accord with external pressure changes. Thus, one may calculate compliance by determining the ratio of the change in volume (of the lungs or thorax) to changes in pressure. It should be noted that because this is an absolute measure, it is non-linear with respect to lung volume. Volume decreases disproportionately as lungs reach their maximal distention (Hlastala & Berger, 1996).

6. PSYCHOLOGICAL/FUNCTIONAL RELEVANCE

Because adequate ventilation is necessary for all physiological systems to function, it is little surprise that alteration of respiration leads to a cascade of changes throughout the body. Such changes affect the entire functioning of the organism including producing physiological and psychological effects. Some of these effects lead to artifacts in recording of the heart or functional imaging. But, as the preceding sections have shown, a diffuse network controls the respiratory system. The actions of this diffuse network lead many different psychological functions to alter respiration.

6.1. Respiratory effects as artifacts

6.1.1. Skin conductance

Skin conductance and other forms of electrodermal activity (EDA) are dramatically influenced by respiration. Asking subjects to make a deep breath is often used to validate the responsiveness and integrity of the recording system. Despite the sensitivity of EDA to respiratory changes, removal of artifacts due to respiration is difficult. EDA is multiply caused (Dawson, 2002) and rhythmic variations are not tightly coupled to respiratory cycle (Rittweger, Lambertz, & Langhorst, 1997). Recently, Schneider and colleagues (2003) have introduced a technique for identification of respiratory artifacts. It is too soon to know if this technique will enter widespread use for the correction of respiratory effects on EDA.

6.1.2. Heart

The effects of respiratory cycle on the heart are well known to psychophysologists. The heart period, the time between successive beats, grows longer during exhalations leading to fewer beats per minute. During inhalation, heart period is shorter and consequently, heart rate appears to increase during this phase of respiration. This oscillatory interaction between the heart and respiratory system is known as respiratory sinus arrhythmia (RSA) and is the result of the influence of a variety of different physiological systems. Normally, evaluation of this interaction can produce an estimate of vagal tone in a subject. A full description of these interactions is beyond the scope of this chapter but the reader is referred to the chapter on cardiovascular psychophysiology in this volume for more extensive explanation of this phenomenon. Voluntary ventilation may introduce noise into this system and adversely influence estimates of vagal tone (Wilhelm, Grossman, & Coyle, 2004). Previous findings have indicated that even small changes such as missing an R spike can adversely affect such findings (Berntson & Stowell, 1998).

6.1.3. fMRI

Because functional magnetic resonance imaging (fMRI) is blood oxygenation level dependent (BOLD), it is reasonable to assume that the system that brings oxygen to the blood would be important in regulating the measured response. Consider this example. Subjects are asked to view a variety of pictures that are meant to evoke fear as well as a group of control pictures. Based on subjective ratings, the fear-producing pictures are effective in their emotional evocation and there are clear differences between the BOLD responses for the two picture types. One might conclude that the brain areas showing increased BOLD response during the fear pictures would be associated with the production of that emotion. In some ways they would, but not perhaps in the ways expected by the experimenters. Fear leads to increased ventilation rate and ventilatory effort (Boiten, Frijda, & Wientjes, 1994) due to airway constriction. Likewise, heart rate increases as does stroke volume (Sinha, Lovallo, & Parsons, 1992). Are the differences found in the brain's BOLD response the cause of these changes or their result? Furthermore, because of increases in stroke volume of the heart or the volume of the rib cage, the physical movement of the brain or volumetric disturbances in the magnetic field may impair the ability to accurately image the subjects during the fear evocation.

Correction of breathing and cardiac-related artifacts in fMRI is still controversial and a variety of papers have recently appeared suggesting several approaches. One of the most common is to gate or mask the responses during the different portions of the breathing cycle. Investigators might choose just the peak inspiratory phase of the cycle to make their measurements in BOLD responses or use a digital filter to isolate only BOLD changes in frequencies

higher than respirations (Brosch, et al., 2002; Zhu et al., 2003).

6.2. Respiratory changes as a result of psychological influence

6.2.1. Emotion

Emotion has long been known to influence respiration. Descriptions of “breath taking” beauty and fear inducing an inability to “catch one’s breath” have been a part of literature and folklore into the ancient past. As mentioned previously, Feleky (1916) recorded the ratio between inspiration and expiration and was able to identify a set of primary emotions. Others followed (Dudley, 1969), but relatively little research has been conducted related to emotion where respiration was the primary physiological variable of interest. Boiten, Fijda, and Wientjes (1994) review this literature and conclude that the major dimensions of emotion that alter respiratory activity are continua of calm-excited and active versus passive coping. They argue that it may be possible to make finer discriminations but the relative paucity of research and interest in this field has impaired our understanding of these phenomena. Subsequent research by Boiten (1998) has specifically addressed the effects of emotion on respiration using both chest and abdominal respiratory strain gauges. Subjects watched short video presentations designed to evoke a variety of emotions. Subjects altered their respiration patterns depending upon the content of the movies with more positive affect being associated with shorter inspiratory cycles. A scene that evoked disgust, led to respiratory pauses. Interestingly, without careful analysis, such pauses might be misinterpreted because long pauses would lead to lower respiratory rates. Such findings serve to illustrate the insufficiency of rate as a helpful measure of respiratory activity. Recently, Gomez, Stahel, and Danuser (2004) conducted a study evaluating respiratory responses to affective pictures confirming the importance of the continua proposed by Boiten and colleagues.

6.2.2. Asthma

Within psychophysiology, asthma is the most widely studied topic related to respiration. The National Institutes of Health report that, in the United States, approximately 15 million persons suffer from this chronic inflammatory disease of the airways. Asthma can be triggered by a reaction to environmental irritants but it is also often triggered by even the suggestion of irritants. Furthermore, it is clearly exacerbated by other stressors in sufferer’s psychological environment. In their recent review of the psychological aspects of asthma, Lehrer et al. (2002) describe the nature of these stressors along with potential triggering mechanisms. They advocate the efficacy of symptom recognition and biofeedback for control of the cascade leading to airway constriction.

Ritz (2004) provides an excellent overview of this complicated and important area of research that is beyond

the scope of this chapter. Just as the lungs are multiply controlled, so are the airways. The feedback, neural, and humoral regulation all interact and make delineating mechanisms of influence in this system difficult. Even so, the importance of this topic requires addressing the mechanisms at work.

6.2.3. Cognitive activity

Clearly, the reduction of the amount of oxygen in the blood stream can produce grave consequences related to brain function and cognitive ability. These hypoxic events may be related to extreme systems break down such as heart fibrillation, drowning, or suffocation but they may also be related to far less dramatic causes. Sleep apnea (Aloia et al., 2004), nocturnal asthma (Bender & Annett, 1999), and even scuba diving (Slosman et al., 2004) have some cognitive sequelae.

There is little evidence that breathing pattern, so long as it supplies sufficient oxygen, affects cognitive activity. The exception to this statement is a maneuver called “forced unilateral breathing.” This exercise originated in yogic training and several studies have demonstrated that occlusion of the left or right nostril alters cognitive function. This is an interesting, varied and surprisingly large literature. Werntz, Bickford, and Shannahoff-Khalsa (1987) found that occlusion of the left or right nostril produces increased EEG amplitudes in the contralateral hemisphere. Contrary to most interpretations of increased EEG amplitude, this finding was interpreted as increased cortical activity and was used to account for behavioral differences associated with the “activated” hemisphere. A different study (Block, Arnott, Quigley, & Lynch, 1989), examined this breathing style on verbal test performance and spatial tasks finding effects for both gender, nostril and task. Males in this study performed spatial tasks better when breathing through the right nostril and the opposite response was found for women. A slightly more recent study by Jella and Shannahoff-Khalsa (1993) found that both men and women showed improved performance during left nostril breathing contradicting the earlier effect in males. Although inconsistent, the preponderance of the literature suggests that right nostril breathing is associated with better verbal performance and left nostril breathing is associated with better spatial performance. These findings have been interpreted as being the result of increased activation in the hemisphere contralateral to the nostril with airflow. Recently, this idea has been extended to research on emotional tones in a dichotic listening paradigm (Saucier et al., 2004).

Although a full review of this literature is inappropriate for this chapter, these studies rarely propose a mechanism by which uninostril breathing might alter hemispheric and/or cognitive activity. Nasal cycle, an alternating ultradian rhythm associated with increased patency of the left or right nostril, is poorly understood and often uncontrolled in these studies. Furthermore, the

odor environment in which these studies are conducted is not described. Lorig et al. (1989) demonstrated that nasal versus mouth breathing had a profound influence on EEG and Lorig and coworkers (Lorig, 1999; Lorig, Malin, & Horwitz, 2005) later found that performance of verbal and other symbolic tasks can be impaired when the subject is challenged with an odor. Because the olfactory system projects ipsilaterally, left nostril breathing of odorized air could lead to poorer performance on verbal or symbolic tasks than right nostril breathing due to intrahemispheric competition. Because no air supply is truly odor-free, this simple and overlooked effect has the potential to account for much of the data in this literature. No study has, however, directly evaluated the connection of odor to the cognitive literature related to unilateral nostril breathing.

7. OTHER RESPIRATORY FUNCTIONS

Although breathing is normally associated with gas exchange, it is also an avenue for other functions related to the movement of air. As indicated in the preceding paragraph, odor acquisition is also a function of the respiratory system. Similarly, the muscles of respiration are also used for controlling the air for speech. Although such functions are certainly not the most important aspects of respiration, they are inextricably linked to the gas exchange system and will be briefly included here.

7.1. Odor acquisition

Humans show a remarkable ability to “tune out” odors (Zelano et al., 2005) despite the fact that they have excellent olfactory sensitivity (Lorig, 1999). Recent evidence from several different laboratories has demonstrated odor-related changes in brain activity despite an absence of awareness for the odor (Kirk-Smith et al., 1983; Lorig et al., 1990, 1991; Sobel et al., 1999; Kline et al., 2000; Jacob et al., 2001). With clear evidence of odor effects even when subjects don’t notice their presence, it appears likely that each inhalation brings new olfactory information to the nervous system. Certainly, this phenomenon is true of other animals. Freeman and Schnieder (1982) and also Chaput (1986) found that the pattern of electrical activity on the olfactory bulb of rabbits was dependent on respiratory cycle. They suggested that the initiation of an inspiration triggered a “template” related to the odor to which the animal was conditioned. Buonviso et al. (2003) found that the primary component of rhythmic activity in the bulb of rats was dependent upon the respiratory cycle. Lorig and colleagues (Lorig et al., 1996), examined the effect of breathing pattern on chemosensory evoked potentials in humans and found that they differed as a function of whether stimuli were delivered in concert with inspiration or out of phase with this cycle further suggesting the production of such an odor template. In a related fMRI study, Sobel and coworkers (Sobel et al., 1998) found that sniffing produced activation patterns different than smelling,

further illustrating that respiratory activity serves to synchronize a variety of neural sub-systems related to odors and their anticipation.

In a recent study, Kay (2005) describes findings that illustrate how the olfactory-respiratory system is controlled. Based primarily on coherence data, it appears that as odor becomes available, activity in the bulb triggers hippocampal activity that forms a re-entrant loop with the bulb and also descends to influence control of the diaphragm. The odor signals an increase in respiratory effort resulting in sniffing. In a curious way, this process is similar to vision. Availability of visual input leads to movement of the eyes to focus the image on the fovea leading to better discrimination. In the case of olfactory stimuli, sniffing is the movement and this changes the dynamics of airflow in the nasal cavity leading to a change in the distribution of chemicals in the mucosa. Although we have not yet found the olfactory epithelium analog of the fovea, the behavior equivalent is clearly present because previous behavioral research has indicated that sniffing is the most efficient and information-rich way in which to evaluate odors (Laing, 1983).

Recently, it has been suggested that respiratory activity is reflexively truncated in response to a bad odor (Frank et al., 2003). For some time, it has been known that airborne mal-odors and irritants can affect breathing including reducing tidal volume (Warren et al., 1992) but only recently has a reflexive mechanism been proposed that might be related to odor hedonics. The argument for the reflexive nature is based on the rapidity of this inspiratory cessation. Inhalatory restriction starts at approximately 300 msec following odor availability. Reaction times to these odors tend to be more than 100 msec later (Overbosch et al., 1989) suggesting that the cessation takes place well before detection. Although this is hardly conclusive evidence of a reflexive connection, it does raise the strong possibility that some hedonic information is encoded prior to the action of central nervous system resources necessary for odor detection.

7.2. Speech

Another important aspect of breathing is providing a medium for speech sounds. Although often overlooked as a function of breathing, this is an important problem for subjects requiring artificial ventilation. Coordination of laryngeal movements with enforced lung movements and the availability of an air supply is often difficult to learn. Relatively few reports describe the pathways and mechanisms by which ventilatory movements are coordinated with speech production. It seems likely that such coordination is a product of feedback between cortical speech areas and the areas associated with voluntary breathing although a recent study with cats highlights the importance of the midbrain. Davis and colleagues (Davis et al., 1996) found that the periaqueductal gray area was associated to both respiratory and laryngeal output and their

findings suggest that it integrates activity for these sets of muscles.

8. CONCLUSIONS

Like the actions of the heart, respiration is clearly a critical and life sustaining process. As might be expected of any process so important to survival, it is multiply controlled and affects many systems of the body. Likewise, it receives broad input for its regulation. Traditionally, psychophysiology has concentrated on other dependent variables. When respiration was measured it was often used as a covariate or control for the variables of primary interest. Clinical medicine, however, routinely examines the activity of this system and has developed many effective strategies for its assessment. It is within medicine that most of the advances in respiratory measurement have been made in the past few decades.

It is always difficult to imagine what the future holds in a research area. Technical and computational advances will certainly continue. There are already strong trends for more portable devices to measure respiration. Additionally, it is likely that the availability of high level mathematical programming languages designed to work with real data (e.g., MATLAB, LabView, etc.) will have a major impact on the ways that this seemingly simple waveform are viewed. It is also clear that advances such as ambulatory monitoring will lead to new and important insights about respiration in the real world. The fact that a system, ambulatory or not, provides simultaneous measures of so many interrelated dependent variables will beg for more sophisticated analyses than are currently being conducted. One might imagine a mathematical function indicating a parameter called metabolic respiratory demand. Such a function would be based on the long-term, nonlinear multiple regression between blood oxygen saturation, cardiac output and inspiratory volume. Knowing two of the variables should predict the third and the deviance between the predicted and actual values for inspiratory volume might be an indicator of "voluntary override." It would certainly be a curious twist of fate that the characteristic that turned early psychophysologists away from studying this system (Wientjes & Grossman, 1998), would become an important area of study in the following century.

It is genuinely puzzling that a system with such broad effects on the brain and body is so relatively unstudied by psychophysiolists. There is far more to this system than it appears. Perhaps, as Wientjes and Grossman (1998) have suggested, we will find new insights into the areas of emotion and cognition in the loose coupling of respiration to the other systems of our bodies.

The Sexual Response

ERICK JANSSEN, NICOLE PRAUSE, AND JAMES H. GEER

1. PROLOGUE

Although physiological responses during sexual activity have been explored as early as in the 1800s (e.g., Mendelsohn, 1896, who described “pulse curves” (EKGs) during sexual intercourse), the first systematic attempts to understand the psychophysiology of sexual response should probably be dated in the first part of the twentieth century, originating with writings on sexual physiology (e.g., Van de Velde, 1926; Dickinson, 1933). These works predated the research of Kinsey and colleagues (Kinsey, Pomeroy, Martin, & Gebhard, 1953), who provided an extensive description of the physiological changes that accompany sexual arousal, and Masters and Johnson (1966), who observed sexual responses in over 650 individuals and summarized their work in a model that has been the stimulus for much psychophysiological research. Initially, researchers relied on direct observation and the use of extragenital measures such as heart rate, respiration, and sweat gland activity to index sexual arousal. Zuckerman (1971), after reviewing the then available literature, concluded that extragenital measures were not specific to sexual arousal. Zuckerman’s review of the literature, coupled with Masters and Johnson’s (1966) report that myotonia and genital vasocongestion were the most reliable indicators of sexual arousal, accounts for the trend in the field toward the development and use of genital response measures.

2. PHYSICAL CONTEXT

2.1. Anatomical substrate

2.1.1. Men

The principal focus of genital response measurement in men is the penis. The key structures mediating erection are the corpora cavernosa and spongiosum. The two corpora cavernosa are surrounded by a thick fibrous sheath, the tunica albuginea, and share a perforated septum that allows them to function as a single unit. The corpora contain a meshwork of small, interconnected compartments (lacunar spaces), which are lined by vascular endothe-

lium and separated by bonds of collagen and smooth muscle (trabeculae). The function of the corpora cavernosa is purely erectile. The corpus spongiosum, which expands to form the glans, also acts as a urinary conduit and an organ of ejaculation. On erection, the corpus spongiosum and the glans develop a modest turgidity.

With the exception of some minor branches from the scrotal and epigastric arteries, the blood supply to the penis is furnished by the two branches of the internal iliac artery, the internal pudendal arteries. After giving off the perineal arteries, they become the penile arteries, which branch off to become a complex of arteries that supplies the penis. Of particular interest are the paired dorsal and cavernous, or deep, arteries of the penis. The dorsal arteries give off circumflex branches and supply blood to the glans penis. The cavernosal arteries run along the middle of each corpus cavernosum, giving off helicine arteries, which open directly into the lacunar spaces (Kirby, 2004). Blood leaves the penis via a number of venous systems, including a network that lies between the smooth muscles and the tunica albuginea. The corpora cavernosa and spongiosum are surrounded by striated muscles. The most important ones, the bulbospongiosus and the ischiocavernosus, support the erect penis and also contract during ejaculation.

2.1.2. Women

The external female genital area is known as the vulva. This area is rich in nerve endings and heavily vascularized. The labia majora, also known as the outer lips, surround the labia minora, or inner lips, which enclose an area called the vestibule. The labia minora fuse to form the clitoral prepuce and fuse under the vaginal opening to form the frenulum. During sexual arousal, the clitoris and the labia minora become engorged, and the latter can increase in diameter by two to three times during sexual excitement (Masters & Johnson, 1966).

The clitoris is composed of the clitoral shaft or corpus, the crura, and the clitoral head or glans. The clitoral body is formed from two corpora cavernosa and a single corpus spongiosum. The bulbs of the clitoris (formerly vestibular

bulbs) were only recently characterized (O'Connell, 1998) and are analogous to the corpus spongiosum in men. The clitoral shaft becomes engorged with blood during sexual arousal but women do not have a subalbugineal layer that would reduce venous outflow producing rigidity (Berman, Adhikari, and Goldstein, 2000).

The organ that has been the principal focus of psychophysiological measurement in women is the vagina. The vagina is an almost anaerobic collapsed canal (Levin, 2003) that is more a potential than a permanent space. The canal is formed by two layers. The innermost layer is a non-secretory, squamous epithelium made of many transverse folds or 'rugae' (Krantz, 1950). Rugae are more prominent in the lower third of the vagina and are thought to provide accordion-like distensibility (Droegemueller, 1992). The epithelium is lined by a lamina propria, which is thick, vascularized connective tissue composed of elastic fibers and a network of blood vessels. Transudate from these blood vessels contributes to vaginal lubrication when forced, by increased pressure in the vessels, through the epithelium to coalesce from sweat-like droplets forming a smooth, lubricative film on the vaginal wall. Small amounts of lubrication are also supplied by the paired greater vestibule, or Bartholin's glands. The two layers are surrounded by the muscularis, or circular smooth muscle (Levin, 1992), which is covered by longitudinal smooth muscle and a fibrous sheath allowing expansion.

Vaginal blood supply originates with the uterine artery, internal iliac artery, and the vaginal artery. The vaginal artery consists of multiple arteries on each side of the pelvis and branches to the anterior and posterior surfaces of the vagina. Vascular responding of the erectile tissues of the introitus and extending to the clitoris is, as with the penis, controlled by the nerves that pass through the nervi erigentes from the sacral plexus. In comparison to men, much less is known about the vascular mechanisms involved in the female genital response.

2.2. Neural/humoral control

2.2.1. Neurophysiology of erection

Erection is essentially a hydrodynamic manifestation, weighing arterial inflow against venous outflow. Cavernous smooth muscles, which are in a tonically contracted state when the penis is flaccid, relax during penile erection (Andersson and Wagner, 1995). This lowers the corporal vascular resistance and results in increased blood flow to the penis. Venous return is diminished by means of a passive occlusion of the subtunical veins pressed against the tunica albuginea.

The spinal cord contains all the necessary components for the coordination and initiation of penile erection (McKenna, 2000). The tone of the penile vasculature and smooth muscles is controlled by both contractant and relaxant factors, which themselves are modulated by local and central processes (Andersson, 2001, 2003). Although the cholinergic, parasympathetic nervous system is the pri-

mary proerection system, normal erection also requires participation of the sympathetic and somatic nervous systems. Parasympathetic nerve endings are sparse in the corpora cavernosa and play primarily a role in the initiation of vasodilatation (Saenz de Tejada et al., 2004). Sympathetic pathways mediate anti-erectile as well as erectile effects. Erection requires inhibition of sympathetically controlled vasoconstriction in the penis, but also activation of sympathetic pathways in the pelvis to assist blood flow to the penis (McKenna, 2000). In addition, full rigidity is dependent on the contraction of striated perineal muscles.

Nonadrenergic noncholinergic (NANC) transmitters, found in both adrenergic and cholinergic nerves (Andersson, 2001), play a central role in penile erection. At present, nitric oxide (NO) is considered to be the principle mediator of corporeal smooth muscle relaxation (Burnett, 1997). NO stimulates the production of cGMP, the second messenger molecule responsible for smooth muscle relaxation. cGMP levels are regulated by the enzyme phosphodiesterase (PDE), of which several subtypes exist. Drugs like sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) exert their effect by blocking the degradation of cGMP through the inhibition of phosphodiesterase-5, which is relatively specific to the penis (it is found in lower concentrations elsewhere, including lungs and aorta). This thus facilitates erection by increasing bioavailable cGMP in the penis (Gonzalez-Cadavid, Ignarro, & Rajfer, 1999; Wagner & Mulhall, 2001).

Our understanding of the supraspinal control of erection lags behind that of the local neurophysiological and biochemical processes (Bancroft, 2000; McKenna, 1998, 2000, 2001). The presence of descending tonic inhibition has been demonstrated in studies in animals and in humans with spinal cord transections or injury, and is believed to be under control of the nucleus paragigantocellularis, or nPGi, and mediated by serotonin (Giuliano and Rampin, 2000). Serotonin, however, can also have facilitory effects, depending on receptor location and subtype, and this may be relevant to the sometimes conflicting findings on sexual effects of serotonin agonists and antagonists (Andersson, 2001). Other areas that are relevant to penile erection include the amygdala, hippocampus, locus caeruleus, periaqueductal gray, and hypothalamus (Bancroft, 2000), of which the medial preoptic area (MPOA) is believed to have a function in the processing of sensory stimuli and the paraventricular nucleus (PVN) in the integration of genital and nongenital autonomic processes (McKenna, 2001).

2.2.2. Neurophysiology of vaginal arousal

Considerably less is known about the neurophysiology of genital response in women than is known about the mechanisms of penile erection. The vaginal epithelium, blood vessels, and smooth muscle are innervated by the sympathetic and parasympathetic divisions of the autonomous nervous system. The striated muscles that surround the vagina are innervated by the somatic nervous system (Levin, 1992). The clitoris, which contains nerve endings

similar in number to those found in the male penis (Bancroft, 1989), is innervated by the pudendal nerve.

A number of peptides and neurotransmitters have been located in the female genital tissues. Among these are nitric oxide (NO) and vasoactive intestinal polypeptide (VIP; McKenna, 2002). Hoyle et al. (1996) failed to find NO synthase, the enzyme that manufactures nitric oxide, in approximately half of a group of pre- and postmenopausal women. According to Levin (1997), the available data point to VIP as the likely major neurotransmitter controlling vaginal blood flow and lubrication.

Central mechanisms of sexual arousal are becoming increasingly investigated in women, particularly as peripheral interventions appear relatively ineffective in improving women's self-reported sexual experiences (Basson, McInnes, Smith, Hodgson, & Koppiker, 2002; Laan et al., 2002). Research suggests that women, although reporting similar levels of arousal¹, display less amygdala activation to sexual stimuli than men (Hamann, Herman, Nolan, & Wallen, 2004). Although counterintuitive (if the amygdala are viewed primarily as an emotion center), the authors suggest that it may be more appropriate to view the amygdala as relevant to motivational processes. However, emotional responses to sexual stimuli appear more predictive of levels of sexual desire in men than in women (Prause, Janssen, & Hetrick, 2003). The use of stimuli that are equally effective in men and women is critical when exploring gender differences in neural activation to sexual stimuli, as otherwise findings may reflect simple differences in sexual arousal levels (cf. Janssen et al., 2003).

Recent research examining sexual functioning in women with spinal cord injuries has provided additional insight into the control of sexual response. Sipski et al. (2001) documented a relationship between sympathetic activation and level of genital vasocongestion in response to sexual stimulation, supporting the conclusion of studies in able-bodied women that sympathetic afferents are important in sexual arousal (Meston & Gorzalka, 1996; Meston & Heiman, 1998). Although Whipple and Komisurak (2002) have suggested that the vagus nerve may be the primary afferent, the mechanism by which genital stimulation uses sympathetic pathways to reach the brain is still debated.

2.2.3. Hormonal control

A number of studies have examined the effects of anti-androgens and exogenous androgens in men. There is also literature on the effects of sexual activity or erotic stimuli on hormone levels. However, the most relevant evidence on the role of sex hormones in men comes from studies in hypogonadal men. These studies have shown that within weeks after androgen withdrawal a decline in sexual desire occurs. When considering erectile func-

tion, a more complex picture emerges. Erections during sleep (nocturnal penile tumescence or NPT) are reduced by androgen depletion and restored with androgen replacement. On the other hand, erections to visual erotic stimuli have been found to continue in spite of androgen withdrawal, although the degree and duration of response may be decreased, (Bancroft, 1995). These findings have led to the distinction between androgen dependent and independent erectile responsiveness (Bancroft, 1989). Variations in androgen levels are, however, not believed to lead to variations in sexual behavior and responsiveness, unless variations are significant, as found in hypogonadal men or in adolescents around the time of puberty (Bancroft, 1989; Halpern, Udry, & Suchindran, 1998).

Most studies on the relationship between reproductive hormones and sexual responsiveness in women have assessed these variables across the menstrual cycle (Meuwissen and Over, 1992). Several studies have found that the level of subjective sexual arousal evoked by fantasy, erotic film, and audiotaped stories and genital physiological response to visual sexual stimuli remains stable across phases of the menstrual cycle (Hoon, Bruce, & Kinchloe, 1982; Meuwissen & Over, 1993; Morrell, Dixen, Carter, & Davidson, 1984; Slob, Koster, Radder, & Van der Werff ten Bosch, 1990), whereas some have found higher subjective sexual arousal during periovulatory than during follicular phases (e.g., Graham, Janssen, & Sanders, 2000) and others found vaginal pulse amplitude changes to be higher in premenstrual than in periovulatory phases (Meuwissen & Over, 1993; Schreiner-Engel, Schiavi, Smith, & White, 1981). Among the factors that may explain this lack of consistency in findings, are differences in the method used for determining cycle phase, variations in experimental design, and differences in subject characteristics (Hedricks, 1994).

Increasingly, researchers are exploring the role of other hormones, such as estrogens, oxytocin, and prolactin in sexual response in men and (pre- and postmenopausal) women. Estrogens are necessary for normal vaginal lubrication, and vaginal dryness associated with menopause can be decreased using hormone replacement therapy. Levels of circulating oxytocin increase during sexual arousal and peak during orgasm in both women and men (e.g., Gimpl and Fagrenholz, 2001). Also, a role for orgasmic-released prolactin as an "off switch" of sexual arousal has been proposed (see Kruger et al., 2005) although the evidence is still inconclusive and other mechanisms may be involved, especially in women (Levin, 2003).

Recently, researchers using evoked response potentials (ERP) have found that P300 amplitudes to sexually (or reproductivity) relevant stimuli increase during ovulation (Krug, Plihal, Fehm, & Born, 2000). Changes in ERP responses to nonsexual stimuli, however, have not been found consistently, and when ERP differences were attributed to menstrual cycle phase, did not appear to affect performance in cognitive tasks (Johnston &

¹ However, the questionnaire used in this study asked about physical arousal (i.e., did not explicitly ask about sexual arousal: Hanann, 2004, personal communication).

Oliver-Rodriguez, 1997; O'Reilly, Cunningham, Lawlor, Walsh, & Rowan, 2004; Walpurger, Pietrowsky, Kirschbaum, & Wolf, 2004). Thus, although menstrual cycle phase may not consistently affect overt responses or behavior, it does appear to have an effect on attention to sexual stimuli. For these reasons, although the impact of menstrual cycle effects on laboratory findings remains to be established, controls for menstrual phase are advised.

3. SOCIAL CONTEXT

3.1. Measurement milieu

The following discussion of the measurement context in sexual psychophysiological research will only touch upon a few relevant issues. For a more extensive discussion, see Janssen (2002), Prause and Janssen (2006), and Rowland (1999). For the discussion of the political context of sex research in general and sexual psychophysiology in particular, see Bancroft (2005).

3.1.1. Ethical issues

Guidelines for the ethical treatment of research participants (e.g., American Psychological Association, 1992) apply "in spades" to research on sexuality. Due to the personal nature of the inquiry, researchers must be sensitive to the concerns of research participants to ensure both the confidentiality of the data and the comfort and well-being of participants. Particularly important is the clear and understandable description of the details concerning genital response measurement, presentation of sexual stimuli, and of any collection of information concerning sexual practices or attitudes. Thus, participants in sex research are told a great deal about the nature of the studies they take part in, and the effects of this approach are not clear. Amoroso and Brown (1973), in a study on demand characteristics in sex research, found that participants attached to electrical recording devices rated stimuli as more erotic than participants rating the same stimuli outside the laboratory. In another study, Hicks (1970) found that experimenter moods and behaviors influenced both physiological records and subjective reports.

To prevent disease transmission, genital devices should be cleaned using disinfectants such as glutaraldehyde (e.g., Cidex Plus) or ortho-phthalaldehyde (e.g., Cidex OPA). These disinfectants function, depending on how long the devices are immersed, as low- or high-level disinfectants or sterilants. Genital measurement devices require a minimum of high-level disinfection, which destroys all pathogenic microorganisms (bacteria, fungi, and viruses) except for endospores. High-level disinfection has been found to kill Herpes Simplex-II (Morokoff, Myers, Hay, & Flora, 1988), but it is unclear whether it also kills Human Papillomavirus (HPV). Until evidence documents the effectiveness of such cleaning agents in destroying HPV, we recommend a prewash with sodium dodecyl sulfate (SDS). SDS is a common component in shampoo (where it is often

listed as sodium lauryl sulfate) that has been shown to kill both HIV and HPV (Howett et al., 1999). Another goal of cleaning is to prevent tissue (e.g., vulvar) irritation. Tissue irritation can result from contact with disinfectants if they are not carefully rinsed off with sterile water.

3.1.2. Volunteer biases

A number of studies have explored differences between volunteers and nonvolunteers for sexuality studies. Differences have been found in sexual experience, frequencies of sexual activity, sex guilt, exposure to erotic materials, and sexual attitudes (e.g., Bogaert, 1996; Morokoff, 1986; Plaud et al., 1999; Strassberg & Lowe, 1995; Wiederman, 1999; Wolchik, Braver, & Jensen, 1985). Some of these studies found psychophysiological studies to be the most susceptible to volunteer biases. However, other studies have failed to find differences between volunteers and nonvolunteers for sex research on personality traits such as extraversion and neuroticism (Farkas et al., 1978), social desirability (Wolchik et al., 1983), and religiosity (Wiederman, 1999). Furthermore, in most cases, the differences that have been found are relatively small. Perhaps more important than differences in averages, however, is whether the *range* of relevant behaviors, attitudes, or experiences is represented in a volunteer sample. For example, Laan and Everaerd (1995), in a meta-analysis of psychophysiological studies involving approximately 300 women, found that 22% of participants had experienced some form of sexual abuse, a proportion similar to that found in the general population. Characteristics of volunteers may, even within a study, affect some variables but not others. Saunders et al. (1985), for example, found volunteer effects on negative affect in response to sexual films, but not on self-reported sexual arousal. Ultimately, the question is not whether differences exist between volunteers and nonvolunteers, but whether such differences influence the validity of our findings and conclusions. That is, the real question is whether the factors responsible for nonparticipation are related to the variables of interest (cf. Tourangeau, 2004).

3.2. Response agreement and within- vs. between-participant designs

A common finding in psychophysiological sex research is that correlations between subjective and genital responses are lower in women than in men (e.g., Laan & Everaerd, 1995). This has lead researchers to speculate about possible gender differences in the role of genital feedback in subjective sexual arousal (e.g., Laan and Janssen, *in press*). Although correlations tend to be higher in men than in women, discordant response *patterns* have been found as frequently in men. An increasing number of studies have shown that experimental manipulations may modify men's degree of erection although not affecting their subjective sexual arousal (Bach, Brown, and Barlow, 1999; Delizonna et al., 2001; Janssen & Everaerd, 1993; Lankveld and v. d. Hout, 2004). Such findings challenge the notion that

subjective sexual arousal in men is strongly influenced by feedback from (changes in) their genitals. Thus, although researchers are largely focusing on the possible explanation of gender differences in correlations between response levels, discordant response *patterns* occur in both men and women, and are not well understood.

Most commonly, correlations between genital and subjective measures of sexual arousal are evaluated in a between-participant design. In this approach, the data used for the computation of correlations are collected across a set of subjects. The resultant statistic reflects the degree to which the two measures covary to a single stimulus presentation. It tells us nothing about individual differences in the relationship between genital and subjective feeling states. In addition, this approach is especially problematic with VPA, a signal that has a relative scale and cannot be calibrated at present, complicating the interpretation of between-subject correlations. Using standardized scores may be an improvement, but this approach forces a normal distribution upon the data and implies linearity of changes that may or may not exist. Although within-participant approaches give us more information about covariance between physiological and subjective responses, they suffer from the problem that response levels will vary from person to person, leading to differences in the range covered by the data. Korff and Geer (1983) applied a within-participant approach that is less sensitive to this problem. Instead of calculating within-participant correlations using the data collected during one sexual stimulus, they computed correlations between stimulus intensity (photos varying in erotic value) and genital change in women. They found, using that methodology, very high within-participant correlations. Within-participant designs also permit the use of the relationship as a dependent variable, allowing researchers to explore how the relationship itself may vary across conditions or individuals.

3.3. Range of applications

Psychophysiological methods are being employed in the exploration of an increasingly broad array of basic and applied questions. The topics include the relationship between subjective and physiological sexual arousal; the interaction between sexual arousal and other emotional states; the activation and inhibition of sexual response; the habituation and conditioning of sexual arousal; the psychophysiology of sexual motivation, desire, and orgasm; the effects of drugs, hormones, and aging on sexual responsiveness; the association between sexual orientation and sexual arousal; and the effects of exposure to erotica or pornography on sexual attitudes and behavior. On a more applied level, sexual psychophysiology is used in studies focusing on the detection and diagnosis of sexual dysfunctions and problematic sexual preferences (e.g., pedophilia), and on the assessment of the effectiveness of pharmacological and psychological treatments. Rather

than attempt to review all research areas (for a collection of reviews, see Janssen, *in press*) we will briefly discuss two categories of clinical psychophysiological research.

3.3.1. Applications concerning arousal and response problems

One of the earliest applications of genital response measurement involves the diagnosis of erectile dysfunction. One of the central questions in the differential diagnosis of erectile dysfunction is to what degree the problem stems from peripheral (e.g., vascular, neurological) problems. Two types of psychophysiological paradigms have been used to evaluate men with erectile dysfunctions. The waking erectile assessment (WEA) approach involves the presentation of erotic stimuli and the determination of whether a normal penile response occurs. The other approach consists of recording erections during sleep to determine if normal nocturnal penile tumescence (NPT) occurs. Sakheim et al. (1985) reported 80% diagnostic accuracy in identifying functional versus organically impaired men using a waking assessment paradigm. Janssen et al. (1994a), found similarly high predictive values using a procedure in which patients were presented with combinations of visual, tactile, and cognitive stimuli.

Although early studies in men with premature ejaculation failed to find evidence for atypical response patterns, more recent studies have both confirmed and challenged some assumptions about the mechanisms involved in ejaculatory problems (see for review, Rowland, Tai, & Brummett, *in press*). For instance, rapid ejaculation in men with premature ejaculation occurs mainly in response to (vibro) tactile genital stimulation, not to erotic stimulation in general. Also, subjective sexual arousal levels are not higher in men with premature ejaculation than in sexually functional men, suggesting that the former are not "hyperaroused," although heart rate during sexual stimulation tends to accelerate in men with premature ejaculation, although it decelerates in sexually functional controls, suggesting that differences in autonomic control exist between men with and without premature ejaculation. Less is known about inhibited or retarded ejaculation.

Vaginal photoplethysmography (see section 4.1.2.3.) does not consistently differentiate women with and without sexual problems (Morokoff & Heiman, 1980), nor is it clear that it should because the measure is relative. However, some researchers have documented reduced VBV for women with arousal problems (Palace & Gorzalka, 1990; Wincze, Hoon, & Hoon, 1976), reported reduced VPA during penetration film clips for women with dyspareunia (Wouda et al., 1998), identified women with sildenafil-responsive arousal and orgasm problems (Basson & Brotto, 2003), predicted orgasm latency (Laan & van Lunsen, 2002), and identified radical hysterectomy patients with extensive vaginal deenervation (Maas et al., 2004).

Individual differences in the relationship between genital and subjective sexual responses may increasingly become a focus in the development and evaluation of interventions for sexual problems in women. Drugs like sildenafil have been found to increase genital blood flow, although not necessarily affecting subjective sexual arousal in women. New pharmacological interventions are being developed that target central mechanisms, including dopamine agonists to increase sexual desire (Bechara, Bertolino, Casabe, & Fredotovich, 2004; Beharry, Hale, Wilson, Heaton, & Adams, 2003; Caruso et al., 2004; Everaerd & Laan, 2000, see also Rosen et al., *in press*). However, some of the effects of these agents resemble those of addictive substances and this warrants caution. More importantly, considering the variable relationship between subjective and genital sexual responses in women, the development of any type of treatment, ideally, should involve the evaluation of both genital and subjective responses.

3.3.2. Applications concerning specific object preferences

The second type of clinical application involves sexual object preferences. Psychophysiological methods have been used to both diagnose and track the progress of treatment of individuals whose sexual preferences involve adolescent or preadolescent children (e.g., Seto, 2001, *in press*). Although adult men with no pedophilic preferences can show sexual arousal to pedophilic stimuli (e.g., Hall, Hirschman, and Oliver, 1995), the use of psychophysiological methods within clinical samples has been found to have high predictive validity. Recent meta-analyses found that genital response to depictions of children was the single best predictor of sexual offense recidivism, exceeding all other indicators of sexual deviancy and any developmental, personality, or demographic variable (Hanson and Bussiere, 1998; cf. Kuban et al., 1999; Seto, 2001).

Similarly, sexual aggressive men and rapists have been studied using psychophysiological methods. Barbaree et al. (1979) reported significant correlations between a statistic obtained by dividing the percent of erection to rape cues by the percent of erection to cues of consenting heterosexual activity and the frequency of previously reported rapes as well as with the tendency to commit violent rapes. Lohr, Adams, and Davis (1997) reported that whereas men with sexually coercive histories showed greater penile responding to coercive cues, males with no history also yielded some arousal to those same cues. Similarly, Janssen et al. (2002) found that male college students with no history of offending who scored low on a measure of sexual inhibition proneness, showed erectile responses to depictions of rape that were indistinguishable from their responses to consensual sexual films. These findings make clear the fact that arousal to a particular stimulus category does not necessarily correspond with behavior. In women there are reports of rape victims responding with vaginal lubrication and even orgasm during a sexual assault (Levin and van Berlo, 2004). Laan et al. (1994) found that women

responded equally with genital arousal to male- versus female-oriented erotica even though the women reported that they found the female-oriented erotica more arousing. Again, care must be taken before one accepts genital responding as the “golden rule” of sexual arousal, and thus sexual object preference. Sexual arousal, as is true for other emotional states, is a complex phenomenon that expresses itself in multiple response systems that are not always closely tied together.

4. INFERENTIAL CONTEXT

4.1. Mensuration and quantification

The following discussion will not cover all possible measures but will only include those that are most widely used.

4.1.1. Male genital measurement devices

The first to measure genital response in men was a simple electromechanical transducer (Ohlmeyer, Brilmayer, & Hullstrung, 1944) that provided a binary signal of the presence or absence of erection. Current research in male sexual arousal relies primarily on continuous measures of penile volume, circumference, and rigidity.

4.1.1.1. Volume. Freund (1963) developed an air volumetric plethysmograph. Less widely used variants of this technique have been described by Fisher et al. (1965), who used water instead of air, and McConaghay (1976). The plethysmograph is positioned on the participant by the experimenter, who places a sponge-rubber ring and plastic ring with an inflatable cuff over the penis. A glass cylinder with a funnel at the top is fitted over the other components, and the cuff is inflated with air. Changes in the size of the penis result in displacement of air, which can be detected by a pressure transducer.

Volumetric devices can be calibrated in terms of absolute penile volume and have the advantage of offering high sensitivity. A limitation of this technique, however, is that it does not allow for the determination of the source of change (e.g., circumference or length). In addition, the apparatus is relatively complex, cumbersome, and sensitive to temperature and movement artifacts.

4.1.1.2. Circumference. Originally described by Fisher and colleagues (1965), the first circumferential measure, the mercury-in-rubber strain gauge, was adapted from a similar transducer used by Shapiro and Cohen (1965). The device consists of a hollow rubber tube filled with mercury and sealed at the ends with platinum electrodes. The operation of the mercury-in-rubber strain gauge depends upon penile circumference changes that cause the rubber tube to stretch or shorten, thus altering the cross-sectional area of the column of mercury within the tube. The resistance of the mercury inside the tube varies directly with its cross-sectional area, which in turn is reflective of changes in the circumference of the penis. Variations of the

mercury-in-rubber gauge have been described by Bancroft et al. (1966), Jovanovic (1967), and Karacan (1969).

Another type of penile strain gauge is the electromechanical strain gauge developed by Barlow and co-workers (1970). This device is made of two arcs of surgical spring material joined with two mechanical strain gauges. These gauges are flexed when the penis changes in circumference, producing changes in their resistance. The resistance changes are in turn coupled through a bridge circuit to a polygraph or computer. The electromechanical gauge does not fully enclose the penis. For this reason, it is more sensitive to movement artifacts and less suitable for studies on nocturnal penile tumescence (NPT) than the mercury-in-rubber gauge. However, mechanical strain gauges are quite sensitive and more rugged than their rubber counterparts. Both types of strain gauge are available from Behavioral Technology, Inc. (Salt Lake City, Utah) and the rubber strain gauge is also manufactured by Hokanson, Inc. (Bellevue, Washington).

4.1.1.3. Comparison studies on volume and circumference measures.

Freund, Langevin, and Barlow (1974) compared the volumetric device with Barlow's electromechanical strain gauge. They presented a group of men slides of male and female nudes. Their results indicated that volumetric plethysmography is more sensitive to changes in penile tumescence. However, considering the type and number of stimuli used, and the absence of a check for habituation, their conclusion most likely pertains to relatively low response levels. McConaghy (1974) compared his adaptation of the volumetric device with a mercury strain gauge. He showed his subjects 10-second shots of male and female nudes that were inserted in a neutral film. In his paper he provides some example recordings, but no statistical analyses. In 1987, Wheeler and Rubin compared the mercury gauge and Freund's volumetric device, using erotic film excerpts, in 6 subjects. In contrast to Freund et al. (1974), they did not find any evidence for a higher sensitivity of the volumetric device. In addition, the authors reported that the volumetric device was more difficult to use and displayed more artifacts than the strain gauge (however, they did not use an inflatable cuff, Kuban et al., 1999). The absence of systematic differences in Wheeler and Rubin's (1987) study may due to the possibility that their film stimuli induced higher response levels than the slides used by Freund and colleagues.

More recently, Kuban et al. (1999) compared the mercury gauge and volumetric device in 42 heterosexual men who were presented with sexual slides and audiotaped narratives. They found that the two devices were comparable at 'high' response levels (>2.5 mm circumference change), where correlations exceeded .80. In contrast, correlations were nonsignificant at lower response levels, where only the volumetric device differentiated responses to images of adult and pubescent females from other (prepubescent) stimuli. Unfortunately, Kuban et al.'s (1999) conclusions were based on between-participant comparisons of low

and high responders, instead of on low and high (i.e., within-participant) response *levels*. Undetermined differences between the two groups (e.g., in attitudes or experience) may have contributed to the findings, rendering as premature the authors' suggestion that lower circumferential responses may be less valid.

Due to the ease of their use, penile strain gauges have remained relatively popular in laboratory use (e.g., Bach et al., 1999; Delizonna et al., 2001; Hoffmann et al., 2004). A number of in vitro studies have shown that both the mercury-in-rubber and the electromechanical strain gauge demonstrate linear outputs, high test-retest reliability, high stability over time, and minor sensitivity to temperature (e.g., Karacan, 1969; Farkas et al., 1979; Earls and Jackson, 1981; Richards et al., 1985; Richards et al., 1990; Janssen et al., 1997). Nowadays, the mercury-in-rubber strain gauge is also available in versions filled with an indium-gallium alloy, which is considered to be even less sensitive to temperature than mercury (Richards et al., 1985).

A potential concern with the use of circumferential measures is the suggestion that penile circumference may show a slight decrease at the onset of sexual arousal (McConaghy, 1974; Abel et al., 1975; Laws and Bow, 1976; see also Kuban et al., 1999). A brief decrease in circumference may represent a problem in that it may be incorrectly interpreted as a decrease in sexual response. Further, it has also been noted that strain gauges may be unreliable at the upper end of the tumescence curve (Earls et al., 1983). This may represent a limitation if the measures are to be used for determining the full range of erectile capacity.

Laws (1977), who was the first to compare the two strain gauges *in vivo*, found discrepancies in measurement with the two devices. Unfortunately, he obtained data from only one participant. Janssen et al. (1997) compared the two penile strain gauges, using indium-gallium instead of mercury for the rubber gauge, in a group of 25 sexually functional men. In addition, they compared two different calibration methods, using a circular and an oval shaped device. The electromechanical gauge calibrated on the circular device reported greater circumference changes. Circumference changes were not different when the oval calibration device was used. In addition, the findings suggested that the electromechanical gauge is more sensitive to changes in penile circumference during initial stages of erection than the rubber gauge, a conclusion that is consistent with earlier in vitro findings (Earls and Jackson, 1981; Richards et al. 1985), and that should be taken into consideration when comparing the advantages and disadvantages of volumetric and circumferential measures (cf. Kuban et al., 1999 and Wheeler and Rubin, 1987, who compared volumetry with the mercury-in-rubber gauge).

4.1.1.4. Rigidity.

One of the first attempts to measure penile rigidity was made by Karacan et al. (1978), who reported the use of "buckling pressure" as a dependent variable in penile responding. This method uses a device that measures the axial force required for the bending

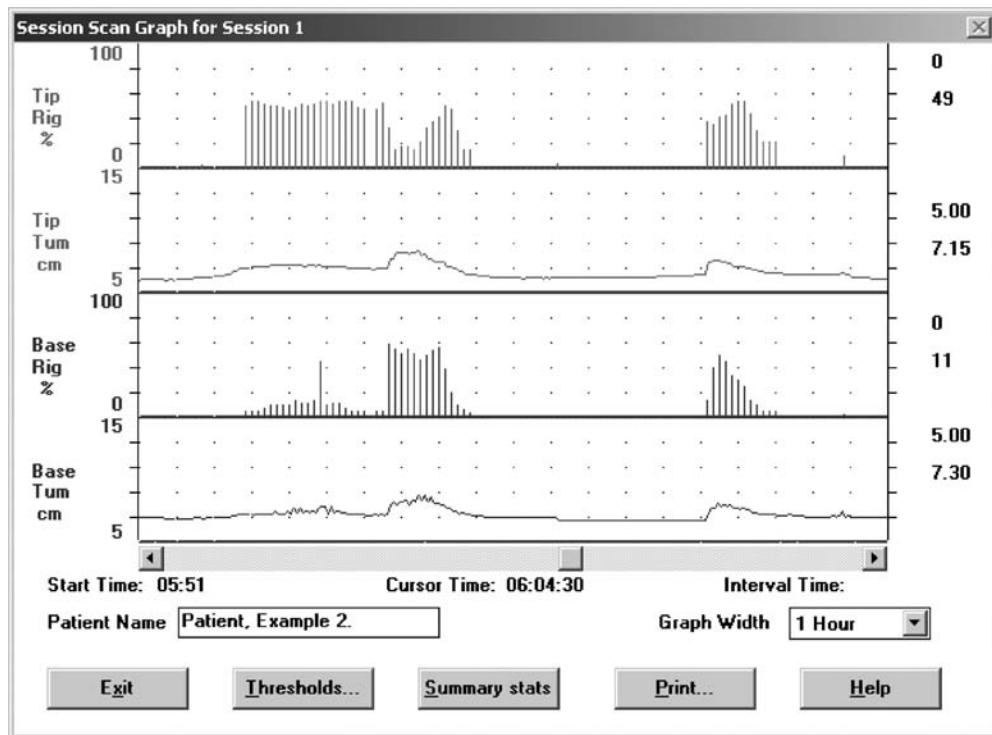

Figure 11.1. Example of output of the RigiScan. The vertical lines represent rigidity and the continuous ones penile circumference as measured at the base (bottom two signals) and the tip (top two signals) of the penis.

of the penis. Although it is mainly used in clinical studies (e.g., Goldstein et al., 2000), and has some predictive value, basic information on the validity and reliability of this method is still largely absent (Schiavi, 1992). Also, the rationale that is typically provided for preferring the measurement of axial over radial rigidity (i.e., intercourse involves mostly axial forces), though sensible, lacks an empirical basis. Other noncontinuous, discrete methods for indexing rigidity include stamp tests, the Snap Gauge, and the Erectiometer (Slob et al., 1998).

Bradley and Timm (1985) first described the RigiScan Plus monitor (Timm Medical Technologies, Eden Prairie, MN), an instrument designed to measure continuously both circumference and radial rigidity, and that can be used in real-time or ambulatory mode. The device consists of a recording unit, that can be strapped around the waist or thigh, and has two loops, one that can be placed around the base of the penis and the other just behind the corona. Each loop contains a cable that is tightened at discrete time intervals. Circumference is measured at 15-second intervals. The RigiScan takes its first rigidity measure when a 20% increase in circumference is detected. This is repeated every 30 seconds (see Figure 11.1). To measure rigidity, the loops tighten a second time after circumference is measured, with a force of 2.8 Newton.

The RigiScan represents the first practical measure of continuous rigidity, and has gained wide acceptance, particularly in clinical research. However, there are no published data on the test-retest reliability of the RigiScan.

Information on the reliability of the device over longer periods of usage is pertinent because in contrast to strain gauges, where routine calibration allows for the test of linearity over time and where replacement is viable, a RigiScan is typically used for a number of years. The importance of developing a calibration method for the RigiScan is stressed by the finding of Munoz, Bancroft, and Marshall (1993) that different RigiScan devices can record different degrees of rigidity. In their study, Munoz et al. (1993) developed a system that provided a relatively constant circumference with variable rigidity. Using this system they found that the RigiScan underestimated circumference, in particular at lower levels of rigidity. This finding was confirmed by a comparison between the performance of the RigiScan and a mercury-in-rubber strain gauge in the measurement of NPT (Munoz et al., 1993).

The measurement procedure used by the RigiScan also raises questions about its potential reactivity. The extent to which the tightening of the loops may induce or modify sexual responses has not been assessed. Relevant to this, Munoz et al. (1993) found fewer NPT episodes in a group of men with erectile problems when a mercury-in-rubber strain gauge was used together with a RigiScan as compared to nights during which only a strain gauge was used.

The two main arguments in support of the development and usage of rigidity measures have face validity: (1) Penile circumference is not a reliable predictor of rigidity, and (2) rigidity is the ultimate, behaviorally relevant measure of erectile capacity. Regarding the first assertion,

two studies have been cited frequently. Wein and associates (1981) reported that significant changes in penile circumference occurred in 23% of normal control patients without sufficient increases in rigidity for vaginal penetration. Earls et al. (1988) reported finding discrepancies in circumference and participants' perception of erectile sufficiency for intromission. Wein et al. (1981), however, based their conclusions on the measurement of buckling force, which lacks proper validation (Schiavi, 1992). As for the second study, it is well established that the perception of erectile responses is biased in patient groups (Sakheim et al., 1987; Janssen and Everaerd, 1993). More importantly, however, with the availability of the Rigiscan, studies would be expected to test the relationship between circumference and rigidity. Remarkably, only one study to date has explored the relationship between the Rigiscan's base and tip circumference and rigidity measures (Levine and Carroll, 1994), and found correlations of $r = .87$ and $r = .88$, respectively.

Regarding the second issue, the key problem in erectile dysfunction is considered to involve a lack of rigidity (e.g., Giesbers et al., 1987). However, the question of what level of rigidity is sufficient has not yet been answered. Wabrek et al. (1986) and Wagner et al. (1986) gathered normative data on vaginal penetration pressure and found that it varied among positions (e.g., supine versus kneeling) and that it was lower during conditions of sexual stimulation. These studies indicate that, at present, any clinical criterion for deciding whether an erection is sufficiently rigid for penetration is a predictor, rather than an absolute measure, of erectile functionality in interactions with a partner.

4.1.1.5. Other measures of genital response in men. Less widely used measures involve the assessment of penile temperature, penile arterial pulse amplitude, and penile EMG. Thermistor devices have been designed to detect temperature changes that may accompany penile tumescence. Solnick and Berrin (1977) found a relatively high concordance between temperature changes and penile circumference. Webster and Hammer's results (1983) supported their findings.

Bancroft and Bell (1985) developed a reflectance photometer for the measurement of penile arterial pulse amplitude. The components of this device are similar to those used in the vaginal photometer, described later. It has been suggested that penile pulse amplitude may provide an index of arterial inflow related to generalizable penile tumescence (Rosen and Beck, 1988). However, the currently available data are insufficient to warrant a judgment on the usefulness of the penile photometer.

Wagner and Gerstenberg (1988) first described electrical activity in the cavernous tissues of the penis, using needle electrodes, and found that the perception of visual sexual stimuli resulted in decreased smooth muscle activity (Wagner & Gerstenberg, 1988; Gerstenberg et al., 1989; Wagner et al., 1989). Although one of the most sensitive measures of male genital response at present, the reliabil-

ity of the technique is still controversial. Various investigators have failed to reproduce the original findings. More problematic, however, is that the interpretation of the signal is hampered by the lack of information on its characteristic features and by the absence of standardized recording techniques. The recording of penile EMG is susceptible to sources of interference such as pelvic and penile muscle contractions, cross-talk due to cardiac action, and respiration (Jüneman et al., 1994). The non-invasive alternative, using surface electrodes, has been less well studied and also may be expected to be sensitive to interference. However, work on a consensus in measuring penile EMG is in progress and recommendations have been made for research that could increase our understanding of the electrophysiology of the corpora cavernosa (Sasso et al., 1997; Jiang et al., 2003).

4.1.2. Female measures

One of the first devices designed to measure female physiological sexual arousal recorded vaginal pH, as an indicator of lubrication (Shapiro et al., 1968). This method proved technically difficult and intrusive (Berman et al., 2001; Wagner & Levin, 1978) and researchers tended to document inconsistent and highly localized pH changes (Wagner & Levin, 1984). A second device, a mechanical strain gauge, was developed to measure clitoral enlargement in women with enlarged clitori from congenital adrenal hyperplasia (CAH), but the device has not been tested in nonclinical samples (Karacan, Rosenbloom, & Williams, 1970). A third, balloon-like device was developed to measure uterine contractions (Bardwick, 1967; Jovanovic, 1971), and another one for vaginal pressure (Berman et al., 2001), but the uterine device proved problematic because its placement could be painful and the device was occasionally extruded (Rosen and Beck, 1988). More recently, researchers are attempting to quantify clitoral blood flow and clitoral size changes using Doppler ultrasonography (Bechara et al., 2004; Khalifé & Binik, 2003; Munarriz, Maitland, Garcia, Talakoub, & Goldstein, 2003). Although the measurements appear to be reliable across analysts (Berman et al., 2001), currently the method requires a technician to hold the device in place during measurement (Khalife, Binik, Cohen, & Amsel, 2000). Finally, researchers are exploring the utility of electromyography, with concentric needle electrodes, in evaluating clitoral autonomic innervation and genital sensitivity (Yilmaz, 2002, 2004). However, further research is needed to further establish its validity and to determine the role of genital sensitivity in sexual arousal.

4.1.2.1. Oxygenation and thermal clearance. Levin and Wagner (1978) described a method in which a heated oxygen probe is used to detect changes in oxygen pressure (pO_2) in the vaginal wall. The device consists of an oxygen electrode and a suction cup that is held on the vaginal wall by a partial vacuum generated in the cup. It is assumed that the more blood present in the tissues, the greater

the amount of oxygen will be perfused across the vaginal epithelium. Using this device, it is possible to reliably determine the level of oxygen in the blood of the tissues located beneath the device. The actual dependent variable used is pO₂, which is expressed in millimeters mercury.

The same device can also measure heat dissipation into the tissues under the transducer. This approach measures the amount of energy (e.g., milliwatts) that is required to keep the temperature of a heated thermistor constant. The heated oxygen probe has contributed to our understanding of the mechanisms underlying genital response in women (Levin, 1992) and the technique has been replicated (Sommer, 2001). An advantage of the device is that it is relatively free of movement artifacts. Disadvantages are the intrusiveness of the procedure and the need to limit duration of measurement sessions to protect the vaginal mucosa from damage from heat and suction needed to hold the device in place (Levin, 1992).

4.1.2.2. Temperature. Fisher and Osofsky (1968) and Fisher (1973) used a thermistor to measure vaginal temperature and found that vaginal temperature reflects core temperature and is relatively insensitive to changes in sexual arousal. Fugl-Meyer, Sjogren, and Johansson (1984) described a radiotelemetric method for measuring vaginal temperature, using a battery-powered transducer mounted on a diaphragm ring. They reported decreases in vaginal temperature, measured during masturbation and intercourse, that were speculated to be the result of vaginal wall edema during sexual arousal (Wagner and Levin, 1978). Advantages of the device include its usability in natural settings. However, in view of the conflicting reports, replication is needed to establish the value of vaginal temperature as a measure of sexual arousal.

Henson et al. (1978) designed a transducer for measuring labial temperature. One thermistor monitors ambient room temperature, another monitors changes in skin temperature at an extragenital site, and a final thermistor is attached to the labia minora using a brass clip. Labial temperature of 9 of the 10 participants in Henson et al.'s study (1978) increased in response to an erotic film. Slob et al. (1990) and Slob et al. (1991) also found an increase in labial temperature in the majority of participants during the presentation of erotic stimuli. Slob et al. (1990) compared women with and without diabetes mellitus and found initial labial temperatures to be lower in the diabetic women. Differences between the two groups disappeared when participants were matched on initial labial temperature.

4.1.2.3. Vaginal and labial pulse amplitude/blood volume. The most widely used method for monitoring genital responses in women is vaginal photoplethysmography. This technique uses a vaginal photometer, originally used by Palti and Bercovici (Palti & Bercovici, 1967) and refined by Sintchak and Geer (1975) and Hoon, Wincze, and Hoon (1976). The device, made by Behavioral Technology, Inc.

(Salt Lake City, Utah), is made of clear acrylic plastic and is shaped like a menstrual tampon. Embedded in the front end of the probe is a light source that illuminates the vaginal walls. Light is reflected and diffused through the tissues of the vaginal wall and reaches a photosensitive cell surface mounted within the body of the probe. Changes in the resistance of the cell correspond to changes in the amount of back-scattered light reaching the light-sensitive surface. It is assumed that a greater back-scattered signal reflects increased blood volume in the vaginal blood vessels (Levin, 1992). Hoon et al. (1976) introduced an improved model of the vaginal photometer that substituted an infrared LED (light-emitting diode) for the incandescent light source and a phototransistor for the photocell. These innovations reduced potential artifacts associated with blood oxygenation levels, problems of hysteresis, and light history effects. The vaginal photometer is designed so that it can be easily placed by the participant. A shield can be placed on the probe's cable so that depth of insertion and orientation of the photoreceptive surface is known and held constant (Geer, 1983; Laan, Everaerd, & Evers, 1995).

The photometer yields two analyzable signals. The first is the DC signal, which is thought to provide an index of the total amount of blood (Hatch, 1979), often abbreviated as VBV (vaginal blood volume). The second is the AC signal, often abbreviated as VPA (vaginal pulse amplitude), which is thought to reflect phasic changes in the vascular walls that result from pressure changes within the vessels (Jennings et al., 1980; see Figure 11.2). Although both signals have been found to reflect responses to erotic stimuli (e.g., Geer, Morokoff, & Greenwood, 1974; e.g., Hoon, Wincze, & Hoon, 1976), their exact nature and source is unknown. Heiman et al. (2004) compared, in 12 women, VPA and genital volume changes as measured using MRI, and found no significant correlations between the two. Heiman and Maravilla (in press) suggested it may be possible that at moderate levels of arousal the vaginal probe might detect changes to vaginal tissue that do not correspond with other genital blood volume changes. (Interestingly, however, the same study reported higher correlations with subjective sexual arousal for VPA than for MRI variables.) The interpretation of the relationship between the photometer's output and the underlying vascular mechanisms is hindered by the lack of a sound theoretical framework (Levin, 1992) and of a calibration method allowing transformation of its output in known physiological events. At present, most researchers describe their findings in relative measures, such as mm pen deflection or change in microVolts. Levin (1997) stated that one of the basic assumptions underlying use of the plethysmograph is that changes in VBV and VPA always reflect local vascular events. In his discussion of findings from studies on the effects of exercise and orgasm on VBV and VPA, however, he suggests that the signals are likely to reflect rather complex interactions between sympathetic and parasympathetic regulatory processes and between circulatory and vaginal blood pressure. However, Prause et al. (2005) found that, whereas VPA

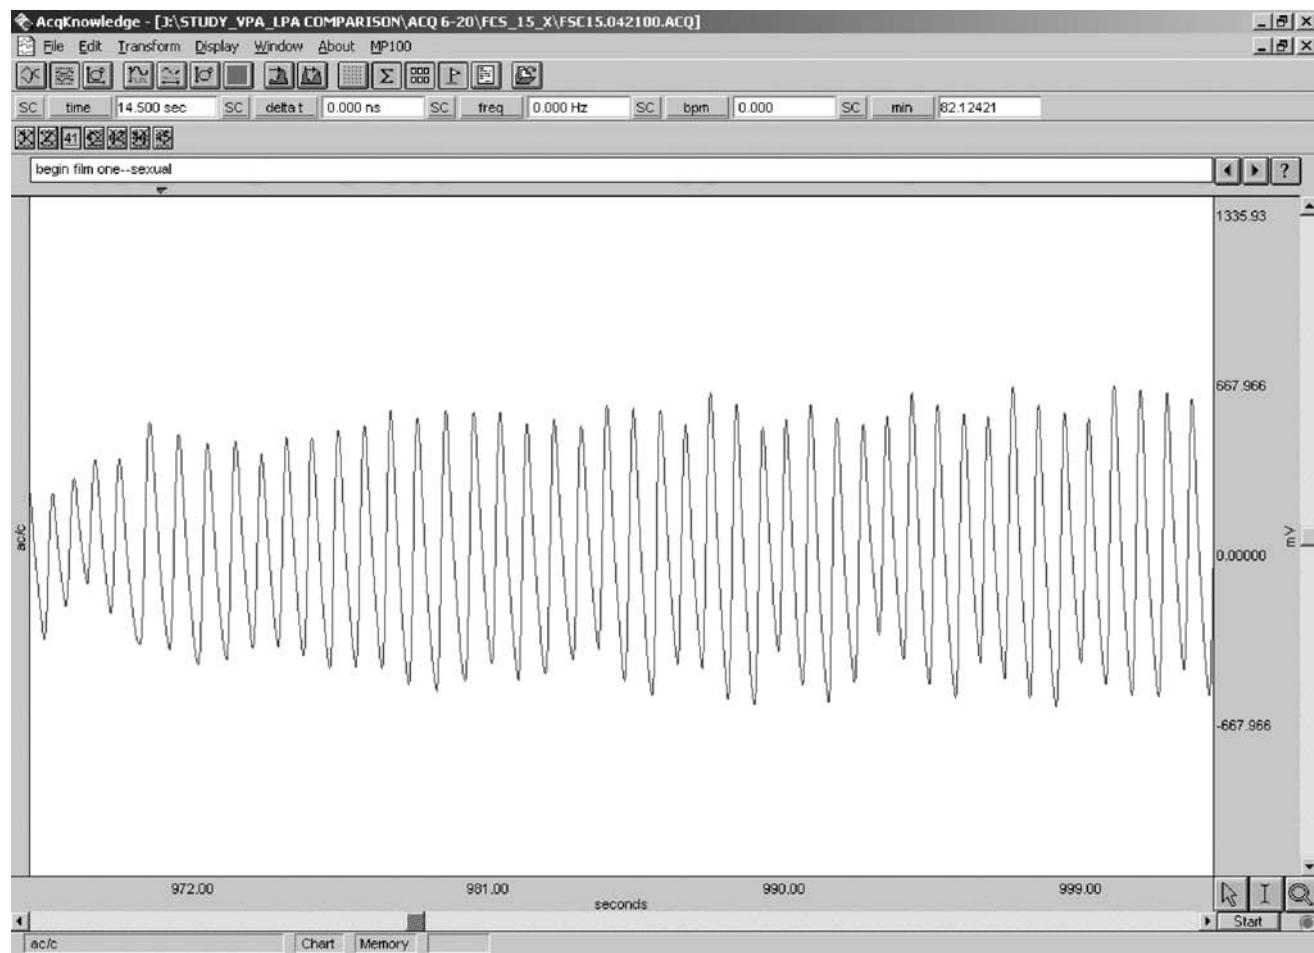

Figure 11.2. Example of a Vaginal Pulse Amplitude (VPA) signal obtained from the vaginal photoplethysmograph.

discriminated between sexual, sexually threatening, and threatening film stimuli, blood pressure (while increased during all three conditions) did not.

The construct validity of VPA is better established than that of VBV. Researchers have reported high correlations between VPA and VBV, particularly with stronger sexual stimuli, but others have found low or no concordance between the two signals (Heiman, 1976; Meston and Gorzalka, 1995). VPA appears to be more sensitive to changes in stimulus intensity than VBV (Geer et al., 1974; Osborn & Pollack, 1977). VPA also corresponds more closely with subjective reports of sexual arousal than VBV (Heiman, 1977). Finally, VBV changes in response to increases in *general* arousal, indicating that VBV is less specific to sexual arousal than VPA (Laan, Everaerd, & Evers, 1995). Two studies have directly assessed the sensitivity and specificity of VPA (Laan et al., 1995; Prause, Cerny, & Janssen, 2005). Both studies measured responses of sexually functional women to sexual, anxiety inducing, sexually threatening, and neutral film excerpts, and found maximal increases in VPA to the sexual stimulus and moderate increases to the sexually threatening film. (Participants also reported intermediate levels of sexual arousal to the sexual-threat stimulus.) On both studies, VPA did

not increase in response to anxiety-inducing stimuli. These results demonstrate response specificity of vaginal vasocongestion to sexual stimuli.

The study by Prause et al. (2005) included the comparison of VPA with a new measure of genital blood flow, the labial photoplethysmograph. Labial pulse amplitude (LPA), as measured by the labial photoplethysmograph, exhibited a degree of specificity to sexual stimuli that was similar to that found for VPA. Additionally, the labial photoplethysmograph demonstrated greater resistance to movement artifacts and a slightly higher correspondence with subjective measures of sexual arousal. Because it is worn externally, researchers can verify the placement of the device by visual inspection. The labial photoplethysmograph, though somewhat more difficult to place and less comfortable than its vaginal counterpart, warrants further development.

4.1.2.4. Comparison studies on temperature and pulse amplitude/blood volume. The literature comparing genital response measures in women is scant. Only one study has compared the measurement of vaginal temperature with vaginal blood flow (Gillan & Brindley, 1979).

However, that study used an atypical photometer (with more than one photocell). No studies have been published on the direct comparison of heat oxygenation and vaginal plethysmography. In contrast, various studies have been reported on the relationship between labial temperature and vaginal blood flow. Henson and Rubin (1978) and Henson, Rubin, and Henson (1982) compared changes in VBV and labial temperature in response to sexual films. Both measures were found to increase during stimulation, although there were large individual differences. Henson and Rubin (1978) found a low, nonsignificant correlation between VBV and labial temperature. Further, only correlations between labial temperature and subjective arousal were significant, leading to the suggestion that physiological changes in the labia might be more easily perceived than intravaginal changes. Although vaginal responses tended to decrease more quickly after stimulus presentations, neither instrument returned to pre-stimulus baseline levels.

In two other studies, C. Henson, Rubin, and Henson (1979) and D. Henson, Rubin, and Henson (1979) compared labial temperature with both the VPA and VBV signals of the vaginal plethysmograph. D. Henson et al. (1979) determined that, although there was considerable intrasubject consistency in response patterns and amplitudes across two recording sessions, labial temperature was the most consistent on both parameters. In the second study, C. Henson et al. (1979) found high correlations between subjective arousal and both VPA and labial temperature changes. VBV correlated less strongly with subjective arousal and returned to baseline more slowly than either VPA or labial temperature.

With respect to the advantages and disadvantages of each device. D. Henson et al. (1979) noted that ambient temperature control is a requirement for use with the labial clip but not with the vaginal transducer. In contrast, movement artifacts are more common with the vaginal probe, and reliable measurement with the thermistor is not precluded by the menses (there are, as yet, no published reports of vaginal photometer readings during menses). Levin (1997) asserted that the output of the vaginal measure, and in particular VBV, is readily invalidated because the photometer can slide over the lubricated epithelium, illuminating new areas of tissue.

Another important difference between the two devices is that the labial thermistor uses an absolute unit of measurement ($^{\circ}\text{C}$), whereas changes in vaginal blood flow are relative. Further, it is not yet known to what extent factors related to individual variations in anatomy and to physiological characteristics, such as resting levels of vaginal muscular tone and vaginal moistness, may affect the amplitude of the vaginal blood flow signal. Finally, although sensitivity of the probe to temperature appears to be minimal, it is in fact the temperature of the light source that is most often a concern. It is not implausible that vaginal temperature itself can alter the probe's output, thus confounding the data (Beck, Sakheim, & Barlow, 1983).

Rogers et al. (1985), in a study on genital responses during sleep, used a measure of integrated VPA and muscle-contraction pressure, which enabled the detection of movement and muscle contractions. It may prove valuable to extend the current design of the vaginal plethysmograph with additional measures of muscle-contraction pressure and temperature.

4.1.3. Cross-sex measurement devices

The desire to directly compare sexual responses in men and women has been the impetus for the development of several measurement devices. Unfortunately, the challenge reaches beyond the mere development of a measure that can be used in similar locations, and is complicated by differences in the innervation and vascularization of the male and female genitalia.

4.1.3.1. Anal blood flow and muscle activity. Bohlen and Held (1979) described a device to monitor intra-anal pressure changes and pulse waves. The design of the probe was based on the observation that genital changes associated with the experience of sexual arousal are a result of increased blood volume and muscle tension throughout the pelvic area (Masters and Johnson, 1966). The device consists of a photometer and pressure transducer encased in a silicone rubber body. An adaptation of this design was used by Carmichael et al. (1994) to measure anal electromyographic activity and blood flow during orgasm. They found that although men and women did not differ in anal muscle tone during baseline testing, higher initial levels of blood flow were measured in women. During both sexual arousal and orgasm, men demonstrated higher levels of anal blood flow and muscle activity.

4.1.3.2. Temperature. Thermistors have been used to measure genital temperature in both sexes but the measurements are obtained from different structures. In contrast, thermography can be used in cross-sex comparisons (Seeley et al., 1980). The methodology is not widely used because it is costly and intrusive. Seeley et al. (1980) compared thermographic images of a male participant engaging in masturbation and a female participant engaging in masturbation. Their results suggested that thermography indeed reflected the presence of sexual arousal. However, the relationship of temperature to physiological events in the genitalia, regardless of the methodology used, is unclear, as studies have not been done to relate thermographic data to vascular responses.

4.1.3.3. Brain and pelvic imaging. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) are fairly recent additions to the toolbox of psychophysologists and have enabled the investigation of blood flow (including size and position) changes of relevant structures and areas in the pelvis and genitalia as well as in the brain during sexual response. In women, the use of pelvic fMRI has shown that the anterior vaginal

wall is stretched and the uterus elevated during coitus, but that the uterus does not balloon as was previously thought (Faix, Lapray, Callede, Maubon, & Lanfrey, 2002; Weijmar-Schultz, van Andel, Sabelis, & Mooyaart, 1999). The finding that the anterior vaginal wall stretches is relevant because it is unknown how the signal of the vaginal photoplethysmograph may be affected by such changes. In men, it has been found that the penis during intercourse in "missionary position" obtains the shape of a boomerang, with approximately one third of its length consisting of the internal root (Weijmar-Shultz et al., 1999). In women, researchers have isolated the clitoris as a target organ, as it exhibits the most sizeable genital changes during sexual arousal (Suh et al., 2004) and clitoral measurements appear reliable (Maravilla et al., 2003). Investigators are still debating, however, whether MRI can document vaginal atrophy in post-menopausal women, and it also remains to be established exactly what physiological changes contribute to the output (Deliganis et al., 2002).

Brain-imaging studies make a unique contribution to the literature because they, in contrast to research in animal models and neurological patients, can be used to study brain mechanisms in nonclinical human populations. Studies using PET and fMRI have found activation during the processing of visual sexual stimuli of the occipitotemporal cortex, orbitofrontal cortex, parietal lobules, putamen, amygdala, insula, claustrum, hypothalamus, as well as the deactivation of several areas of the lateral temporal cortex (Stoleru and Mouras, *in press*, Canli and Gabrieli, 2004).

Future research will, through the comparison of different populations and types of stimuli, undoubtedly refine our understanding of the role of specific brain areas and systems in sexual response and behavior. For example, imaging techniques can be applied to the study of gender differences in brain activation to different stimulus modes (e.g., visual, tactile, auditory, imaginary) as well as stimulus characteristics (e.g., heterosexual/homosexual, explicit/romantic, aggressive). Similarly, brain-imaging techniques can be used in research on sexual dysfunction (e.g., Stoleru et al., 2003) and its treatment (e.g., Montorsi et al., 2003). Stoleru and colleagues (2003) found that men with low sexual desire exhibited less activation of parietal regions (involved in emotional and motor imagery) and decreased *deactivation* of the medial orbitofrontal cortex (involved in the inhibition of motivated behavior) as compared to a control sample. When it comes to treatment, Montorsi and colleagues (2003a, 2003b) evaluated, also using fMRI, the effects of the first officially approved centrally acting drug for the treatment of erectile dysfunction, apomorphine, in men with psychogenic problems. Apomorphine was associated with increased activation of parietal areas and, consistent with Stoleru and colleagues' (2003) findings, greater deactivation of the medial OFC.

These examples merely serve to illustrate the potential for brain-imaging methods to lead to new insights and hypotheses in the study of sexual response. Yet, researchers

in this area face a number of challenges. For instance, the study of central processes using imaging techniques would benefit from the inclusion of measures of peripheral (genital and spinal) mechanisms. Unfortunately, the use of genital measures in MRI scanners is at present problematic (cf. Montorsi et al., 2003a). Also, it is unclear to what degree other autonomic (e.g., cardiovascular, respiratory) processes may be a confound, and thus threaten internal validity, in imaging studies of sexual arousal, which further emphasizes the need for including additional physiological measures. For example, Arnow and colleagues (2002) found correlations in the range of .3 and .5 between changes in respiration and changes in penile tumescence, introducing the possibility that the relationship between brain activation and sexual response in their study was mediated by (or reflected) changes in respiration. Another matter that requires attention involves the reliance on relatively large numbers of (often discrete) sexual stimuli. In contrast to traditional psychophysiological sex studies, imaging approaches have relatively specific requirements for the averaging of responses over time and across stimuli, making it more challenging to control for the effects of habituation, sensitization, or boredom. This may be especially problematic if differences in brain activation between groups of patients and controls or men and women really reflect differences in, for example, the speed of or propensity for habituation.

Although research in this area is increasingly guided by theoretical models (e.g., Redoute et al., 2000), most imaging studies still rely on "emotionally neutral" control stimuli. Progress in this area will depend on the use of designs and reference conditions that will allow the assessment of the specificity of changes (increases or decreases) to sexual systems by comparing sexual with other emotional stimuli. Although brain-imaging techniques represent a promising approach to the study of neural structures and processes, they are, like any other emergent technique, subject to methodological (e.g., the reliance on subtraction methods) and conceptual (e.g., the presence or absence of differential brain activation does not necessarily prove or rule out a role for a specific region) challenges, and researchers should be critical of the assumptions underlying the collection and interpretation of brain-imaging data (Cacioppo et al., 2003).

4.1.4. Measurement of subjective sexual arousal

The construct of sexual arousal, its necessary and sufficient conditions, its phenomenology, and its distinction from other components of sexual response (e.g., sexual desire), is receiving renewed and growing interest from researchers (e.g., Everaerd, Laan, & Both, 2003; Graham et al., 2004; Rowland, 1999). Although the physiological measurement of sexual arousal is a maturing science, the operationalization and assessment of subjective sexual arousal is still relatively undeveloped and poses challenges of its own. According to Mosher's (1980) involvement theory, subjective sexual arousal consists of awareness of

physiological sexual arousal, sexual affects, and affect-cognition blends. Mosher, Barton-Henry, and Green (1988) developed a scale that measures these three dimensions but, while one of the few self-report measures with known psychometric properties (see Mosher, 1998), is rarely used in its original form. Most researchers use adaptations of this measure or comparable questions derived from the work of others (e.g., Heiman & Rowland, 1983; Henson et al., 1979).

Some researchers also use continuous measures of sexual arousal. Wincze, Hoon, and Hoon (1977) first reported on a lever capable of swinging through a 90° arc that participants could operate to indicate their degree of sexual arousal. Other researchers (e.g., Janssen et al., 1997; Laan et al., 1995) have employed a variant of this technique using horizontally placed sliders with lights providing subjects with feedback. Although rating scales and continuous measures have been found to yield roughly equivalent results (Steinman et al., 1981), both approaches have their disadvantages. One disadvantage of discrete measures of subjective sexual arousal is that they are retrospective in nature. The use of a continuous measure requires participants to monitor their response continuously, and thus may yield distractions or lead to "speculating" (Masters & Johnson, 1970). Thus, the reactivity of this measure may depend on participant characteristics (e.g., clinical versus nonclinical), a possibility that warrants more research. An obvious advantage of the continuous measure is that it allows for the evaluation of subjective responses throughout an entire stimulus episode. Peak levels of sexual arousal may be comparable with continuous and discrete measures, but when the peak occurs can be determined only with continuous measures. In addition, continuous measures allow for the calculation of within-participant correlations. With physiological measures where calibration of the signal is not possible (e.g., VPA), within-participant correlations are more reliable and informative than between-participant correlations.

4.2. Signal recording and processing

In contrast to many other areas of psychophysiological research, no guidelines exist for the measurement of sexual arousal, and the current lack of standardization of signal recording, processing, and analysis, complicates the evaluation and comparison of research findings². Signal processing and data reduction appear to be the most significant sources of error variability. Although the more commonly used measurement systems (Contact Precision Instruments, Boston, MA; BIOPAC Systems, Inc., Goleta, CA) come with software containing basic signal processing tools, procedures for artifact detection and removal,

especially relevant in the analysis of VPA, are not standardized in these programs and often are not described in sufficient detail in publications. Automated algorithms exist in related fields for correcting artifacts similar to those seen in VPA (Kaiser & Findeis, 1999; Linden & Estrin, 1988) and could vastly decrease VPA processing time and increase standardization. Others have attempted to use Fourier analysis to select relevant VPA components (Polan, 2003; Wouda et al., 1998), but this approach is still confounded by movement artifacts that may cross into the desired frequency band (Prause & Janssen, 2004).

Another source of error in sexual response measurement is related to variations in device placement. Although measurement devices are usually put in place by participants, visual inspection of placement could increase measurement accuracy and reliability. However, with measures such as penile strain gauges, "improper" device selection or placement cannot always be prevented. For example, a gauge that fits well on a flaccid penis may prove too small for an erect penis. Placement of the vaginal plethysmograph can be standardized by using a shield (Geer, 1983; Laan et al. 1995) and this practice is recommended. A placement shield, however, will not prevent inaccurate readings due to (phasic or tonic) muscle contractions. As for the labial thermistor, little is known about the effects of placement and how changes in size or volume of the labia affect the output of the device. In view of this, we emphasize the importance of carefully checking all genital response data for outliers before performing statistical analyses.

Meuwissen and Over (1993) and Julien and Over (1981) examined whether the Law of Initial Values (LIV) applies to the measurement of genital responses and reported inconsistent findings. Not uncommonly, positive instead of negative correlations are found between baseline and response levels (e.g., Heiman et al., 2004, reported baseline-response level correlations of $r = 0.89$ for VPA and $r = 0.84$ for clitoral volume in women). Recent reconceptualizations of LIV (e.g., Jin, 1992) propose that within the middle range of initial states, higher initial values are expected to be related to greater (not smaller) reactivity. Only when an initial value reaches its upper limit, a tendency to reversed responses may occur. Although LIV may account for a portion of the variance, more research is needed to determine how it relates to constitutional (e.g., anatomical differences) and physiological factors in psychophysiological sex studies.

4.3. Models of sexual response

One of the first models of sexual response was introduced by Havelock Ellis in 1906. His two-stage model differentiates between a stage of "building up" (tumescence) and climactic release (detumescence). This model was extended by Moll (1908/1912) who described a *curve of voluptuousness* which consisted of four phases: the build-up of sexual excitement (the ascending limb), a high, stable level

² In 1998, SexLab, a listserve with companion website (www.indiana.edu/~sexlab) was established to facilitate standardization and stimulate discussion of methodological issues among sexual psychophysiologists.

of sexual excitement (the equitable voluptuous sensation), orgasm (the acme), and the cessation of the sexual impulse (the decline).

4.3.1. The sexual response cycle

Although initially introduced as little more than a frame of reference, Masters and Johnson's (1966) four-stage model is probably the best-known model of sexual response to date. The model, reminiscent of Moll's curve of voluptuousness, describes the genital and extragenital responses that occur in humans during sexual behavior. The phases are (1) excitement phase, (2) plateau phase, (3) orgasmic phase, and (4) resolution phase. Although few would dispute the impact of Masters and Johnson's model on subsequent research and the development of sex therapy, it has been subjected to serious criticism. For example, the separation of sexual response into four discrete stages has been challenged (Robinson, 1976). The distinction between excitement and plateau phases is especially problematic, as there is no empirical support for an identifiable plateau phase. Similarly, the universality of the model has been questioned (Tiefer, 1991). Also, Masters and Johnson did not describe adequately their methods and their data were not quantified nor presented in a form that permits evaluation by others. Finally, the studies were restricted to the observation of physiological changes; psychological factors were not measured.

Kaplan (1977, 1979) presented a modification of Masters and Johnson's model in which she replaced their first stage by a "desire" phase. Her second and third phase, the excitement and orgasm phase, are similar to Masters and Johnson's first and third phases. Kaplan's model has been influential in the formulation of the American Psychiatric Association's diagnostic manuals since the *Diagnostic and Statistical Manual III* (APA, 1980).

4.3.2. Cognitive-affective models

Models of sexual response such as Masters and Johnson's suggest that some preprogrammed mechanism exists that is activated by adequate sexual stimulation (Janssen & Everaerd, 1993). They fail, however, to describe what exactly constitutes effective stimulation. In fact, Masters and Johnson's definition of the term is circular: Effective stimulation produces a response, and a response is evidence for effective stimulation. Another problem with models such as Masters and Johnson's is that they do not provide an explanation for the many regulatory processes related to sexual response, nor do they account for the many variations in subjective experience of sexual response and the complicated variation in stimulus and response parameters from such models.

Although a number of other sexual response models have been proposed over the years (e.g., Bancroft, 1989; Byrne, 1977), only a few originated from or are based on psychophysiological research. One such model was proposed by Barlow (1986). In a series of studies, he found support for a number of factors differentiating men

with erectile problems from men without sexual problems. Together, these findings provided the basis for his model, which emphasizes the interaction between autonomic activation and cognitive processes. Sexual response patterns are conceptualized as forming either a positive or a negative feedback system, both starting with the perception of an explicit or implicit demand for sexual performance. This results in either positive or negative affective evaluations, both triggering autonomic arousal. The increase in autonomic arousal enhances attention for those features of the sexual situation that are most salient. Continued processing of erotic cues produces genital response, and ultimately leads to sexual approach behavior. Continued processing of nonerotic issues (e.g., consequences of not responding) interferes with sexual arousal and ultimately leads to avoidance behavior. By combining cognitive-affective and physiological features of sexual response, this type of conceptual approach holds genuine promise of yielding substantial theoretical progress.

Barlow's original model was based on studies of men. Palace (1995a) presented a similar model, based on studies in sexually functional and dysfunctional women, in which the summation of autonomic arousal and perceived and expected levels of genital response leads to an optimal sexual response. The model is based on studies showing that increased autonomic arousal and positive false feedback can enhance sexual responses in women (Palace, 1995b; Palace & Gorzalka, 1990). Thus, Palace emphasizes the relevance of expectations, as does Barlow (see also Wiegel et al., 2005), and both models emphasize the interaction between autonomic and cognitive processes and highlight the importance of feedback.

In constructing their models, Barlow and Palace both recognize the complexity of the interrelationships among response components, yet they essentially treat sexual arousal as a unified construct. Instances of discordance, however, suggest that genital and subjective sexual responses are, at least to a certain degree, under the control of different mechanisms (Bancroft, 1989). Janssen, Everaerd, Spiering, and Janssen (2000) presented a model that highlights the interaction between automatic (unconscious) and controlled (conscious) cognitive processes and proposes that different levels of processing can differentially affect subjective and physiological sexual arousal. The model states that unconscious processes are relevant to explaining the automaticity of the genital response, whereas subjective feelings of sexual arousal are believed to be under control of higher-level, conscious cognitive processing (see also Janssen and Everaerd, 1993; Laan and Everaerd, 1995; Laan and Janssen, *in press*). Support for the model is provided by studies exploring the role of unconscious processes in the activation of genital responses and sexual meaning (e.g., Janssen et al., 2000; Spiering et al., 2003; Spiering et al., 2004). A basic assumption of the model is that sexual stimuli may convey more than one meaning. Thus automatic and controlled cognitive processes may help explain differences in outcome in

situations that convey sexual meaning while simultaneously activating negative meanings. Janssen et al. (2000) proposed that in these situations, automatic processing of sexual meaning initiates genital response, whereas controlled processing of negative meaning may result in decreased or nonsexual subjective experience.

5. EPILOGUE

Psychophysiology has matured into an important approach in studies on human sexuality. In addition to a growing number of studies on basic mechanisms of sexual response, an impressive body of practical information has accumulated, particularly related to the study of dysfunctions and to methods for the assessment of sex offenders. Progress in the laboratory study of human sexuality, however, is contingent upon methodological advancements. More than 15 years ago, Rosen and Beck (1988) noted that methods in sexual psychophysiology are based more on the availability and ease of use of particular transducers than upon a sound understanding of the underlying processes of sexual arousal. These concerns are still relevant today. For example, Rosen and Beck questioned the reliance on the vaginal photometer, pointing out that basic physiological studies (e.g., Wagner & Ottesen, 1980) "highlighted serious limitations in the vaginal photoplethysmograph as an adequate measure of genital engorgement" (p. 340). The development of new measures, especially of genital response in women, would indeed be a welcome contribution to the field of sexual psychophysiology.

Although the variable relationship between genital responses and subjective reports of sexual arousal in women has been documented extensively, and while experiential and laboratory differences have been found to influence this relationship (for review see Prause & Janssen 2006), the mechanisms involved are not well-understood. More generally, our understanding of the role of feedback from the genitals, and how it interacts with other processes that affect behavior, is still limited. Harking back to the early views of James-Lange, there is a continuing interest in peripheral feedback. Lang's (1994) discussion of the importance of that view and the more contemporary perspectives in emotion theory (e.g., Damasio, 1994) reemphasize the importance of the question of the role of feedback, and possible gender differences therein.

The role of individual differences has, as yet, not received much attention in sexual psychophysiology. Bancroft and Janssen (2000, 2001) proposed a model that postulates that sexual response depends on the balance between sexual excitation and inhibition, and that individual differences exist in the propensity for both. Just as future sexual response models should, at least ideally, attempt to incorporate predictions about the interrelationships between physiological and subjective responses, sexual psychophysiology could benefit from the development of conceptual approaches that contribute to our understanding of individual differences in sexual response and

behavior. This would be especially relevant in respect to questions about the development of problematic or unusual response (e.g., sexual dysfunction, paraphilic interests) and behavioral (e.g., sexual "compulsivity," sexual risk taking) patterns. Although such approaches could include the exploration of both general and more specific, sexuality-related (e.g., sexual inhibition proneness or erotophilia/phobia) aspects of personality, they also should include the consideration of interindividual variability in response patterning as reflected by, for example, individual differences in conditionability (Hoffmann, 2005).

Another unanswered question alluded to earlier is how to conceptualize and deal with the fact that sexuality is often surrounded with both positively and negatively valenced emotions. Some research suggests that sexual arousal may simply be a case of a highly arousing positive emotional state (Carretié, Hinojosa, & Mercado, 2003), whereas other studies have shown that sexual stimuli are processed differently from other emotional stimuli and are processed differently by the two genders (Geer & Manguno-Mire, 1997). Although it has been argued (Everaerd, 1988) that sexual arousal should be considered to be among the emotions, it is not clear whether its study would benefit most from a discrete or dimensional (e.g., circumplex) theoretical approach. What's more, some may contend that sexual arousal is not a prototypical emotion exactly *because* it often involves the co-activation of positive and negative affect, where other emotions are assumed to show stability in valence. However, findings of studies combining within- and between-subjects approaches increasingly challenge the notion that negative and positive emotions are mutually exclusive (e.g., Larsen, McGraw, & Cacioppo, 2001; Scollon, Diener, Oishi, & Biswas-Diener, 2005). Also, imaging studies (e.g., Canli, 2004; Cunningham, Raye, & Johnson, 2004) suggest "that positive and negative do not subtract from one another in our brains in the way that circumplex models tell us they should" (Zautra & Davis, 2004, p. 1099; cf. Cacioppo & Berntson, 1994). Either way, the advantage that the study of the sexual emotions holds is the specificity of the genital response. Although there is some independence of genital responding and subjective or cognitive events, there is also amazing specificity. Certainly there is no other domain in emotion and psychophysiology in which the physiological response system is as closely tied to the feeling state and stimuli under study.

Albertus Magnus noted, in the 1200s, that "pleasure is attached to intercourse so that it will be more desired, and thus generation will continue" (Book IX, Ch 3, Kitchell & Resnick, 1999). This is the premise that suggests that living animals are "prewired" to respond to relevant stimuli and engage in behaviors that will insure perpetuation of the species. Evolutionary psychology with its emphasis on natural selection is directly related to such a conceptualization. Three areas have been the principal focus in evolutionary approaches to sexuality: mate selection, jealousy, and attractiveness (Allgeier & Wiederman, 1994).

Psychophysiology provides a useful tool for the study and advancement of these research areas.

The future lies, we believe, in the amalgamation of interdisciplinary efforts. Specifically, the explosion of methodologies for assessing brain function will have a powerful impact. As methodologies become increasingly available to study the individual's brain functioning in naturalistic settings, our theories and conceptualizations may be altered dramatically. This does not mean that the measurement of peripheral processes and genital responses will become lost in the shuffle. It appears that peripheral feedback is important and information only from central events will not have the full picture available. In a similar vein, increasing attention to cognitive psychology and the neurosciences with the availability of sophisticated experimental paradigms will play an increasingly important role in the study of sexuality. The combination of studying brain function, cognitive and affective processes, and peripheral mechanisms can be expected to provide researchers with novel, powerful, multi-method approaches that will advance our understanding of the psychophysiology of sexual response and behavior.

The Skeletomotor System: Surface Electromyography

LOUIS G. TASSINARY, JOHN T. CACIOPPO, AND ERIC J. VANMAN

The brain recalls just what the muscles grope for; no more, no less... (Faulkner, 1936, p. 143)

The principal function of the nervous system is the coordinated innervation of the musculature. Its fundamental anatomical plan and working principles are understandable only on these terms. (Sperry, 1952, p. 298)

INTRODUCTION

The sophistication of the skeletomuscular system enables the vast repertoire of adaptive reflexes and skilled actions characteristic of behavior. The electrophysiological signals associated with active muscles have been of interest for centuries due to the complexity of their organization and dynamics, their clinical applications, and their value as indices of and possible contributors to behavioral processes.

In this chapter, we provide an introduction specifically to psychophysiological research on the skeletomotor system.¹ We begin by reviewing the history of this research and by articulating some of the major issues, limitations, and advantages of surface electromyography (EMG) as a noninvasive measure of muscular activity. We then review briefly the physiological basis of EMG and summarize guidelines for surface EMG recording in humans. We continue with a discussion of the social context for EMG recording and of psychophysiological principles and common paradigms that have emerged from research on the skeletomotor system. For EMG signals to be of theoretical significance, one must consider conjointly the historical, physical, social, and inferential contexts in which these signals are acquired.

HISTORICAL CONTEXT

In this section we identify two distinct themes in the development of electromyography in psychophysiology.

¹ Additional information on electromyography generally can be found in Basmajian and DeLuca (1985), Johnson and Pease (1997), Loeb and Gans (1986), or Ludin (1995).

The first is the history of the physiology of the muscles, which derives from the writings of the early Greek philosophers, and from the scientific renaissance in the seventeenth century. The second is the history of psychophysiological research, which began in earnest with the work of such figures as Duchenne (1990/1862), Spencer (1870), Darwin (1873/1872), and James (1890), all of whom emphasized relatively subtle patterns of muscular actions as a way of characterizing and understanding human behavior generally.

Muscle physiology

The history of muscle physiology can be traced back to the fourth century B.C.E., when Aristotle provided clear descriptions of coordinated motor acts (e.g., locomotion and the importance of the mechanism of flexion) in his books *De Motu Animalium* and *De Incessu Animalium*. The field of neurophysiology can be traced to Francesco Redi's deduction in 1666 that the shock of the electric ray fish (*Torpedo torpedo*) emanated from specialized muscle tissue (Wu, 1984). It was not until the early nineteenth century, however, that a sensitive instrument for measuring small electric currents was invented (i.e., the galvanometer). In 1833, Carlo Matteucci used such a device to demonstrate an electrical potential between an excised frog's nerve and its damaged muscle. Du-Bois Reymond, a student of the renowned physiologist Johannes Müller, built upon Matteucci's then recent publication, eventually publishing the results of an extensive series of investigations on the electrical basis of muscular contraction as well as providing the first *in vivo* evidence of electrical activity in human muscles during voluntary contraction (Basmajian & De Luca, 1985).

The study of the thermodynamics of muscle contraction owes a debt to another of Müller's students, Hermann Ludwig Ferdinand von Helmholtz. Fueled by the desire to abolish the notion of vital forces underlying muscular actions, von Helmholtz began an investigation into the chemical transformations occurring in frog muscle during contraction. Put simply, he reasoned that the heat of

combustion combined with the transformation of food material should produce a quantity of heat measurable at the muscle surface during contraction. By stimulating an isolated muscle through its nerve and employing a sensitive thermocouple he was able to demonstrate a rise in temperature during contraction. This demonstration not only provided the experimental basis for his classic paper on the conservation of energy, but also proved instrumental in focusing subsequent investigations on the central problem of understanding the physiochemical processes involved in converting neural energy to mechanical work (Hill, 1959).

Based on experimental observations using electrical stimulation, muscle physiologists during the eighteenth and early nineteenth century attributed graded muscular responses to graded variations in the intensity of the stimulation. Until late in the nineteenth century, many erroneously inferred from the strong correlation between the intensity of exogenous electrical stimulation and the intensity of contraction that the actual size of the neural impulses was proportional to the stimulus intensity. Experimental work around the turn of the century (e.g., Lucas 1909), however, challenged this belief, strongly suggesting that graded muscular responses resulted from the firing of individual contractile units rather than from variation in the size of the nerve impulse. Direct evidence for the “all-or-none” character of the response of muscle fibers was finally obtained by Frederick Pratt and his colleagues in the early 1900s (Pratt, 1917; Pratt & Eisenberger, 1919). They applied graded electrical stimulation to individual muscle fibers while simultaneously photographing the spatial displacement of mercury droplets sprinkled previously over the muscle surface and observed that additional fibers contracted coincident with each quantal step in the displacement of a mercury droplet.² The foundations of modern electromyography were finally laid in the 1930s with publications of Adrian and Bronk (1929), Lindsley (1935), Jacobson (1927), and the introduction of the differential amplifier (Mathews, 1934).

Skeletomotor activation and patterning

Detecting myoelectric signals using surface electrodes remained difficult throughout the nineteenth and early twentieth centuries. Electrically stimulating a muscle cutaneously was considerably simpler, however. Perhaps best known for this work was Guillaume Duchenne de Boulogne, who used this technique in the mid-nineteenth century to investigate the dynamics and function of the human facial muscles *in vivo* (Duchenne, 1990/1862). Not surprisingly, Charles Darwin corresponded with Duchenne in an effort to evaluate his own observations about facial

expressions and emotion (Cuthbertson, 1990), as well as those observations of earlier writers with whom he was familiar (see Tassinary & Geen, 1990; Geen & Tassinary, 2002).

Darwin's interest in muscular action was based upon his belief that many behaviors were in part inherited. He focused his inquiry on the expression of emotions in man and animals to buttress this belief and presaged contemporary studies of the patterns of muscle contractions and facial actions that are undetectable to the naked eye with his conclusion that “... whenever the same state of mind is induced, however feebly, there is a tendency through the force of habit and association for the same movements to be performed, though they may not be of the least use” (Darwin, 1873/1872, p. 281).

The somatic elements of William James's (1884) theory of emotions and the various motor theories of thinking prevalent at the turn of the century (e.g., Washburn, 1916) further fueled interest in objective measures of subtle or fleeting muscle contractions. Among the more creative procedures used to magnify tiny muscular contractions were sensitive pneumatic systems used to record finger movements during conflict situations (Luria, 1932) as well as elaborate lever-based systems to record subtle tongue movements during thinking (Thorson, 1925). Sensitive and specific noninvasive recordings, however, awaited the development of metal surface electrodes, vacuum tube amplifiers, and the cathode-ray oscilloscope early in this century which enabled the pioneering work of Edmund Jacobson (1927; 1932) on electrical measurements of muscle activity during imagery. The results of these studies and others (e.g., Davis, 1938) demonstrated that EMG responses were evoked by psychologically relevant tasks (e.g., recall a poem), were minute and highly localized, and often occurred in the part of the body that one would use had the task called for an overt response. This work was subsequently criticized primarily for not definitively achieving mentally quiescent comparison periods (e.g., Humphrey, 1951; Max, 1937), but successful replications of this early work using different comparison tasks have been reported (McGuigan, 1966; 1978).

Enduring issues

Subsequent research using surface EMG has extended these early observations, documenting patterns of covert skeletomotor activity that differentiate both within and between emotional and cognitive processes (e.g., see reviews by Cacioppo, Klein, Berntson, & Hatfield, 1993; Fridlund & Izard, 1983; McGuigan, 1978; Tassinary & Cacioppo, 1992) as well as between normal and clinical populations (e.g., van Boxtel, Goudswaard, & Janssen, 1983; Gehricke & Shapiro, 2001; Hazlett, McLeod & Hoehn-Saric, 1994; Wolf et al., 2004). The enduring important issues in this research include the extent to which recorded EMG responses reflect specific or global

² Interested readers may wish to consult Fulton (1926), Huxley (1980), Keynes and Aidley (1991), or Needham (1971) for more in-depth coverage of the history of muscle physiology.

activation, as well as to what extent they reflect characteristics of the situation, the individual, or the processing task. Not surprisingly, it has proven advantageous to monitor multiple EMG responses across time using sophisticated designs with multiple control conditions and to employ time-locked recording procedures. For example, Cacioppo, Bush, and Tassinary (1992) examined simultaneously the effect of communicative intent and stimulus valence, using both social and asocial stimuli, on EMG activity at five discrete sites on the face. Their results suggest (1) that facial EMG activity continues to be modulated by both affective and communicative processes even when it is too subtle to produce a clearly perceptible expression and (2) that muscles in the brow and periocular regions are more responsive differentially to both processes than muscles in either the forehead, cheek, or perioral regions.

Two general features of the physical architecture of the skeletomotor system also present some enduring inferential challenges to surface EMG recording. First, is the sheer number of muscles. Most of the striated muscles are bilaterally symmetrical in pairs, with several hundred distinct muscles throughout the human body. Second is the alluring aggregate simplicity of the muscle as a functional unit. That is, from such a perspective, each striated muscle can be characterized as a linear actuator, with the potential states being limited to onset of contraction, offset of contraction, and relaxation (Tomovic & Bellman, 1970). The structural arrangements of the striated muscles as agonist-antagonist pairs, or through their interdigitation, however, expand dramatically the number of actions that can be achieved using these deceptively simple elements. The relatively small number of muscles in the head and face, for instance, have been estimated to enable the encoding of some 6,000 to 7,000 appearance changes (Izard, 1971; see Figure 12.1).

The challenges that derive from these architectural features are several. First, it is feasible to obtain measurements over only a small number of muscles in the human body in any given experiment. Yet because the action of the striated muscles is multiply determined, monitoring activity from a single site may only provide global or ambiguous information about the associated psychological or behavioral process. Ekman (1982) observed, for instance, that emotions, with the possible exception of happiness, cannot be identified by the activity of a single muscle, echoing an earlier call for the necessity of recording from more than one muscle group during emotional reactions (Lindsley, 1951).

Second, many movements can be achieved by the actions of different or differently activated striated muscles. Electromyographic responses may therefore appear unreliable if the focus is solely on the behavioral output rather than the mechanisms by which these movements were achieved (e.g., Gans & Gorniak, 1980; Kelso, Tuller, Vatikiotis-Bateson, & Fowler, 1984). Third, the imperfect selectivity of surface electrodes and the close proxim-

ity of the various striated muscles make it difficult to pinpoint exactly which muscles are contracting. Hence, when using surface electrodes, it is typically appropriate to refer to EMG signals as reflecting activity from sites or regions (e.g., *zygomaticus major* muscle region). Fourth, surface EMG recording, although noninvasive, can be obtrusive and potentially reactive. Electrodes attached to the surface of the skin with wires connected to preamplifiers, for instance, can restrict an individual's movement or make the individual tense or self-conscious, or sensitive to experimental demand characteristics. Finally, although acknowledged standards for the placement of surface electrodes to detect activity in particular muscles or muscle regions do exist (i.e., Fridlund & Cacioppo, 1986; Zipp, 1982), these have not been adopted universally (see Andreassi, 1995, p. 149; McGuigan, 1994, p. 225) and, consequently, comparisons across laboratories or across individuals and sessions within laboratories remain somewhat problematic.

Progress has been made in overcoming many of these limitations (e.g., De Luca & Knaflitz, 1992; Kumar & Mital, 1996; Fridlund & Cacioppo, 1986; Tassinary, Cacioppo, & Geen, 1989), and this progress is reviewed in the sections that follow. In addition, surface EMG recording offers several unique advantages that complement the study of overt behavior through traditional means. First, EMG responses, in contrast to measures such as response latencies or verbal reports, can be collected continuously without the individual's attention or labor. Second, the detection and quantification of EMG signals as a measure of muscle activation can be performed with the assistance of computers more sensitively, reliably, and quickly than can fine-grain analyses of overt behavior (Tuomisto, Johnson, & Schmidt, 1996; cf. Cohn, Zlochower, Lien, & Kanade, 1999; Himer, Schneider, Koest, & Heimann, 1991). Third, analyses of subtle somatic patterns and their time course may provide a means of differentiating underlying mechanisms of control over similar overt behaviors (Allain et al., 2004; Ghez & Krahauer, 2000; Hasbroucq et al., 2001).

Finally, many subtle psychological processes or events are not accompanied by visually perceptible actions or significant visceral changes (e.g., Graham, 1980; Rajecki, 1983). Darwin (1873/1872) recognized this limitation in the study of emotional expressions, stating that "the study of expression is difficult, owing to the movements being often extremely slight, and of a fleeting nature" (p. 12). It is now clear that fast or low-level changes in EMG activity can occur without leading to any visible movements. Facial expressions, for instance, result from displacements of skin and connective tissue due to the contraction of muscles that create folds, lines, and wrinkles in the facial skin and the movement of landmarks such as the brows and corners of the mouth (e.g., Rinn, 1991). Although muscle activation must occur if these facial distortions are to be achieved, it is possible for muscle activation to

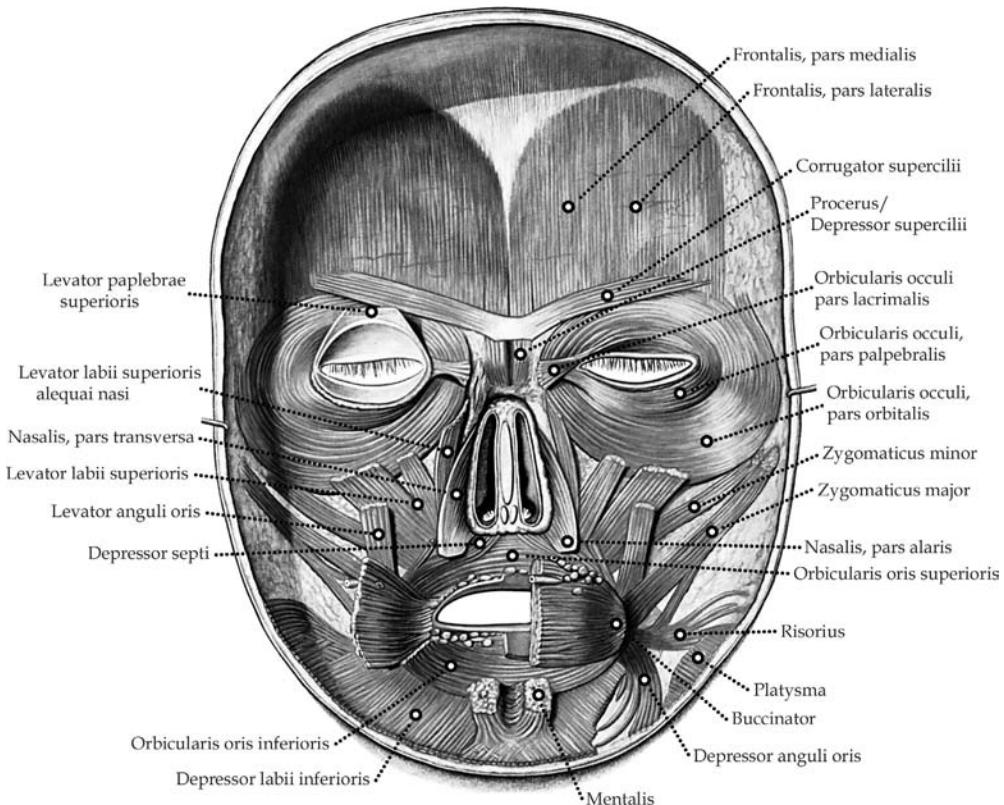

Figure 12.1. Schematic representation of the facial musculature, as viewed from behind the face (modified from Figure 137 of Pernkopf, 1980). Overt facial expressions are based on contractions of the underlying musculature sufficiently intense to result in perceptible dislocations of the skin. More common perceptible effects of strong bilateral contractions of the depicted facial muscles include the following, divided into the major regions of the face. Muscles of the lower face: *depressor anguli oris*, pulls lip corners downward; *depressor labii inferioris*, depresses lower lip; *orbicularis oris (superioris and inferioris)*, tightens, compresses, protrudes, and/or inverts lips; *mentalis*, elevates chin boss and protrudes lower lip; *platysma*, wrinkles skin of neck and may draw down both lower lip and lip corners. Muscles of the middle face: *buccinator*, compresses and tightens cheeks, forming dimples; *levator labii superioris alaeque nasi*, raises center of upper lip and flares nostrils; *nasalis pars alaris*, tightens or flares the ala of the nose; *nasalis pars transversa*, produces transverse wrinkles across the nose and may pull down the medial part of nose; *depressor septi*, pulls down septum and protrudes upper lip; *levator labii superioris*, raises upper lip and flares nostrils, exposing canine teeth; *zygomaticus major*, pulls lip corners up and back; *zygomaticus minor*, draws the upper lip backward, upward and outward; *risorius*, retracts lip corners. Muscles of the upper face: *corrugator supercili*, draws brows together and downward, producing vertical furrows between brows; *procerus/depressor supercili*, pulls medial part of the brows downward and may wrinkle skin over bridge of nose; *frontalis pars lateralis*, raises outer brows, producing horizontal furrows in lateral regions of forehead; *frontalis pars medialis*, raises inner brows, producing horizontal furrows in medial region of the forehead; *levator palpebrae superioris*, raises and pulls back upper eyelids; *orbicularis oculi pars orbitalis*, tightens skin surrounding eyes, causing “crow’s feet” wrinkles; *orbicularis pars palpebrae*, tightens skin around eyes, causing lower eyelids to rise; *orbicularis oculi pars lacrimalis*, compresses the lachrymal sacs and facilitates effective tearing. Descriptions are consistent with those in Hislop and Montgomery (2002), Ekman and Friesen (1978), Gray (1918/2000), Izard (1971), Kendall and McCreary (1993), and Weaver (1977).

occur in the absence of any overt action if the activation is weak or transient or if the overt response is very rapid, suppressed or aborted (see Cacioppo et al., 1992). This holds for nonfacial striated muscles as well (see Coles, Gratton, Bashore, Eriksen, & Donchin, 1985; de Jong, Coles, Logan & Gratton, 1990; McGarry & Franks, 1997; Lutz, 2003).

In the face, the uncoupling of muscle activation and observable movement is due in part to the structure and elasticity of the facial skin, fascia, and adipose tissue, as

well as due to the unique architecture of the facial musculature. The muscles of expression are attached to other muscles, bones, or a superficial musculoaponeurotic system (SMAS; Mitz, 1976; Kikkawa, Lemke, & Dortszbach, 1996) that extends throughout the cervicofacial area; not unlike a loose chain, the facial muscles can be pulled a small distance (i.e., contracted slightly) before exerting a significant force on the points to which they are anchored. In addition, the elasticity of the SMAS, facial skin, and adipose tissue forms a complex low-pass mechanical filter,

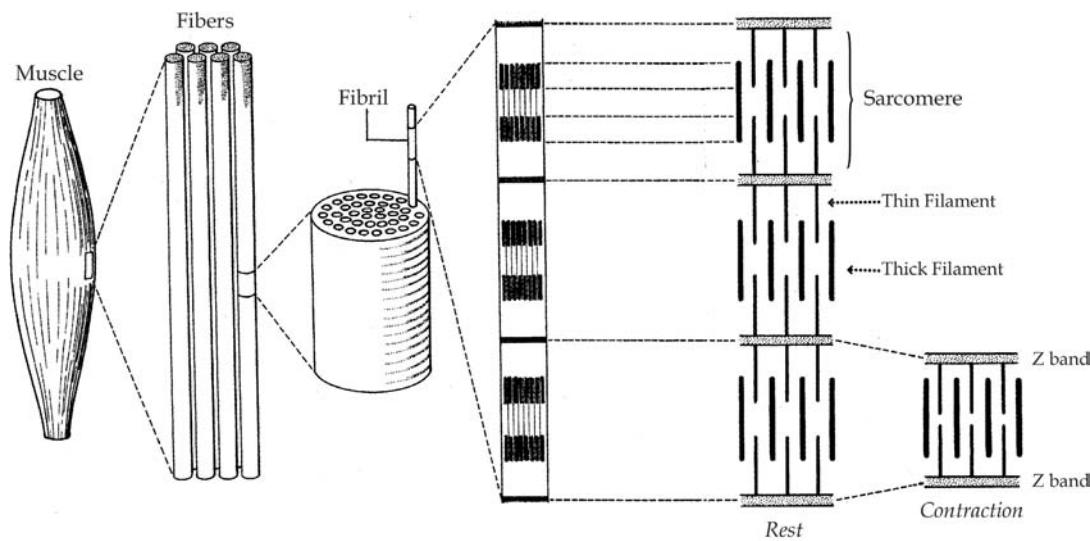

Figure 12.2. Diagram of the structure of the muscle with increasing magnification going from left to right. The bottom right corner of the figure illustrates the microgeometric changes that occur with contraction. (Modified from Figure 10.7 of Schmidt-Nielsen, 1997).

attenuating the visible effects of very brief or slight contractions yet allowing the displacement and bulging of the face due to sustained or moderate contractions (Partridge, 1966; Waters, 1992; Gousain, Amarante, Hyde, & Yousif, 1996)

In summary, measures of EMG and of observable muscular actions each have unique advantages and disadvantages. Neither is necessarily better or more capable of capturing completely the information provided by the other. A general congruence between the results based on EMG recordings and those obtained through fine-grain analyses of overt behavior is to be expected given the physiological basis of the surface EMG (see what follows), although EMG recordings and fine-grain behavioral observations do not coincide completely (Ekman, 1982; Girard et al., 1997). Therefore, the wealth of information that exists regarding nonverbal behavior during such processes as sleeping, thinking, communicating, dissimulating, and feeling (see Feldman & Rime, 1991; Russell & Fernández-Dols, 1997; Tyron, 1991) provides a rich theoretical resource for research on subtler, more fleeting responses or on underlying mechanisms.

PHYSICAL CONTEXT

An understanding of the physical system one is studying and the bioelectrical principles underlying its responses serve several important purposes. These include the development of operational definitions and procedures, the ability to discriminate signal from artifact, the maintenance of a safe environment for both experimenters and research participants (see Greene, Turetsky, & Kohler, 2000) and, ultimately, the guidance of inferences based on physiological data (see Cacioppo, Tassinary, & Berntson, this volume, Chapter 1). In this section, therefore, we review the physical basis of the surface EMG.

Anatomical and physiological basis of the surface electromyogram

Muscles perform many different functions (Smith & Kier, 1989). Their orchestrated activation maintains posture, causes reflexive movements, and produces both spontaneous and voluntary movements that occur across many different scales of space and time.³

Fundamentally, muscle is a tissue that both generates and transmits force. Striated muscle, in particular, is a hierarchical material made up of a very large number of parallel fibers whose diameters are orders of magnitude smaller than a millimeter and yet may be up to several centimeters in length (see Figure 12.2). The term “striated” comes from the fact these fibers are actually bundles of thinner structures, known as *fibrils*, which have repeating cross striations throughout their length known as Z-lines or Z-bands. Electron microscopy reveals that between these striations (an area known as the *sarcomere*) are a series of thick and thin filaments bound together by a system of molecular cross-linkages. The thick filaments are made up of the protein myosin and lie in the center of the sarcomere between the thin filaments. The thin filaments are composed of the proteins actin, tropomyosin, and troponin, are discontinuous and are attached either at one end or the other of the sarcomere. During contraction, conformational changes in the cross-linkages lead to only very slight changes in the length of the filaments but cause substantial changes in the distance between Z bands as the thick filaments slide in between the thin filaments (Schmidt-Nielsen, 1997).

³ A detailed description of the central organization and control of the motor system, although important, is beyond the scope of the present chapter. Interested readers can consult Kandel, Schwartz, and Jessell (2000) for an overview and a recent review article by Morecraft et al. (2004) for more detailed information on the central organization and control of the facial motor system in particular. See also Solodkin, Hlustik, & Buccino, this volume, Chapter 22.

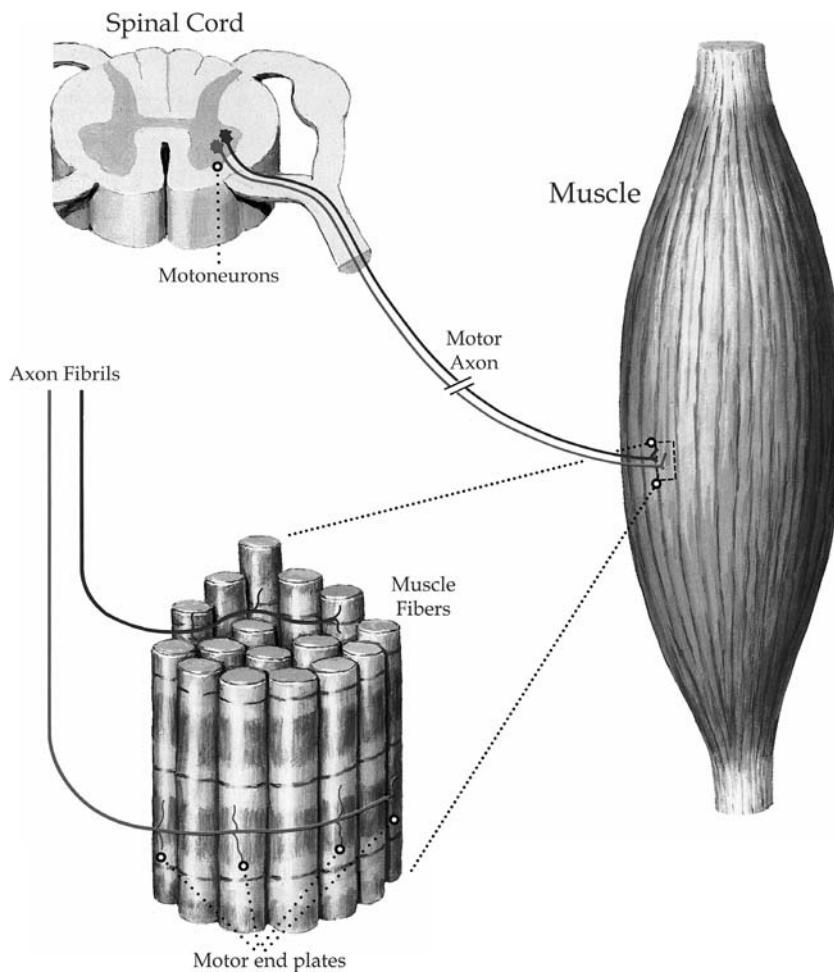

Figure 12.3. Diagram of two motor units. (Modified from slide 3705 of Netter, 1991).

Each striated muscle is innervated by a single motor nerve whose cell bodies are located primarily in the anterior horn of the spinal cord or, in the case of the muscles of the head, in the cranial nerves of the brain stem. All behavior – that is, all actions of the striated muscles regardless of the brain processes involved – result from neural signals traveling along these motor nerves. For this reason, the set of lower motor nerves has been designated the final common pathway (Sherrington, 1923/1906).

The motor nerve traveling to the muscle consists of axons of numerous individual motoneurons, which as a collective are referred to as a motoneuron pool. Each motoneuron axon divides into a number of small branches, termed axon fibrils, just before reaching the muscle; each axon fibril, in turn, forms a junction, called a motor end plate, on an individual muscle fiber. Each motoneuron innervates a number of interspersed muscle fibers within a muscle, and each muscle fiber is usually innervated by only one motoneuron. The spatial distribution of motor endplates on the muscle surface is not random but forms at most a few clusters (typically only one) and these are referred to as innervation zones. An important functional consequence of this structure is that muscle fibers do not contract individually but rather the entire set of muscle fibers innervated by a single

motoneuron contracts in consonance. Therefore, the most elementary functional unit within the final common pathway is the motoneuron cell body, its axon, its axon fibrils, and the individual muscle fibers innervated by these axon fibrils. This functional physiological entity is called the motor unit, a concept proposed by Liddell and Sherrington (1925) and subsequently quantified by Eccles and Sherrington (1930) (see Figure 12.3).

The axons of the motoneurons within a motoneuron pool vary in diameter and this structural feature also has important functional consequences. Generally, the smaller the diameter of a motoneuronal axon, the smaller the number of axon fibrils, the smaller the number of muscle fibers it innervates, and the smaller the size of its cell body. Hence, activation of muscle via small motoneurons produces smaller and more precise actions than activation of the same muscle by the depolarization of large motoneurons. In addition, the smaller the diameter of the motoneuron, the lower the critical firing threshold of its cell body and the more fatigue resistant (i.e., greater glycolytic capacity) are the muscle fibers it innervates. These relationships constitute the size principle (Henneman, 1980)

and it contributes to our ability to control force in a smooth and graded fashion. More specifically, the initial force of contraction produced by a muscle is attributable to small motoneurons discharging intermittently and then discharging more frequently. Stronger muscle contractions are attributable to the depolarization of increasingly large motoneurons within the motoneuron pool concurrent with increases in the firing rates of the smaller motoneurons already active. As muscle contraction approaches maximal levels, further increases in force are attributable primarily to the entire pool of motoneurons firing more rapidly. This cascade of processes appears to be regulated by unidimensional increases in the aggregate neural input to the motoneuronal pool, a process referred to as "common drive" (De Luca & Erim, 1994; Brown, 2000).⁴

The number of muscle fibers innervated per motoneuron, known as the innervation ratio, varies even more dramatically across than within muscles. Consistent with the principles outlined in the preceding, muscles with low

⁴ Although the size principle provides an elegant explanation for many phenomena related to the "voluntary" control of force there is some evidence that the principle may not hold when multi-degree of freedom muscles are involved, a phenomenon referred to as task-dependent muscle partitioning (see Desmedt & Godaux, 1981; Abbs, Gracco, & Blair, 1984).

innervation ratios are capable of producing actions more rapidly and with greater precision than are muscles with high innervation ratios. For example, the small extrinsic muscles of the eye, which are capable of very fast and fine movements, have innervation ratios around 10:1, whereas the relatively large and more slowly acting postural muscles, such as the gastrocnemius (i.e., superficial foot extensor muscle of the calf), have innervation ratios of around 2000:1 (Loeb & Ghez, 2000).

The depolarization of a motoneuron results in the quantal release of acetylcholine at the motor end plates. The activating neurotransmitter acetylcholine is quickly metabolized by the enzyme acetylcholinesterase so that continuous efferent discharges are required for continued propagation of muscle action potentials (MAPs) and fiber contraction. Nonetheless, the transient excitatory potential within a motor end plate can lead to a brief (e.g., 1 ms) depolarization of the resting membrane potential of the muscle cell and a MAP that is propagated bidirectionally across the muscle fiber with constant velocity and undiminished amplitude. The MAP travels rapidly along the surface of the fiber and flows into the muscle fiber itself via a system of T-tubules, thus ensuring that the contraction (known as a twitch) involves the entire fiber. The physiochemical mechanism responsible for the “twitch” involves a complex yet well-characterized self-regulating calcium-dependent interaction between the actin and myosin molecules.

A small portion of the changing electromagnetic field confederated with these processes passes through the extracellular fluids to the skin and it is these voltage fluctuations that constitute the major portion of the surface EMG signal. The voltage changes that are detected in surface EMG recording do not emanate from a single MAP but rather from MAPs traveling across many muscle fibers within a motor unit (i.e., motor unit action potential, or MUAP) and, more typically, from MAPs traveling across numerous motor fibers due to the activation of multiple motor units. Thus, the EMG does not provide a direct measure of tension, muscular contraction, or movement but rather the electrical activity associated with these events. More specifically, the surface EMG signal represents the ensemble electromagnetic field detectable at the surface of the skin at a given moment in time. Normally, both the details of the individual MAPs and the precise muscular origins of the signal are not recoverable (cf. Khan, Bloodworth, Woods, 1971). Reliable, valid, and sensitive information about the aggregate actions (or inactions) of motoneuron pools across time, however, can nonetheless be obtained by careful attention to the elements of surface EMG recording and analysis (e.g., see Cacioppo, Marshall-Goodell, & Dorfman, 1983; Lippold, 1967; De Luca & Knaflitz, 1992).

SIGNAL DETECTION

In this section we outline principles and technical issues involved in obtaining valid measures of EMG activity. As

outlined above, the ensemble surface EMG signal emanating from the muscle is the result of the spatio-temporal summing of a quasi-random train of MUAPs. The aggregate signal is characterized by a frequency range of several hertz to over 500 Hz and by amplitudes ranging from fractions of a microvolt to over a thousand microvolts. These frequency and amplitude characteristics are broader than most bioelectrical signals of interest to psychophysologists, and they overlap a variety of disparate bioelectrical signals (e.g., the electroencephalogram and the electrocardiogram) as well as the ubiquitous external 50/60 Hz signals emanating from most AC-powered equipment (see Marshall-Goodell, Tassinary, & Cacioppo, 1990). Consequently, the detection of EMG signals from a localized muscle region requires careful attention to noise reduction and grounding practices, electrode site preparation and placement, and appropriate differential preamplification and preliminary signal conditioning in order to eliminate extraneous electrical noise, minimize the detection of irrelevant bioelectrical signals, and enhance the signal-to-noise ratio.

Noise reduction and grounding

Noise has been defined by many authors as simply any unwanted signal. In the present context, it is important to note that EMG signals can be obscured by noise from many sources. These include but are not limited to external electrical sources, physiological responses whose frequency and amplitude characteristics overlap those for EMG recording, EMG signals emanating from task-irrelevant muscles (i.e., cross-talk), and EMG signals from target sites that result from “irrelevant” actions presumed to be minimized or eliminated by the design of the experiment (e.g., movement artifacts).

The most problematic exogenous electrical noise in the laboratory is narrowband noise because it arises from several common sources, radiates through walls and air, and overlaps in frequency with the EMG signal. For example, 50/60-Hz noise emanates from AC power lines, lights, relays, and transformers. Televisions, video monitors, and most computer terminals use cathode-ray tubes (CRTs), and these tend to generate high-frequency electrical noise (ranging from 15 kHz to several MHz). Although many EMG preamplifiers include filters to eliminate such noise, filters are neither completely selective nor entirely effective. Special-purpose notch filters, for example, attenuate frequencies to a varying degree on both sides of 50/60 Hz – a bandwidth that can represent a significant portion of the total power in an EMG signal – and strong signals in the high frequency range can appear under the “alias” of small signals in the EMG bandwidth. It is therefore important to minimize electrical noise prior to amplification. This can be done through appropriate placement and shielding of equipment and careful grounding of the research participant and laboratory equipment (Bramley, Bruun, Buchthal, Guld, & Petersen, 1967; Fridlund & Cacioppo, 1986; McGuigan, 1979). Wideband noise (white noise) is

usually attributable to the Brownian motion intrinsic to electronic devices. This noise is unavoidable but can be minimized by keeping electrode impedances low, amplifier filters set tightly to the proper bandwidth, and using calibrated high-grade equipment.

With respect to grounding, a research participant affixed with electrodes should be grounded at one and only one point on her or his body and any equipment touched by the participant should ideally be nonconductive. If multi-channel recordings are to be made, the grounds for each channel should be strapped together and a single ground electrode attached. This procedure further minimizes 50/60 Hz noise in the recordings and enhances the safety of the participant by eliminating the possibility of ground loops (i.e., unintended current flow due to imperfect grounding).

Biological noise includes all endogenous signals that are not part of the bioelectrical signal of interest. In the sections that follow, we outline several procedures for minimizing biological noise. The careful and correct placement of a ground electrode, however, does not prevent artifacts from cross-talk, one of the primary sources of biological noise. Put simply, this is because the impedance into the ground electrode tends to exceed the access impedance of the volume-conductive tissues between the spurious current source and the recording electrode(s). Additional details and discussions are provided by Loeb and Gans (1986) and Basmajian and De Luca (1985).

Electrode selection and placement

Psychophysologists, nearly without exception, use surface rather than needle or fine-wire electrodes for EMG recording. This is due primarily to the noninvasive nature of surface recording and to the fact that the research questions posed thus far by psychophysologists involve muscles or sets of muscles rather than motor units within muscles. Surface EMG electrodes are less sensitive to exact anatomical placement because they detect the summated MAPs from an indeterminate cluster of motor units rather than a single unit.⁵ This aggregate response develops in an orderly manner such that surface EMG recordings correlate well with the overall level of contraction of muscle groups underlying and near the electrodes, especially when limb movement is constrained and contractions are neither minimal nor maximal (Lawrence & DeLuca, 1983; Lippold, 1967).

Because most EMG amplifiers are AC coupled the electrical stability of the electrodes is not as important as, for instance, when recording skin conductance (see Dawson, Schell, & Filion, this volume). Nonpolarizing electrodes such as silver-silver chloride electrodes, however, can be used very effectively in nearly all recording situations. Tin, stainless steel, gold, or the platinum family of noble met-

als can be used effectively in many recording situations, although the lack of chemical equilibrium at the metal-electrolyte junction does make this class of electrode inherently more noisy and susceptible to artifact. In addition, stainless steel may be contraindicated when recording low-frequency, low-amplitude signals (Cooper, Osselton, & Shaw, 1980). As a result, the silver-silver chloride electrode is – in most research applications – the electrode of choice.

Surface electrodes can be constructed to be either active or passive. If passive, the electrode consists simply of a detection surface. If active, the input impedance of the electrode is made artificially high using proximal microelectronics.⁶ Essentially, these microelectronics consist of a low-gain differential preamplifier with very high-input and very low-output impedances built into the electrode housing. Locating the first stage of high-impedance amplification as close as possible to the detection surfaces renders this class of electrodes relatively insensitive to the vagaries of the electrode-skin interface; and the low output impedance minimizes artifacts due to any movement of the cable connecting the electrode to the main amplifier. These advantages are obtained, however, at the cost of increased noise levels, higher expense, and typically much greater mass. Surface electrodes are also available in a variety of sizes. Electrodes with small detection surfaces and housings allow closer interelectrode spacing and consequently higher selectivity. Such factors as the electrode size, electrode positioning and interelectrode distance over a particular site can affect the detected EMG signals and hence should be held constant across experimental conditions. For example, a smaller spacing shifts the bandwidth to higher frequencies and lowers the amplitude of the signal.

Fridlund and Cacioppo (1986) found that electrodes with 0.5-cm diameter detection surfaces and 1.5-cm diameter housings are used commonly for limb and trunk EMG recording, and miniature electrodes with 0.25-cm diameter detection surfaces and 0.5- or 1.0-cm diameter housings are used for facial EMG recording. They and others (Basmajian & De Luca, 1985) advocated, based on a variety of criteria, the use of a 1.0-cm interdetector surface spacing whenever possible. Given a circular detection surface, however, the inter-detection-surface spacing is limited by the diameter of the electrodes. This is unfortunate because, *ceteris paribus*, the larger the size of the detection surfaces, the larger the amplitude of the signal that will be detected and the smaller the electrical noise that will be generated at the skin detection-surface interface. Some investigators have advocated the use of a rectangular rather than a circular detection surface based on the reasoning that a “bar” will, in general, intersect more fibers (De Luca, 1997). No empirical research, to our knowledge, has explicitly addressed the issue but simulation studies have been conducted (see Farina, Cesari, & Merletti, 2002).

⁵ Placement with respect to the innervation zone of the muscle, however, is an important consideration because both the amplitude and frequency spectrum of the EMG signal vary as a function of this spatial relationship.

⁶ Further discussion of these two different classes of surface electrodes can be found in Basmajian and De Luca (1985).

Regardless of the optimal detection surface geometry, however, only closely spaced electrodes and differential amplification can yield spatially selective surface EMG recordings. For example, using only these two basic procedures, a study of the human nasal musculature demonstrated a remarkable degree of specificity with passive surface EMG electrodes (Bruintjes, von Olphen, Hillen, & Weijts, 1996).

Specification of surface electrode placements over target muscle groups is important to ensure that findings are comparable across individuals, sessions, or laboratories. Several studies offer empirically and anatomically derived recommendations for EMG recording for facial, masticatory, and articulatory muscle activity using subdermal electrodes (e.g., Compton, 1973; Fridlund & Cacioppo, 1986; Isley & Basmajian, 1973; O'Dwyer, Quinn, Guitar, Andrews, & Neilson, 1981; Seiler, 1973; Vitti et al., 1975), and additional studies have examined the reliability of EMG measurements in relatively large, well-defined muscles (Gans & Gorniak, 1980; Komi & Buskirk, 1970; Martin, 1956), as well as offered suggestions for the placement of surface electrodes (see Cram, Kasman, & Holtz, 1998). This research supports a general principle of electrode orientation for spatially sensitive and specific differential recording over a given muscle region. Put directly, electrodes should be placed proximal and oriented parallel to voltage gradients of interest and, simultaneously, be placed distal and oriented perpendicular to voltage gradients of extraneous signal sources (e.g., other muscles). Successful implementation of this principle is limited by the underlying anatomy, the magnitude of interfering signals, the availability of reliable anatomical landmarks, and the presence of task-related complications (e.g., obstruction of vision).

For specific electrode placements on the face,⁷ Tassinary et al. (1989) provided relevant data for the *corrugator supercili*, *depressor supercili*, and *zygomaticus major* muscle regions, regions that have proven informative in studies of emotion. Based on anatomical data regarding the location of these muscles (see Figure 12.1), several experiments were conducted to isolate the sites for surface EMG recording that met the general principle outlined in the preceding. Participants twice posed a series of facial actions and expressions while facial EMG activity was recorded. The activity of a specific muscle or set of muscles was verified using the Facial Action Coding System (FACS, Ekman & Friesen, 1978). The surface recording sites identified as providing both sensitive and relatively selective measures of activation of specific muscle regions are illustrated in the top panel of Figure 12.4.

Tassinary, Vanman, Geen, and Cacioppo (1987) provided relevant data for recording over the perioral muscle region and, in particular, for detecting silent language processing. Five sites in the perioral region were compared for their ability to differentiate facial actions due to the acti-

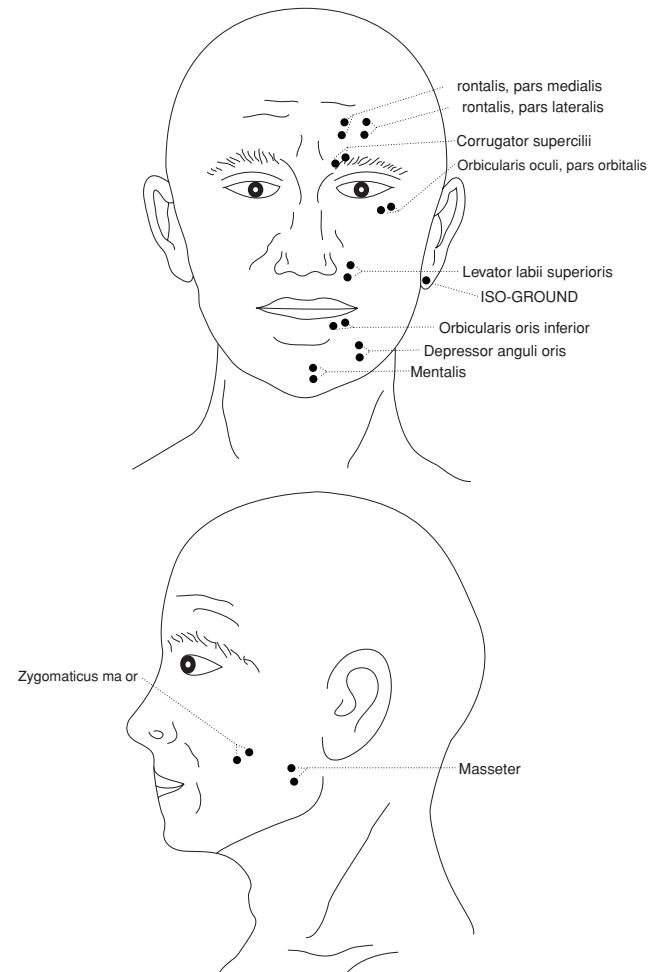

Figure 12.4. Suggested electrode placements for surface EMG recording of the facial muscles, based on Fridlund and Cacioppo (1986). (Modified and redrawn from Figure 6 of Cacioppo et al., 1990c).

vation of discrete facial muscles in the perioral region. In addition to four sites located over the *mentalis*, *orbicularis oris superior*, *orbicularis oris inferior*, and *depressor anguli oris* (see Figure 12.1), a standard electrode site (i.e., “chin”), recommended by Davis (1952) and routinely used in sleep research (Pivik, this volume, Chapter 27) to measure general perioral EMG activity, was included. Activation of specific muscles or sets of muscles was again achieved by poses and was verified using the FACS. Following their correct performance of the poses on two separate occasions, participants were asked to read affectively neutral passages silently, subvocally, and aloud. Only EMG responses recorded over the *mentalis*, *orbicularis oris inferior*, and “chin” muscle regions differentiated quiescent baseline activity from silent reading. Of these three sites, only the site over the *orbicularis oris inferior* muscle region demonstrated high discriminant validity when poses activating this versus proximal superficial muscles were contrasted.⁸

⁷ To record muscle activity involved in movements of the limbs and neck, Zipp (1982) recommended placements first identified by Davis (1952).

⁸ This is to be expected for the “chin” site because the distances between the electrodes are sufficiently large that recordings over this region should be sensitive but nonselective.

Site preparation

Surface EMG electrodes can be attached to the skin in a variety of ways, but the most common is via double-sided adhesive tape. A highly conductive medium (paste or gel) is used routinely between skin and the detection-surface. This medium serves to stabilize the interface between the skin and each detection surface through minimizing movement artifacts (by establishing an elastic connection between the detection surface and the skin), reducing inter-electrode impedances (by forming a conductive pathway across the keratinized layers of the skin), and stabilizing the hydration and conductivity of the skin surface.

Prior to the application of the conductive medium and electrodes, the designated site on the skin surface is usually cleaned to remove dirt and oil and typically abraded gently to lower interelectrode impedances to 5 or 10 k Ω . The electrodes are then commonly affixed in a bipolar configuration, as illustrated in Figure 12.4. The proximity of the ground electrode to the EMG sites being monitored is less important than the impedance of the skin-ground contact in helping to minimize extraneous electrical noise in EMG recording. Consequently, care and reflection can and should be used to ensure a stable and low-impedance connection to ground. Finally, to avoid obstructing movement due to the attachment of surface electrodes, thought should be given to the orientation of electrode collars and wires. Electrode wires, for instance, should be draped and secured to minimize distraction, annoyance, or obstruction of movement or vision.

Preamplification and signal conditioning

Electromyographic signals are “small” in two ways: They have low voltage and low current. An amplifier supplies both voltage gain (turning low into high voltages), which can be controlled by the investigator, and current gain, a function of the ratio of the input and output impedances of the amplifier. Electromyographic signals are amplified using differential amplifiers wherein the difference signal between two electrodes (with respect to a third, ground electrode) is amplified and carried through the signal processing chain. Any bioelectrical or extraneous electrical signal that is common to both electrodes (the “common-mode” signal) is therefore attenuated (see Marshall-Goodell et al., 1990).

An older and more traditional method of recording EMG signals is referred to as monopolar and involves the placement of one electrode over each target site (i.e., muscle or muscle group) of interest. The difference signal between the activity recorded at each target site and a common reference electrode (which, in theory, is in contact with an isoelectric site on the participant’s body) is amplified and carried through the signal processing chain. However, the *bipolar* method is now the most commonly used method of recording EMG signals. Electrode pairs are aligned parallel to the course of the muscle fibers, and this alignment –

coupled with the high common-mode rejection capable of modern differential amplifiers – produces relatively sensitive and selective recording of the activity of the underlying muscle groups (Basmajian & De Luca, 1985; see also Cooper et al., 1980, Chapter 3).

Monopolar or “common reference” recording is characterized by (1) a much more general pickup region than bipolar recording and (2) an increased sensitivity to variations in the absolute level of electrical activity, assuming the ground electrode reflects an isoelectric state. Bipolar recording, in contrast, is more sensitive to variations in the gradient of electrical activity between the two active electrodes and is less susceptible to cross-talk. An elaboration of traditional bipolar recording, referred to as double-differential recording, promises to be even more spatially selective (De Luca & Merletti, 1988; Lowery, Stoykov, & Kuiken, 2003). In the simplest version of this technique, three rather than two detection surfaces are placed in a line over the muscle of interest. Detection surfaces d₁ and d₂ are fed into one differential amplifier, detection surfaces d₂ and d₃ are fed into a second differential amplifier, and the outputs of the two differential amplifiers are fed into yet a third differential amplifier. The argument is that synchronous activity detected in pairs d₁-d₂ and d₂-d₃ indicates a source of electrical activity that did not propagate along the contracting muscle (i.e., crosstalk) and that the addition of the second stage of differential amplification will remove such influences. This particular technique can be seen as a simple unidimensional linear spatial filter, and both theoretical and experimental research suggest that even greater spatial resolution in surface EMG recording is possible with more complex weighted electrode arrays (Disselhorst-Klug, Silny, & Rau, 1997; Lynn, Bettles, Hughes, & Johnson, 1978).

A schematized representation of a sequence of raw EMG signals is presented in the upper panel of Figure 12.5. As noted in the preceding, some filtering of the raw EMG signal is performed to increase the signal-to-noise ratio, decrease 50/60 Hz or ECG/EEG artifact, and reduce cross-talk. The primary energy in the bipolar recorded surface EMG signal lies between approximately 10 and 200 Hz (Hayes, 1960; van Boxtel, Goudswaard, & Shomaker, 1984). Between 10 and 30 Hz, this power is due primarily to the firing rates of motor units; beyond 30 Hz, it is due to the shapes of the aggregated motor unit action potentials (Basmajian & De Luca, 1985). Attenuating the high frequencies in the EMG signal (e.g., using 500-Hz low-pass filters) reduces amplifier noise but rounds peaks of the detected motor unit action potentials. Retaining sharp signal peaks may be important for waveform or spectral analysis but is less critical for obtaining overall estimates of muscle tension. Attenuating the low frequencies (e.g., using 90 Hz high-pass filters) reduces 50/60 Hz noise from AC power lines, EEG and EKG artifacts, and to some extent, cross-talk (due to the intervening tissue’s preferential transmission of low frequencies) but also eliminates a significant and sizable portion of the target

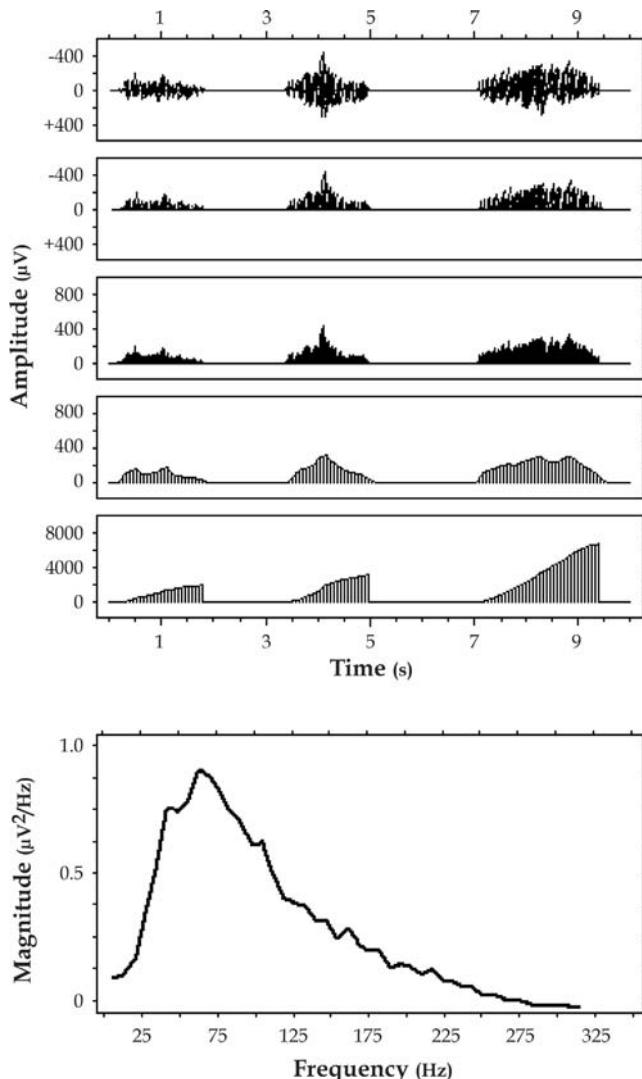

Figure 12.5. Common alternative representations of the surface EMG signal. The top five smaller panels depict three distinct non-fatigued responses. Going from top to bottom: the first represents “raw” (amplified and band-pass filtered only) waveforms; the second, half-wave rectified waveforms; the third, full-wave rectified waveforms; the fourth, “smoothed” waveforms; and the fifth, true integrated waveforms. The larger bottom panel depicts what one of these responses might look like if represented in the frequency domain. (Modified from Figure 7 of Cacioppo et al., 1990c).

EMG signal. Use of an overly restricted EMG signal passband may result in inaccurate appraisal of the level and form of EMG activity or a failure to detect small changes in the level of EMG activity. Hence, selection of an EMG detection passband must proceed based on susceptibility to artifact, presence of extraneous electrical noise at the source and high frequency noise internal to the amplifier, consideration of the amplitude of the EMG signals to be detected, need to minimize cross-talk, and variations across conditions in muscular fatigue. A passband from 10 to 500 Hz is satisfactory for most psychophysiological recording situations (van Boxtel, 2001); if low-frequency artifact and cross-talk are problematic, then a 20 or 30 Hz high-pass filter may be used (possibly in combination with

the double-differential recording technique) but the investigator should realize one consequence of this selection is that weak signals from the target muscle may also be attenuated.⁹

The two most common signal conditioning techniques are integration and smoothing, terms that are often confused. True *integration* is the temporal summation or accumulation of EMG activity, whereas *smoothing* typically refers to performing integration with a built-in signal decay and is accomplished either by low-pass filtering or some type of signal averaging. Because the total energy in the EMG signal in any epoch of time is roughly equivalent to the rectified and smoothed EMG response, considerable economy in terms of data acquisition and signal processing can be achieved by rectification and smoothing prior to digitization when frequency components of the raw signal are not of interest.

The most frequently used on-line “smoother” in psychophysiological research remains the *contour following* integrator, an electronic device consisting primarily of a precision rectifier connected to a simple first-order low-pass filter. Its output represents a running average of ongoing EMG activity by providing a varying voltage proportional to the envelope of the EMG signal. Short time constants provide sensitivity to momentary fluctuations in EMG signals and so are useful when measuring a rapidly changing EMG signal. A long time constant blurs rapid changes and hence the associated output can severely underestimate or overestimate EMG signal amplitude at any point in time as well as compromise precise measurements of response onset and offset. Conversely, if EMG signals that vary slowly are of primary interest, relatively short time constants may be too sensitive to momentary EMG fluctuations and the economic advantages of smoothing will be sacrificed. Despite the popularity of simple contour following integrators, a variety of more sophisticated quantitations that overcome many of these limitations have been available generally for two decades (Paynter filters, pulsed sampling integrators, etc.; see Loeb & Gans, 1986).

QUANTIFICATION AND ANALYSIS

Many investigators have performed frequency analyses on surface EMG recordings to determine whether there are shifts in the EMG spectra (i.e., changes in magnitude or power across frequency) as a function of some psychological or physiological variable. A particularly robust finding is that shifts in the central tendency of the EMG spectra (e.g., median frequency) are associated with muscle fatigue (e.g., Mulder & Hulstijn, 1984; Merletti, 1994; van

⁹ One important implication is that a failure to find significant treatment differences in EMG activity could be due to the selection of an inappropriate recording bandpass rather than to an actual absence in EMG activity across treatments. It is often advisable, therefore, to use a wide bandpass during recording and subsequently apply filters to copies of the stored data.

Boxtel, Goudswaard, & Janssen, 1983). The persistent lack of attention to spectral analyses of the surface EMG in psychophysiology, however, continues to be attributable primarily to the fact that sophisticated spectral analyses have proven no more sensitive to psychological processes than relatively inexpensive amplitude and time-based analyses (Dollins & McGuigan, 1989; McGuigan, Dollins, Pierce, Lusebrink, & Corus, 1982).

Signal representation

Electromyographic activity unfolds over time and, like many other psychophysiological responses, the complexity of the raw signal enjoins data reduction. Whether represented in the time, amplitude, or frequency domains the first step involves the conversion of the digitized signal to a descriptive (e.g., physiological) unit of measurement. The numbers assigned to EMG signals of different amplitudes depend on: (1) the electrical unit chosen for description of the signal, (2) the accuracy of the calibration procedure and amplifier's gain setting, and (3) the type of integration method and length of time constant or reset criterion used. Here we focus on the first two factors; interested readers can consult Fridlund and Cacioppo (1986) and Basmajian and De Luca (1985) for additional details.

EMG activity as a voltage-time function.

EMG signals can be viewed as a voltage-time function, where the ordinate represents bounded signal amplitudes and the abscissa represents discrete intervals of time. The quantification of the amplitudes at each unit of time is determined by the direction and magnitude of the measured voltage and is expressed typically in units of microvolts (μV). The EMG voltage-time envelope, like the motor unit action potential, is bipolar and asymmetrical about electrical zero.

Most psychophysiological research using EMG has focused on some variation of EMG signal amplitude as the dependent variable. Simple averaging of the raw EMG amplitudes is uninformative, however, because the nature of the signal ensures that the average expected value is zero. Counting or averaging the peaks in the EMG signal, or tallying its directional changes or zero crossings, are relatively easy methods to implement and are useful for gauging differences in EMG activity provided a sufficiently high sampling rate is used (Loeb & Gans, 1986, Chapter 17). Lippold (1967) maintained that the total energy in an EMG signal at a given moment in time, or what he referred to as the integrated EMG signal, represents overall muscular contraction more accurately than the number or average amplitude of peaks in the EMG signal. Subsequent research has largely corroborated Lippold's assertion (Basmajian & De Luca, 1985; Goldstein, 1972). As discussed above, muscles consist of large numbers of homogeneous units, generating similarly sized action potentials all recruited at similar levels of effort. Consequently, increments in the level of effort are generally found to be more accurately reflected in an

integral-based measure rather than in a frequency-based measure, such as the zero-crossing or inflection count per unit time, which will tend to saturate (i.e., increasing firing rate will differentially affect the area under the amplitude-time envelope, rather than the number of zero-crossings or inflections). However, EMG signals consisting of low rates of widely varying spikes (e.g., those generated by small numbers of recruited motor units or closely spaced differential electrodes) generate poorly fused and noisy integrals, whereas the zero-crossing or simple inflection counts may reflect more accurately the level of effort (Loeb & Gans, 1986, Chapter 17). The irony, therefore, is that the ubiquitous parameter used routinely to quantify EMG activity (i.e., integration) works best, theoretically, when the movements are *forceful, overt* and *extended* in duration, whereas the typical psychophysiological laboratory environment results in movements that are *weak, covert*, and *epigrammatic*. Recent laboratory results consistent with this reasoning suggest that simple inflection counting is specifically sensitive to covert activation (e.g., less than $10 \mu\text{Vs}$). (Tassinary, 2005; see Figure 12.6). Such methods, though intriguing, remain highly experimental. We therefore focus the remainder of our review on the more commonly used integration methods.

The phrase "integrated EMG" has been used in this research to refer to the output of several different quantification techniques. Two of the most common parameters in contemporary research are the arithmetic average of the rectified and smoothed EMG signal and the root-mean-square (rms) of the raw EMG signal.¹⁰ Both processing techniques transform the EMG voltage-time function into a waveform that is nonnegative and bounded in time and amplitude. The moment-by-moment amplitude of this function represents an estimate of the total energy of the signal across time; the mean amplitude of this voltage-time function represents the average level of electrical energy emanating from the underlying muscle region(s) during a given recording epoch; and the integral of this function (e.g., the sum of the amplitudes) represents the total electrical activity (i.e., the size of the response) emanating from the underlying muscle region(s) during the recording epoch.

One unfortunate consequence of the traditional focus on the amplitude domain of the EMG signal is that the form of the response across time has been largely ignored (see Cacioppo, Martzke, Petty, & Tassinary, 1988; Hess et al., 1989). A notable exception is Malmo's (1965) use of "EMG gradients" (Davis & Malmo, 1951), defined as an "[e]lectromyographic (EMG) voltage that rises continuously

¹⁰ The rms of the EMG signal is calculated by summing the squares of each EMG amplitude within a recording bin, and performing the square root. The rms is superior to mean rectified amplitude as a measure of sinusoidal alternating current and Basmajian and DeLuca (1985) have extended this argument to motor unit action potentials as well. It is of interest to note that the measures of mean amplitude, rms amplitude, and total electrical energy are closely related mathematically, with each emphasizing a different aspect of the amplitude distribution of a waveform. Interested readers may wish to consult Dorfman and Cacioppo (1990).

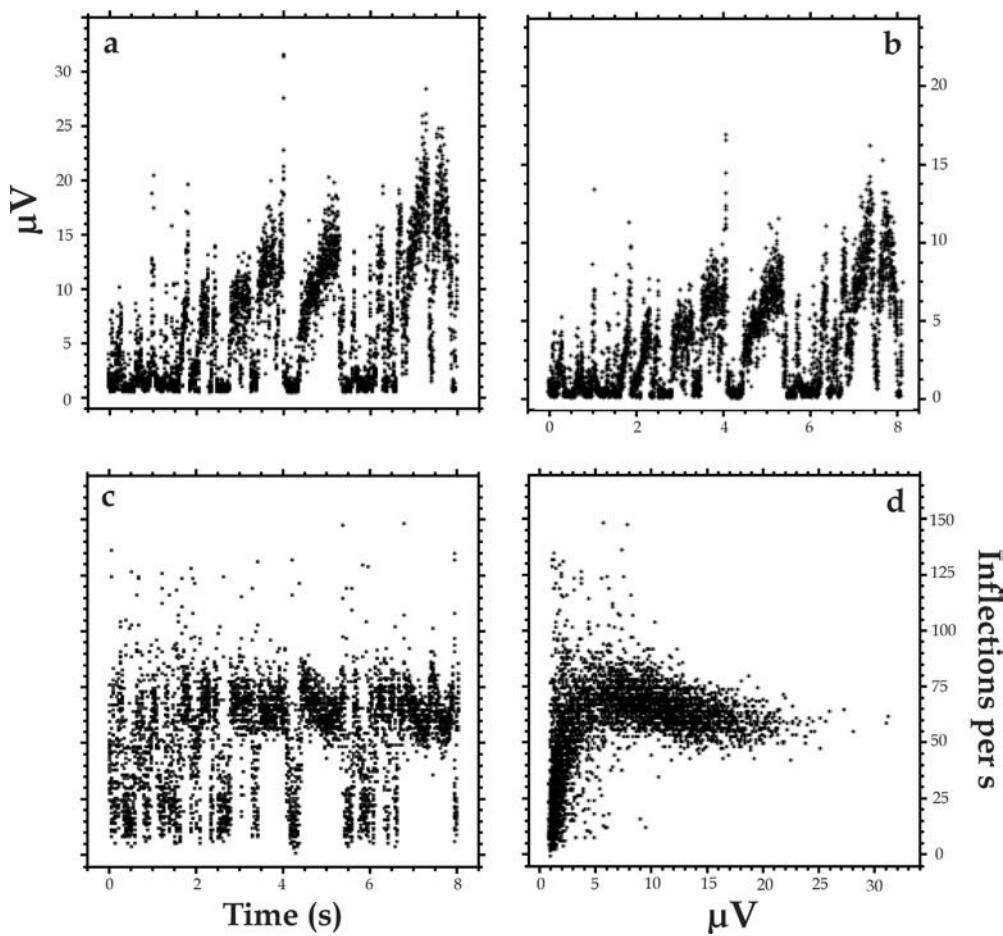

Figure 12.6. Four different plots of three different ways of representing the same eight minutes of EMG activity recorded over the left *zygomaticus major* muscle region of a single female subject while watching an amusing episode from the film *Much Ado About Nothing* (1993). The EMG signal was bandpass filtered (3–1000 Hz) and sampled at 6000 Hz. The data displayed represent discrete values computed over nonoverlapping intervals 100 ms in duration. Panel a: Root mean square values of the EMG activity expressed as a function of time. Panel b: Amplitude-weighted inflection counting of the EMG activity expressed as a function of time. Panel c: Simple inflection counting of the EMG activity expressed as a function of time. Panel d: Simple inflection counting expressed as a function of the root mean square. Data from Tassinary (2005). As is visually apparent in Panels a and b, there is very little difference between the root mean square and amplitude-weighted inflection counting representations, both of which are integral-based measures. In stark contrast, the simple inflection counting representation shown in Panel c, a frequency-based measure, appears unrelated to either of the prior representations. Panel d, however, reveals a very striking relationship between the root mean square and simple inflection counting representations; that is, the frequency of inflections increases rapidly from 0 to approximately 10 microvolts of EMG activity as indexed by the root mean square and then remains remarkably constant for further increases in EMG activity.

during motor performance or mental activity and falls precipitately at the end” (Malmo & Malmo, 2000, p. 145; see also Malmo, 1975). Electromyographic gradients are still used successfully to assess variations across time in tonic muscle tension; these gradients are depicted by plotting EMG amplitude for two or more consecutive recording epochs (e.g., Braathen & Svebak, 1994; Rimehaug & Svebak, 1987; Ritz et al., 1999).

Baselines

As in psychophysiology generally, it is often desirable to obtain response measures that are uncontaminated by the

basal (prestimulus) level of activity. The notion of basal activity, however, can be ambiguous when applied to EMG signals. This is because the true physiological baseline for EMG activity is zero; hence, the lowest empirical baseline for EMG recording is actually the level of noise in the recording system.

In laboratory practice, muscles seldom show zero activity because the alert research participant is rarely completely relaxed. It is therefore important to consider the EMG activity that exists in the absence of experimental stimuli in order to assess individual differences and also to help achieve a measure of the experimental treatments free from prestimulus EMG activity. In assessing basal EMG

activity, care is required to avoid any confounding of measurements with task-irrelevant activity (e.g., adaptation, fatigue, apprehension). The procedures commonly used include recording during prestimulus periods and recordings during pseudotrials (Johnson & Lubin, 1972; Jennings & Gianaros, this volume, Chapter 34). The use of pseudotrials has the advantage that assessments are obtained under conditions that – except for the lack of experimental stimuli – are identical to the experimental trials.

A closed-loop baseline procedure offers an alternative to the use of pseudotrials (McHugo & Lanzetta, 1983). Briefly, the presentation of experimental stimuli or treatments is programmed to be contingent on acceptably low levels of somatic activity across the recording sites. Task-specific EMG responses are thus quantified while minimizing the confounding effects of extraneous muscular activity or basal differences in somatic activity across treatments, a procedure that is reminiscent of Jacobson's (1932) use of progressive relaxation in studies of EMG and imagery. A closed-loop baseline procedure also has the advantage over simple change scores in that time series and waveform moment analyses (Dorfman & Cacioppo, 1990) can be performed with fewer restrictions. A potential liability of the closed-loop procedure, however, is that both the speed and accuracy with which acceptably low levels of EMG activity are achieved may be partially a function of experimental condition or idiosyncratic strategies, and designs employing this procedure may shape participants inadvertently in subtle ways that complicate interpretation. For this reason, most EMG-based psychological investigations have not employed this procedure, whereas some variant of this procedure is used routinely in investigations of physiological constructs such as muscle fatigue (Roy et al., 1997).

SOCIAL CONTEXT

Psychophysiological research was once thought to be exempt from the laboratory artifacts that have led others to consider the physical and social context in which the research was conducted (e.g., Rosenthal & Rosnow, 1969). The vulnerability of physiological responses to instructional sets (Sternbach, 1966), intentional distortions (e.g., Ekman, 1985; Honts, Devitt, Winbush, & Kircher, 1996), ethnicity (e.g., Rankin & Campbell, 1955; Vrana & Rollock, 1998), and social presence (e.g., Cacioppo, Rourke, Marshall-Goodell, Tassinary, & Baron, 1990; Geen & Bushman, 1989) vitiates this notion. Nowhere is this vulnerability more apparent in psychophysiology than in studies of the skeletomotor system (Cacioppo, Petty, & Tassinary, 1989). The evidence clearly suggests that vigilance with respect to these factors can contribute to the construction of more sensitive, artifact-free psychophysiological experimentation and, hence, to stronger inferences (Cacioppo, Marshall-Goodell, & Gormezano, 1983; Gale & Baker, 1981).

Social factors have been found also to moderate the influence of nonsocial factors on physiological responding.

This point, too, is perhaps clearest in studies of skeleto-motor response. The expression of emotion, for instance, can be magnified, attenuated, or masked because of the presence of others and comprehensive psychophysiological theories must accommodate such moderating influences (see reviews by Cacioppo & Petty, 1986; Gardner, Gabriel, & Diekman, 2000).

Social factors as laboratory artifacts

Gale and Baker (1981) noted that experimenter-participant interactions are particularly important in psychophysiology because the procedures may involve touching, partial removal of clothing, skin abrasion, and the application and removal of sensors. This somewhat unique and extended interaction may result in participants becoming anxious, distracted, or aware of the experimenter's expectations and significant laboratory artifacts may be introduced.

Demand characteristics

To the extent that participants can discern the experimental hypotheses and manipulate their actions accordingly, EMG studies are vulnerable to experimental demand confounds (Orne, 1962). Fridlund and Izard (1983) argued that many facial EMG studies of emotion and emotional imagery could be interpreted in terms of demand characteristics. Specifically, they reasoned that placing multiple electrodes on a person's face can make the person acutely aware of her or his facial expressions. Participants who desired to please the experimenter or contribute to "science" might alter their expressions in accordance with what they believed were the experimental hypotheses. Particularly susceptible, they suggested, were studies in which the experimental hypothesis was obvious, such as the early studies of facial EMG activity during emotional imagery (e.g., Schwartz, 1975). Not all prior research using facial EMG to study emotion was susceptible to this interpretation (see Cacioppo & Petty, 1981a), and more recent studies whose designs minimized experimental demands have continued to find that subtle emotions can be discriminated using facial EMG (Cacioppo et al., 1992; McHugo, Lanzetta, & Bush, 1991; Hess, Banse, & Kappas, 1995; Greenwald, Cook, & Lang, 1989; Dimberg, 1997).

Although experimental demands do not appear to be necessary for facial EMG patterning to emerge during emotions, they nevertheless remain a potential source of bias. Procedures contrived to minimize such biases include: (1) providing participants with plausible alternative hypotheses; (2) employing cover stories that divert attention away from the physiological recording; (3) utilizing engaging experimental tasks; (4) placing multiple non-functional sensors over other areas of the body to reduce the salience of the functional sensors; and (5) designing the laboratory setting to be comfortable and free of unnecessary equipment. The level of experimental demand can also be assessed directly either through a funnel debriefing

procedure that involves gradually revealing more and more of the hypothesis to participants while gauging their awareness of the hypothesis, or by including a “simulation” condition in which the EMG study is described explicitly to a naive group of participants who are then asked to predict how they would or should respond in such a situation.¹¹

Evaluation apprehension

Naive participants may be apprehensive about participating in research involving the use of electrodes and electrical recording equipment. Such apprehension, although possibly of interest in its own right, may create a level of tension or hypervigilance in the participant that is unrepresentative and that can obscure the effects of the experimental treatments. This apprehension is in addition to the potential apprehension that participants may feel about being evaluated by experimenters who are presumably experts in human behavior. Rosenthal (1966) suggested that this “evaluation apprehension” may also lead participants to distort their actions in a socially desirable fashion. If an experimenter’s behavior or experimental treatment makes participants especially anxious or aware that they are being evaluated, then the data may be significantly biased.

Procedures for minimizing evaluation apprehension, in addition to those outlined in the preceding section, include: (1) providing a tour of portions of the laboratory to prospective participants to brief them on the tasks and procedures involved in the study prior to seeking informed consent or scheduling them for participation; (2) substituting “sensor” or “biosensor” for “electrode” when communicating with participants; (3) allowing time before the beginning of the experimental procedures for participants to adapt to the laboratory; (4) using buffer trials or tasks to allow adaptation to the experimental procedure; (5) employing a closed-loop baseline to ensure participants are not unduly tense or aroused prior to initiating the next trial; and (6) minimizing the sense participants may have that they are being scrutinized by automating procedures, assuring them that their responses are anonymous, and using unobtrusive monitoring methods (e.g., hidden cameras; see Kappas, Hess, & Kleck, 1990) during the experiment.

Social factors as determinants

In the previous section, we saw that the nature of the interaction between the experimenter and participant is

¹¹ For instance, Cacioppo, Petty, Losch, and Kim (1986) placed a small set electrodes on the head and neck as well as on the face and body of their participants who were told that this array of sensors was placed around their brain to help isolate and identify the involuntary neural processes involved in processing pictorial stimuli. To the extent that the electrodes on the body and the nonfunctional electrodes on the neck and head diverted attention from voluntary facial actions, which debriefing suggested they did, then this explanation was both accurate factually and successful at minimizing experimental demand.

a source of both bias in psychophysiological research and a means for its solution. In this section, we briefly review illustrative research demonstrating how social factors can also moderate the influence of nonsocial factors on EMG responses.

Audience effects

The classic observations of Charles Darwin (1872/1873) suggested that facial expressions of emotion were universal. Most members of both the scientific community and the lay public, however, would undoubtedly agree that felt emotions are not always accompanied by perceptible expressions. According to an influential “neurocultural” model proposed by Paul Ekman (1972) to explain communalities and variations in facial expressions, a given emotion will not always be displayed in the same fashion due to the influence of personal habits, situational pressures, and cultural norms. In an early study on such “display rules,” Japanese or American students were exposed to a disgusting film while being videotaped unobtrusively or with an authoritarian experimenter present (Friesen, 1972). Results revealed that both the Japanese and American students displayed revulsion while viewing the film in solitude, but the Japanese students masked their feelings of revulsion by smiling during the film when the experimenter was present. A study of racial bias suggested the opposite dissociation between expression and self-report may occur as well when examining covert responses (Vanman, Paul, Ito, & Miller, 1997). In the context of a cooperative task, White participants tended to report more liking for Black partners while simultaneously showing greater increases in the EMG activity recorded over the brow region, a result indicative of greater negative affect and interpreted by the authors as evidence of racial prejudice (see also Dambrun, Despres, & Guimond, 2004). In a subsequent study, racial bias indicated by EMG activity – but not self-reports – was related to White participants’ preferences for a Black or White applicant for a fellowship (Vanman, Saltz, Nathan, & Warren, 2004). The ability of affective stimuli to evoke small but reliable changes in facial EMG activity even in the absence of awareness (e.g., Ravaja, Kallinen, Saari, & Keltikangas-Jarvinen, 2004; Tassinary, Orr, Wolford, Napps, & Lanzetta, 1984; Wexler, Warrenburg, Schwartz, & Janer, 1992) combined with the possibility that minute levels of activity may be imperceptible to both observers and producers (Max, 1932; Epstein, 1990) provides a plausible explanation for why such covert responses may be less susceptible to audience effects.

The influence of an observer on people’s facial expressions of emotion emphasizes the multiple roles played by behavioral responses. Because the skeletomotor system is the only means individuals have of approaching, avoiding, or modifying elements in their physical environment, one might expect that overt somatic responses in part reflect or serve to gratify certain goals or desires. An individual who accidentally touches a hot platter is likely to exhibit a rapid

withdrawal, just as an individual who smells a foul odor is likely to express disgust and rapidly either stop breathing or rapidly exhale (Tassinary, 1985).

The skeletomotor system is also an individual's primary means of communication and of effecting change in the social environment. It is not surprising, therefore, that overt somatic responses such as facial expressions can be affected strongly by the perceived presence of observers. Kraut and Johnson (1979), for instance, related the observed frequency of smiling to simultaneously occurring events in a wide range of naturalistic settings (e.g., bowling alleys, public walkways, hockey arenas). Their results indicated that people were most likely to smile while speaking with other people; they were significantly less likely to smile perceptibly to a presumable positive event (e.g., bowling a strike) when their faces were unobserved than observed. Related findings have been reported by Chovil (1991), Fridlund (1991), Gilbert, Fridlund, and Sabini (1987), Jäncke & Kaufman, 1994 and Jäncke (1996). Fridlund (1994) argued forcefully that such results provide strong evidence against the two-factor neurocultural model and strong evidence for a one-factor behavioral ecology model. A wide variety of results (e.g., Cacioppo et al., 1992; Geen, 1992; Hess, Banse & Kappas, 1995; Davis et al., 1995; Vanman et al., 1997; see also Russell, Bachorowski, & Fernández-Dols, 2003), however, suggest that a more rather than less inclusive and sophisticated model is necessary and this prevision is consistent with the multitude of neural systems contributing to the coordination and control of the facial musculature (Fanardjian & Manvelyan, 1987; Jenny & Saper, 1987; Petrides, Cadoret, & Maxkey, 2005).

Facial expressions of emotion are not the only somatic responses that are affected by the presence of observers. Chapman (1974), for instance, monitored EMG activity over the forehead region as participants listened to a story while unobserved, watched by a concealed observer, or watched by an unconcealed observer. Chapman found that EMG activity over the forehead region was higher during the story when the participant was observed than when unobserved and slightly though not significantly higher when the observer was present than when concealed. Groff, Baron, and Moore (1983) further demonstrated that the presence of observers led to more vigorous motor responses. These data fit well with observations made as far back as the late 1890s (Tripplett, 1898), demonstrating that an individual's performance on a task can be altered dramatically simply by moving the task from a nonsocial to a social context. Zajonc (1965) organized much of this research with his proposal that the presence of conspecifics lowered the threshold for the single most likely response to a task (see reviews by Geen & Gange, 1977; Bond & Titus, 1983). The important point here is that not only performance but also physiological responses such as EMG activity have been found to vary as a function of the presence of observers (see Cacioppo & Petty, 1986, pp. 658–664).

Mimicry

Mimicry refers in this context to the elicitation of a localized motor response through witnessing the same response being performed by another. Evidence for motor mimicry includes such demonstrations as wincing at another's pain (Vaughan & Lanzetta, 1980), straining at another's effort (Markovsky & Berger, 1983), and spontaneously imitating another's evident emotion (Dimberg, 1982, 1990; Lundqvist & Dimberg, 1995). Motor mimicry in psychology has traditionally been conceptualized as primarily intrapersonal, representing either primitive empathy, a conditioned emotional response based on one's direct experience, or an expression of vicarious emotion (Allport, 1968), and as such is closely related to the concept of emotional contagion (Hatfield, Cacioppo, & Rapson, 1993; Hess, Philippot, & Blairy, 1999). Consistent with this framework, Dimberg (1982; 1990) reported that subtle decreases in EMG activity over the *corrugator supercilii* muscle region and increases in EMG activity over the *zygomaticus major* muscle region were observed when participants viewed pictures of smiling faces, whereas the opposite pattern of facial EMG activity was observed when participants viewed pictures of angry faces. Lanzetta and his colleagues (Englis, Vaughan, & Lanzetta, 1982; Lanzetta & Englis, 1989) provided evidence that counterempathic as well as empathic processes can result in subtle changes in facial EMG activity.

Studies by Bavelas and colleagues (Bavelas, Black, Lemery, & Mullett, 1986; Bavelas, Black, Chovil, Lemery, & Mullett, 1988) suggest the form and intensity of *visible* motor mimicry is influenced strongly by the communicative significance of the mimesis. For instance, in their earlier study, the victim of what appeared to be a painful injury was either increasingly or decreasingly visible to the observing participant. Results revealed that the pattern and timing of the observer's motor mimicry was affected significantly by the visibility of the victim. Subsequent research has found that differences in emotional empathy due to different attachment styles also affect motor mimicry (Sonnby-Borgström & Jönsson, 2003), but that neither mimicry nor imitation necessarily have cognitive sequelae (see Graziano et al., 1996). Thus, the research on mimicry is consistent with the preceding suggestion that social factors can influence somatic responding in the service of interpersonal (i.e., communicative) goals as well as personal feelings and emotions (cf. Gallese, 2003).

INFERENTIAL CONTEXT

One of the challenges in psychophysiological research involving surface EMG is to create paradigms that allow strong inferences (Platt, 1964) about psychological constructs based on somatic responses. Cacioppo et al. (1990) proposed that much of the variety and complexity in the experimental paradigms in this area can be characterized in terms of the function (Independent vs. Dependant variable) and the proximal origin (Endogenous vs.

Exogenous) of a somatic response, resulting in four generic paradigms referred to as Outcome, Conditional Probability, Reflex Probe, and Manipulated Response paradigms. Within these general paradigms, answers have been sought to questions regarding the psychological, behavioral, and health significance of somatic activity and the extent to which skeletomotor activity reflects specific or global activation; phasic, tonic, or modulated thresholds for activation; and characteristics of the stimulus situation or the individual's disposition.

Outcome paradigm

Outcome paradigms continue to be the most prevalent in psychophysiology. The essence of such paradigms is that a psychological or behavioral process is manipulated while one or more physiological (e.g., EMG) responses are monitored. Edmund Jacobson's (e.g., 1932) pioneering EMG studies mentioned at the beginning of this chapter are cases in point as are any studies based on subtractive or additive factors methodology (Sternberg, 1969; Cacioppo & Petty, 1986).

For over half a century, studies conducted within this general paradigm on phasic EMG responses have found that reliable and oftentimes minute patterns of EMG activity accompany thought, emotion, and imagery despite large variations within and between individuals (e.g., Bartholow, Fabiani, Gratton, & Bettencourt, 2001; Bakker, Boschker, & Chung, 1996; Cacioppo, Petty, Losch, & Kim, 1986; Lang, Greenwald, Bradley, & Hamm, 1993; Malcolm, Von, & Horney, 1989; Sloan, Bradley, Dimoulas, & Lang, 2002; Shaw, 1940). In an illustrative early study, Schwartz, Fair, Salt, Mandel, and Klerman (1976) reported that clinically depressed subjects displayed higher levels of EMG activity over the brow muscle region (*corrugator supercilii*) and lower levels of EMG activity over the cheek muscle region (*zygomaticus major*) when they imagined unpleasant experiences than when they imagined pleasant ones. Nondepressed subjects displayed patterns similar to those produced by the depressed subjects, but the pattern accompanying unpleasant imagery was attenuated in the nondepressed subjects. Numerous studies conducted since have expanded upon these basic findings and consistently demonstrated that affect-laden stimuli, whether imagined or perceived, result in similarly patterned changes in the facial musculature (e.g., Arndt, Allen, & Greenberg, 2001; Gehricke & Shapiro, 2001; Hu & Wan, 2003; Jänke, 1996). Much of this research has demonstrated that both EMG activity over the brow and cheek regions vary inversely as a function of the affective valence of the stimulus. However, in a recent study that used affective pictures, sounds, and words as stimuli, Larsen, Norris, and Cacioppo (2003) found that positive affect decreased and negative affect increased activity over the brow region, but only positive affect affected activity over the cheek region. Larsen et al. concluded that *zygomaticus major* may not be reciprocally activated by positive and negative affect, although

the extent of the generality of this specificity is not known yet. Additional recent studies have also begun to examine muscles hypothesized to be linked to specific emotional states (i.e., disgust) as opposed to generalized affect (Stark et al., 2005).

Although, as we have noted, most EMG research in psychophysiology has focused primarily on specific phasic changes in EMG activity, a parallel tradition of research has focused on general or tonic changes in tension, activation, or arousal (see reviews by Freeman, 1931; Duffy, 1962; Malmo & Malmo, 2000; van Boxtel & Jessurun, 1993). Germana (1974), for instance, suggested that although skilled or habitual actions are characterized by a well-orchestrated patterning of skeletomotor activity, response uncertainty leads to a general activation of the musculature. He speculated that general activation across functionally disparate muscle regions signifies extensive preparation for overt behavior, and proposed that both novel and partially conditioned stimuli are the most likely to produce response uncertainty. Interestingly, recent research provides partial support for Germana's suggestion that generalized somatic activation during response uncertainty reflects an equalization of response probabilities (e.g., see Fabiani, Gratton, & Federmeier, this volume, Chapter 4), and this suggestion has been incorporated into a heuristic model of emotion (Cacioppo, Berntson, & Klein, 1992) via the proposal that psychologically relevant somatic activity may range from completely undifferentiated tonic activation to emotion-specific patterns of phasic activation.

Research with respect to motivational states has tended to focus on the significance of EMG gradients in the task-irrelevant musculature (e.g., Rimehaug & Svebak, 1987). In an illustrative study, participants played one of two versions of a video game that required they stop a "ball" from passing across the screen by maneuvering a video "bat" to intercept the ball (Svebak, Dalen, & Storfjell, 1981). In the easy version, an unimpeded ball bounced across the screen in approximately 3 s, whereas in the difficult version the ball traveled at approximately twice this rate. Both versions required the subject to engage in continuous performance for 150 s, and EMG activity was recorded over the forearm flexor of the passive arm during baseline and task periods. Results revealed the EMG gradient associated with the difficult game to be significantly steeper than that associated with the easy game. Van Boxtel and Jessurun (1993) also reported strong EMG gradients recorded from the forehead, brow, and lip muscle regions during performance on difficult and extended tasks, and concluded that such activity provides a sensitive index of the degree of exerted mental effort.

In a similar vein but on a shorter time scale, Davis (1940) recorded EMG activity over several muscle regions (e.g., forearm extensors) as participants performed a choice reaction time task under unwarned, fixed foreperiod or variable foreperiod conditions. Davis observed that (a) EMG activity was higher in the foreperiod when the participant was warned as opposed to unwarned, (b) EMG

activity began to rise approximately 200–400 ms following the warning signal and continued to rise until the overt response was completed, and (c) EMG activity was higher (and reaction time shorter) with a fixed than variable foreperiod. Davis concluded that the EMG responses during the foreperiod reflected preparation for the upcoming response. In a similar paradigm, van Boxtel, Damen, and Brunia (1996) recorded EMG activity over several pericranial muscle regions as participants performed a fixed foreperiod simple reaction time task involving either an auditory or visual reaction signal. The responses were performed with the hand or foot. Throughout the warning interval they observed that (a) neck muscle EMG activity remained relatively unchanged, (b) forehead, brow and lip EMG activity systematically increased, and (c) periocular, cheek, and temple EMG activity systematically decreased. Van Boxtel et al. interpreted this pattern of activation in the task-irrelevant pericranial musculature to be in the service of increasing perceptual sensitivity rather than facilitating response preparation.

There is thus no more consensus within the EMG field than within other fields of psychophysiology regarding which measure best reflects general motivation, tension, or activation. Meyer (1953) suggested eyeblink rate provided the best overall measure of generalized tension and Meyer, Bahrick, and Fitts (1953) reported that individuals who score high on anxiety inventories also have high blink rates. Rossi (1959) found a similar relationship, however, between manifest anxiety scores and EMG activity over the forearm extensors. Similarly, Davis, Malmo, and Shagass (1954) administered white-noise blasts at 1 minute intervals to both normals and individuals with anxiety disorders. Results revealed that although the noise blast evoked a slightly larger EMG response over the forearm extensor region in the anxious than normal individuals, the more significant difference occurred during recovery following the stressor. The elevation in EMG activity in normals was sharply delimited, returning to basal levels within seconds of the termination of the noise burst, whereas the elevation in EMG in the anxious subjects lingered.

Fridlund, Hatfield, Cottam, and Fowler (1986) replicated and extended these findings using EMG measures over the head, neck, and limbs. Participants first rested quietly for 15 minutes and then were exposed to 5 minutes of 105 dB binaural white-noise stimulation. High, in contrast to low, anxious participants exhibited higher levels of EMG activity primarily over the head and neck preceding the stimulus and more generally during the stimulus. An idiographic principal components analyses of EMG activity during these periods failed to reveal evidence for a general, inter-correlated tensional factor; instead, the EMG elevations in the highly anxious subjects consisted largely of uncorrelated response bursts. This pattern of EMG responses was interpreted to indicate a state of heightened activation or a lower threshold for activation. Consistent with this interpretation, Britt and Blumenthal (1992) reported that the latencies of auditory startle responses in participants low

in state anxiety were intensity dependent, whereas those high in state anxiety responded with equal latency regardless of stimulus intensity.

Woodworth and Schlosberg (1954, pp. 173–179) suggested that EMG activity, particularly in the neck region (e.g., splenius, upper trapezius), may be a somewhat unique indicator of the level of activation due to the possibility that a disproportionate share of proprioceptive impulses to the central nervous system originated in this muscle region. This suggestion is interesting in light of the sparse evidence for the notion of a coherent tensional factor (e.g., see Fridlund, Fowler, & Pritchard, 1980). In accord with this suggestion, Eason and White (1961) had subjects perform a variety of vigilance tasks (e.g., rotary tracking) while recording EMG activity over the splenius, upper trapezius, lower trapezius, and the deltoid and biceps of the right arm. The major finding in these studies was that the general level of EMG activity (most consistently that recorded over the neck muscles) varied as a function of the effort subjects expended on tasks. Waersted and Westgaard (1996) recorded surface EMG activity from 20 different sites while participants performed a complex 2-choice reaction time task designed to demand continuing attention yet require minimal activity. The major finding in this study was that attention-related activity was most clearly observed over the frontalis and upper trapezius muscle regions.

In summary, substantial increases in task difficulty, the subjective effort expended on tasks, or stress have been found to lead to elevated EMG activity during preparatory periods as well as during the performance of effortful engaging tasks. In addition, an inhibition of EMG activity over irrelevant musculature is sometimes observed during such tasks, particularly when the response to the task is well practiced (e.g., see Germana, 1974; Goldstein, 1972; Brunia & van Boxtel, 2000).

Double-dissociation design. Whether changes in EMG activity reflect particular actions or general somatic attitudes often has important theoretical implications. The double-dissociation design (Teuber, 1955) is considered to be one of the more powerful in this regard. This experimental design is so named because (a) one or more treatments that should evoke a specific response is contrasted with one or more treatments that should not evoke the expected response, and (b) one or more measures of the target response are included as well as one or more measures of a nontarget response. The former establishes discriminant validity of the treatments, whereas the latter demonstrates the discriminant validity of the responses.

To illustrate, there has long been a hypothesis that silent-language processing is associated with increased activation of the speech (e.g., perioral) musculature (see McGuigan, 1978). As McGuigan (1970) noted previously, there are a number of studies demonstrating that EMG activity over the perioral musculature increased from basal levels when individuals engaged in silent-language

processing. These results alone are not particularly informative because such a psychophysiological outcome could be attributed to aspects of the task that had nothing to do with speech processing per se. A slight tensing of lips, for example, might be associated with orthographic or auditory processing or possibly to general increases in tension or arousal due to concerns about task performance. The inclusion of nonspeech as well as speech tasks addresses the first of these interpretational problems, and the measurement of EMG activity over nontarget as well as target sites addresses the second.

In most applications of the double-dissociation paradigm, different subjects or stimuli are used to achieve treatments that theoretically should and should not evoke a specific somatic action or pattern. In a particularly comprehensive series of studies, McGuigan and Bailey (1969) recorded EMG activity over the chin, tongue, and forearm muscle regions while subjects silently read, memorized prose, listened to prose, listened to music, and attentively listened to "nothing." Results revealed that EMG activity over the perioral musculature was uniquely associated with the performance of silent language tasks.

Double dissociation with constant stimuli. Although the outcome observed by McGuigan and Bailey (1969) is consistent with the hypothesis that silent-language processing leads to increased perioral EMG activity, Cacioppo and Petty (1979b; 1981b) noted that the grounds for such an inference would be strengthened further if the participants and the physical characteristics of the target stimuli were held constant within the double-dissociation paradigm. To achieve this refinement, EMG activity was monitored over the inferior *orbicularis oris* and the superficial forearm flexor muscle regions while participants evaluated a series of trait adjectives presented visually. The treatment conditions were altered by varying systematically the dimension of evaluation rather than by varying either participants or stimuli. Specifically, for half of the trait adjectives participants were asked to evaluate the stimulus semantically ("Is the following descriptive of you?"), and for the other half they were asked to evaluate the stimulus graphemically ("Is the following printed in uppercase letters?"). Results revealed EMG activity over the perioral region to be greater during the semantic task, whereas EMG activity over the nonpreferred forearm did not differ as a function of task. Because the type of stimulus presented or type of participant tested was held constant, the inference that silent-language semantic processing involving short-term memory leads to increased EMG activity over the perioral muscle region appears more secure.

It must be noted, however, that inferences derived from outcome paradigms are tentative at best when using even the most rigorous of designs. The data obtained from additive and subtractive factors designs in general, as well as double dissociation designs in particular, are indeterminate to the extent that continuous causal functions are dichotomized arbitrarily (Cook & Campbell, 1979, p. 12),

the underlying mechanisms are nonlinear (McClelland, 1979), or relevant factors are overlooked (Cacioppo, Petty, & Morris, 1985). The continuing controversy over the evidence for parallel brain systems for item memory and category knowledge (Knowlton & Squire, 1993; Nosofsky & Zaki, 1998; Smith & Minda, 2001) illustrates clearly the diagnostic limitations of interpretations based solely on the results from such designs.

Conditional probability paradigm

Most psychologists, like many psychophysiologists, have sought to use physiological data to infer psychological or behavioral constructs such as anxiety, emotion, deception, and depression. Typically, the target physiological events have been identified as those that have been shown to vary as a function of the theoretical construct of interest. Electromyographic activity over the forehead region has been of interest, for instance, because anxiety, tension, and mental effort are often accompanied by increased EMG activity over this site. However, knowing that the manipulation of a psychological or behavioral factor leads to this particular skeletomotor response does not logically imply that this response indexes the psychological or behavioral factor. Put succinctly, the probability of Event A given Event B cannot be assumed to equal the probability of Event B given Event A, and the former cannot even be derived unless both the latter and the probability of Event B given the absence of Event A are known. Put more concretely, the utility of a skeletomotor response to serve as an index of a theoretical construct is weakened by the occurrence of such responses in the absence of the construct of interest (see Cacioppo, Tassinary, & Bernston, this volume, Chapter 1).

Although one cannot logically identify all possible factors that might influence a target response or response pattern, its ability to index a theoretical construct can be defined as the extent to which the construct of interest is present given the presence of the target response or response pattern. That is, one can block on the presence or absence of a skeletomotor response (or on variations of this response) and analyze the extent to which the construct of interest is evident. In so doing, an endogenous skeletomotor response pattern functions as the independent rather than the dependent variable.

Cacioppo et al. (1988) utilized a conditional probability paradigm to examine the extent to which specific forms of EMG response over the brow region indexed particular emotions evoked during an interview. As noted above, previous research has demonstrated that mild negative imagery and unpleasant sensory stimuli tend to evoke greater EMG activity over the brow (*corrugator supercilli*) and less EMG activity over the cheek (*zygomaticus major*) and ocular (*orbicularis oculi*) muscle regions than mild positive imagery and pleasant sensory stimuli. This previous research did not address whether facial EMG responses provided a sensitive and specific index of

particular emotions, however, because there are a multiplicity of events that can affect facial EMG activity. To address this question directly, Cacioppo et al. (1988) obtained both facial EMG and audiovisual recordings while individuals were interviewed about themselves. A while later individuals were asked to describe what they had been thinking during specific segments of the interview marked by distinctive EMG responses over the brow region in the context of ongoing but stable levels of activity elsewhere in the face. Consistent with the notion that the expressive components of emotion are "...sometimes brought unconsciously into momentary action by ludicrously slight causes." (Darwin, 1872/1873, p. 184), inconspicuous EMG responses over the *corrugator supercilii* muscle region were observed to covary with subtle variations in emotion during the interview even though the overt facial expressions evinced by subjects were rated similarly across conditions by observers. Furthermore, it was reasoned that certain forms of EMG activity in the context of an interview, such as brief jagged bursts rather than sustained smooth mounds, would be especially predictive of variations in emotion due primarily to theoretical differences in the probability of such responses in the absence of emotion. Smooth modulations in EMG activity over the brow region were thus hypothesized to reflect equally both paralinguistic signaling and emotional expression, whereas abrupt modulations in EMG activity over the same region were hypothesized to be much less likely to be associated with paralinguistic signaling. Support for this reasoning was also found. These results illustrate the power of the conditional probability paradigm and provide evidence that specific patterns of facial EMG response can actually index variations in emotion, at least within this limited context.

Shimizu and Inoue (1986) completed a study of sleep and dreams that bears on the utility of perioral EMG activity as a marker of silent-language processing. Electroencephalographic (EEG), electrooculographic (EOG), perioral EMG, and nonoral EMG activity were recorded during sleep. Participants were awakened during either rapid eye movement (REM) or Stage 2 sleep, as determined by inspection of the EEG and EOG recordings. When participants reported dreaming they were asked whether or not they had been speaking in their dreams. Dream recall during REM sleep occurred in approximately 80% of the awakenings, and it occurred during Stage 2 sleep in approximately 28% of the awakenings. Awakenings without dream recall were excluded from further analyses, as were awakenings preceded by phasic discharges in the perioral musculature that were accompanied by any whispering or vocalization. Results revealed that when phasic discharges over the perioral musculature were observed within the 30s preceding the awakening, subjects reported having been speaking in their dreams in 88% of the awakenings from REM sleep and 71% of the awakenings during Stage 2 sleep. Moreover, when phasic discharges over the perioral musculature were not observed within the 30s preceding the awakening, subjects reported having been

speaking in their dreams in only 19% of the awakenings from REM sleep and in none of the awakenings during Stage 2 sleep.

In summary, previous research has indicated (a) that situations in which participants report emotional reactions are accompanied by patterned EMG activity in the facial musculature, (b) that effortful tasks that require cognitive resources influence the EMG activity in task-irrelevant muscles, and (c) that silent language processing is accompanied by EMG activity in the perioral musculature. The research reviewed in this section further suggests that autochthonous EMG activity can be used to mark episodes of affect and silent-language processing in some limited contexts.

Reflex probe paradigms

Reflexes generally refer to any automatic reaction of the nervous system to stimuli impinging upon the body or arising within it (Merton, 1987).¹² Although there have been clear analytical attempts to define the concept of the reflex in precise logical and empirical terms from within both physiology (Sherrington, 1923/1906) and psychology (Skinner, 1931), the definition of the reflex and the functional significance of reflexes in the intact organism remain active topics of research (e.g., Berkinblit, Feldman, & Fulson, 1986).

From a physiological perspective, reflexes can be defined as a discrete type of behavior mediated by a reflex arc, thus providing both functional and structural constraints on the definition (Gallistel, 1980). Structurally, a reflex arc is an anatomical entity consisting of: (a) receptors tuned to transduce specifiable classes of environmental stimuli into neural signals; (b) sensory neurons that conduct the output signals from the receptors to the central nervous system (CNS); (c) mediators, either a single synapse or a small set of interneurons, that relay the sensory output to an appropriate subset of motoneurons or neurohumoral cells; (d) motoneurons or neurohumoral cells that conduct the signal from the CNS to particular effectors; and (e) the effectors themselves, which affect the environment as a function of neural and/or hormonal input.

Since the turn of the century, the scientific study of the reflex has proceeded in two directions. Disciplines concerned with the control of movement (e.g., neurophysiology) have generally followed the tradition of Sherrington (1923/1906) and examined reflexes as integral to the regulation of behavior. Predicated on this view of the reflex as a relatively invariant unit of behavior, the accompanying research and theory has focused on specifying the rules by which reflexes combine to generate coordinated, goal-directed movements.

In neurology and psychophysiology, however, the reflex is viewed in a manner more consistent with the behaviorist generalization of the concept articulated by Skinner (1931). In the field of neurology this conceptualization led

¹² The reader further interested in the history of the reflex is encouraged to consult the monographs by Fearing (1930), Liddell (1960), or Swazey (1969).

initially to widespread confusion, with the early part of the century referred to as an open season for the “hunting of the reflex” (Wartenberg, 1946). During this time, any stimulus-response correlation was “fair game” to be named and reified. An unfortunate result was that many reflexes were “discovered” by one author after another, each time renamed and claimed to be unique. However, it is now possible to use parameters of reflex responses as markers of CNS function because of increasingly detailed information about the neural circuits mediating specific reflexes (Davis, Walker, & Myers, 2003) and the publication of detailed guidelines for the EMG recording of reflexes (e.g., Blumenthal et al., 2005).

As a tool in the investigation of psychological processes, surface electromyography provides an ongoing record of muscular activity while minimally interfering with the behavior under study. The unique advantage of the reflex probe paradigm, however, is that it allows estimation of changes in the excitability of spinal and brainstem motor structures that may be manifest in neither overt behavior nor in peripheral EMG activity. The use of the reflex as a probe into ongoing psychological processes further exemplifies the examining of variations in reflex characteristics as a function of third variables. Although Skinner (1931) intended this experimental procedure to be used to quantify the influences of external variables on the reflex behavior of intact organisms, the logic of the situation allows one to use variations in reflex strength as an indicant of internal psychological processes as well. In the former case the focus is on the description of behavior, whereas in the latter case one infers the operation of either intervening variables or hypothetical constructs.

Early investigations of reflexes revealed that psychological factors (i.e., attention) affected aspects of reflex responsivity. Clinical neurologists looked upon these influences as nuisance variables, factors that could increase the likelihood of both false positives and false negatives in their diagnosis of CNS function. The enormous potential to use such procedures in psychophysiological investigations, however, was apparent from the turn of the century (Dodge, 1911; Golla & Antonovitch, 1929). Surprisingly, for reasons that remain somewhat unclear (see Ison & Hoffman, 1983), the use of this technique remained sporadic until the mid-1960s, when the power of the reflex probe paradigm for psychophysiological inference was first seen most clearly in the work on attention (Anthony, 1985), activation, and response preparation (Brunia & Boelhouwer, 1988). More recently, it has been conscripted to reveal the motivational substrate of affective processes (e.g., Bradley, Cuthbert, & Lang, 1999; see Bradley & Lang, this volume, Chapter 25).

Reviews of numerous experiments on the modulation of the blink reflex by manipulations affecting attention have concluded that the amplitude and/or latency of the blink can be used in specific situations to measure how attention is allocated to different sensory modalities (Anthony, 1985; Hackley, 1999). Specifically, in paradigms in which the subject is warned of an impending target stimulus,

the amplitude of the blink is reliably enhanced or suppressed in the warning interval as a function of the match or mismatch, respectively, between the modalities of the two stimuli. In addition, reliable changes in the degree of facilitation or inhibition across the warning interval suggest that the selective allocation of attention may begin as early as the onset of the warning stimulus but that the rate of allocation speeds up dramatically approximately 2 s before the onset of the target stimulus.

Brunia and Boelhouwer (1988) reviewed a large and well-established body of experiments on the modulation of Achilles tendon, Hoffman, and blink reflex amplitude as a function of a wide range of tasks. They concluded that such changes in amplitude are a function of both aselective (i.e., activation) and selective (i.e., response preparation) processes and associate these hypothetical processes with major pathways in the central nervous system; aselective activation effects are hypothesized to be the result of activity in the reticulo-spinal and reticulo-bulbar pathways, and selective preparation effects are hypothesized to be the result of activity in the cortico-spinal and cortico-bulbar pathways. They also presented evidence to suggest that three distinct independent phases in the reflex amplitude function exist in the interval between the presentation of a warning stimulus and the execution of a movement, and argue that these empirically defined phases can be linked to the information processing operations of stimulus evaluation, motor preparation, and response execution. Finally, they (see also Davis, 1940; van Boxtel et al., 1996) presented evidence that there are situations in which changes in reflex amplitude (a) are redundant with nonprobed surface EMG activity (after the onset of the imperative stimulus), (b) stand in contraposition to surface EMG activity (during the foreperiod in an already activated muscle), and (c) occur in the absence of surface EMG activity (during the foreperiod in task-irrelevant muscles and, after practice, in the task relevant muscles as well).

Over the past two decades the reflex probe technique (specifically, the blink reflex) has been employed increasingly in psychophysiology to investigate basic affective processes, although these were preceded by much earlier investigations (Burtt & Tuttle, 1925). Bradley et al. (1999) reviewed the literature to date and evaluated the theoretical implications of this research. Although the exact time course of affective as well as attentional modulation of the blink reflex are sensory modality and task dependent (Neumann, Lipp, & Pretorius, 2004; Vanman, Boehmelt, Dawson, & Schell, 1996), sufficient consistency across studies exists to support the proposition that reflex modulation by affective valence occurs principally in the context of contemplative situations that both enthrall and induce. Viewed in this manner, augmented blink amplitudes observed during the perception of menacing events signalize the prefatory activation of defense or avoidance responses. Conversely, attenuated blink amplitudes observed during the perception of enticing events signalize the prefatory activation of consummatory or approach responses.

In summary, the reflex probe paradigm has been useful when simply recording surface EMG activity has proven to be either insensitive or polysemous. In these contexts, variations in reflex amplitudes have been used to track the allocation of attention, the recruitment of motivational systems, and the preparation for action. It is important to note, however, that this paradigm is inherently more intrusive, potentially less efficient, and only possibly more sensitive than either of the previous two paradigms. The decision regarding which paradigm to use in a given application depends heavily on the nature of the question asked as well as on the social context of the experiment.

Manipulated response paradigm

Questions about the contributions of skeletomotor actions to psychological states or processes have been addressed also by manipulating skeletomotor actions to achieve the desired configuration, verifying the configuration using some observational procedure such the FACS, and measuring the outcome variables of interest (e.g., subjective states, autonomic responses). Although skeletomotor actions have occasionally been manipulated through explicit operant conditioning procedures (e.g., Hefferline, Keenan, & Harford, 1959; Hutchinson, Pierce, Emley, Proni, & Sauer, 1977; Laurenti-Lions et al., 1985; Kleinke & Walton, 1982), the most common approaches have been to instruct subjects either to exaggerate or suppress general skeletomotor configurations (e.g., McCanne & Anderson, 1987; Cacioppo et al., 1992) or to achieve a particular pose by unobtrusively varying the actions of individual muscles (e.g., Strack, Martin, & Stepper, 1988; Larsen, Kasimatis, & Frey, 1992).

In an illustrative study utilizing the muscle-by-muscle induction variant of this general approach, Levenson, Ekman, and Friesen (1990) instructed participants to contract individual muscles until prototypes of the expressions of happiness, sadness, fear, anger, disgust, or surprise were constructed. The construction of each emotional expression was preceded by the construction of a nonemotional expression. Each expression was held for 10 s and was subsequently verified as having been achieved using the FACS. Averaged data during emotional faces minus that during nonemotional ones revealed that the (a) anger face was associated with elevated heart rate, skin conductance levels, and palmar skin temperature, (b) fear and sad faces were associated with elevated heart rate and skin conductance levels, (c) disgust face was associated with elevated skin conductance levels, and (d) the happy and surprise faces were associated with relatively unchanged levels of heart rate, finger temperature, and skin conductance.

Results obtained using the muscle-by-muscle induction paradigm have occasionally been inconsistent and are often open to alternative explanations (see Tourangeau & Ellsworth, 1979; Boiten, 1996). Methodological issues that may contribute to inconsistent results and flawed interpretations include (a) improper controls for somatic ten-

sion or effort, (b) floor and ceiling effects in emotional responding, and (c) the inherent difficulties associated with specifying and constructing appropriate expressions with naturalistic durations and trajectories while simultaneously controlling for the intensity and the inconspicuousness of the facial configurations. Relevant commentaries and reviews are provided by Cappella (1993), Hager and Ekman (1981), Laird (1984), Levenson (1992), and Neumann and Strack (2000).

Vaughan and Lanzetta (1981) employed the exaggeration-suppression variant of this paradigm to assess the possible influence of facial expressions on vicarious emotional arousal. Subjects were exposed to a videotaped model displaying pain, ostensibly from receiving electric shocks. One group of subjects was instructed to inhibit any facial expressions when the model was shocked, a second group was instructed to amplify their facial expressions when the model was shocked, and a third (control) group received no instructions about modulating their facial expressions. Results revealed that the amplify group exhibited larger skin conductance responses, heart rate increases, and facial EMG activity in response to the model's display of pain than the other two groups, which did not differ from one another.

Wells and Petty (1980) tested the hypothesis that affect-pertinent bodily movements might similarly influence attitudinal responses toward a persuasive appeal. Specifically, head movements (nodding in agreement or wagging in disagreement) were chosen for study because of their strong association with agreeing and disagreeing responses in a wide variety of cultures (Eibl-Eibesfeldt, 1972) and vertical head movements led to greater agreement with the message in both cases than did horizontal head movements. A conceptual replication and extension of this work by Cacioppo, Priester, and Berntson (1993) found similar compatibility effects for arm flexion and extension, a finding reminiscent of a related compatibility effect reported by Hugo Münsterberg over a century ago (as cited in Bebbe-Center, 1932, p. 339; cf. Foerster & Strack, 1997). This work has recently been extended further, demonstrating the ability of surreptitious feedback from particular facial muscles to ameliorate implicit racial bias (Ito, Chiao, Devine, Lorig, & Cacioppo, 2006).

APPLICATIONS

As described throughout this chapter, surface EMG has proven valuable in studying a wide variety of basic psychological and behavioral processes. This technique has also proven useful in applied contexts. In what follows we list a few general areas to illustrate the breadth of its application.

Detection of deception

The physiological detection of deception, both in research and forensic settings, routinely involves monitoring

autonomic reactions to a series of test questions. Regardless of the test used (i.e., Control Question, Concealed Knowledge, or Relevant/Irrelevant), the validity of the test depends on the ability of a pattern of physiological responses to sensitively and specifically index deceit (see Iacono, this volume, Chapter 29). Not surprisingly, the possibility that countermeasures might be used to defeat or distort the polygraph exam has raised concerns about its usefulness (Lykken, 1998). By pressing their toes hard against the floor or biting their tongues, for example, examinees can generate autonomic responses that foil the polygraph exam (e.g., Honts, Hodes, & Raskin, 1985). In an attempt to prevent such physical countermeasures from undermining the validity of the exam, Honts, Raskin, and Kircher (1987) recorded surface EMG activity from the examinee's gastrocnemius and temporalis (i.e., jaw closing muscle of the temple) during a typical exam. Such measurement enabled the detection of 80 percent of the research participants who used either tongue biting or toe pressing to defeat the exam, thus auguring the addition of surface EMG to the list of physiological measures used in the routine detection of deception. Surprisingly, nearly two decades have passed since this seminal publication and surface EMG measurement in either research or forensic polygraphy remains the exception. We believe this is likely because surface EMG is perceived (incorrectly) to be a recondite technique only applicable to the use of physical countermeasures and some studies suggest that purely mental countermeasures might be equally effective in defeating either the control question or the concealed knowledge test (Honts, Raskin, & Kircher, 1994; Honts, Devitt, Winbush, & Kircher, 1996; cf. Olivers & Nieuwenhuis, 2005). As such, it finds occasional application as a manipulation check (Honts et al., 1994) but is not used routinely to improve the predictive validity of the lie detection test.

Polysomnography

For at least the past 40 years it has been known that sleep is not a unitary phenomenon but rather a multistage process. In general, the transition from wakefulness to sleep is accompanied by a decrease in alpha activity (8–13 Hz), a general slowing of EEG activity, a prominence of activity in the theta range (3–7 Hz), and the occurrence of vertex sharp waves. During the transition between wakefulness and Stage 1, slow horizontal eye movements occur, blink rate declines, and muscle tonus is generally reduced relative to waking levels (Perry & Goldwater, 1987). Stage 2 sleep is typically defined by the sporadic presence of two unique EEG waveforms (K-complexes and spindles) and the relative absence of delta activity (.5–2 Hz). Stages 3 and 4, also known as "slow-wave sleep," are typically differentiated from Stage 2 and from each other by the relative proportion of delta activity. Rapid eye movement (REM) sleep is defined by the occurrence of a relatively low-voltage, mixed frequency EEG, the absence of K complexes

and spindles, the presence of sporadically occurring eye movements, and markedly decreased tonus in the pericranial musculature (Ancoli-Israel, 1997; Pivik, this volume, Chapter 27).

The facial muscles are somewhat unique with respect to the rest of the musculature because they appear, paradoxically, to show both distinctly decreasing tonus as a function of sleep depth (Jacobsen et al., 1964; Jacobsen et al., 1965) as well as to be responsive precisely to the processing of both internal (Shimizu & Inoue, 1986) and external stimuli (Sumitsuji et al., 1980). This clear differentiation of tonic levels from phasic activity allowed a team of researchers (Leifting et al., 1994) to use chin EMG alone to differentiate between wakefulness and sleep (using tonic EMG levels) and between quiet (non-REM) and paradoxical (REM) sleep (using phasic EMG parameters) in young infants. In addition, an investigation of the influence of sleep on the muscles of the upper airway (Wheatley et al., 1993) revealed that a decided drop in the tonic level of activity in the alar nasalis muscle occurred coincident with the onset of stage 2 sleep. Surface EMG has also been used effectively to study (a) leg spasms in nocturnal myoclonus ("restless leg syndrome"), (b) abdominal actions in airway apneas (breathing difficulties due to paradoxical sleep-related epiglottal collapse), and (c) nocturnal bruxism, or tooth grinding (see Pressman & Orr, 1997).

Headache and stress reduction

A popular use of surface EMG is in clinical biofeedback for tension headache and stress reduction. This use stemmed from a clinical report by Budzynski and Stoyva (1969), who used EMG activity from a bilateral forehead site over the *frontalis*. In a typical clinical regimen, patients hear tones or clicks whose pitch or rate varies with the envelope of the smoothed, rectified electromyogram and they learn to lower the tone or click rate by relaxing their muscles. Such a procedure was promulgated as a treatment for muscle contraction ("tension") headache, but this procedure was soon extended to general stress management (e.g., Stoyva & Budzynski, 1974).

The rash of *frontalis* EMG biofeedback studies published in biofeedback's halcyon days consisted mostly of case reports and uncontrolled clinical trials (see Alexander & Smith, 1979, for review), and the claimed incremental efficacy over simple relaxation or meditation techniques remains controversial. The 1980s witnessed a devaluation of the role of muscle tension in "tension" headache (Chun, 1985), and an emphasis on vascular dysfunction, secondary ischemia, and nociceptive metabolites in the etiology (Pikoff, 1984). The past two decades, however, have seen a revival in the use of surface EMG in both the diagnosis and treatment of tension headaches. EMG levels in the neck and forehead of children prone to severe headache, for example, have been reported to be both higher and more variable than those of matched group of controls during the performance of cognitive tasks (Pritchard, 1995),

with similar results reported for adults (Bansevicius & Sjaastad, 1996; Jensen, 1999). At least one study has also found trapezius or frontalis EMG biofeedback training to be significantly more effective in the treatment of tension headaches than simple progressive relaxation therapy (i.e., Arena et al., 1995).

Psychosomatic medicine researchers in the 1940s and 1950s were interested in painful, idiopathic muscular contractions occurring in stress or conflict (see Malmo, 1965, for a review), and these examples of "symptom specificity" have occasionally been treated with EMG biofeedback to relax the muscles. Somewhat surprisingly, the mean level of surface EMG activity has been found to be unrelated to the development of pain during stressful conditions (Bansevicius, Westgaard, & Jensen, 1997), while EMG activity recorded surreptitiously during rest periods, is particularly predictive of future muscle pain (Veiersted, 1994).

Physical medicine and rehabilitation

The use of EMG biofeedback in physical medicine was pioneered by John Basmajian in the early 1960s and soon led to the widespread use of surface EMG to enhance recovery of function in muscles that were rendered nonfunctional by stroke, illness, and accidents. In the rehabilitation setting, feedback derived from the surface EMG signal is used, depending upon the disorder, either to relax or tense spastic muscles or to activate atrophied or functionally denervated muscles (see Basmajian, 1989).

Electromyographic biofeedback in rehabilitation is now standard procedure. With respect to diagnosis, there are also promising results in the use of the surface EMG signal to classify muscle impairments in persons with lower back pain (Roy et al., 1997; Oddsson et al., 1997). These techniques are based on the phenomenon of the compression of the power spectral density spectrum of the EMG signal towards lower frequencies during sustained contractions and the fact that this change is associated with the metabolic concomitants of muscle fatigue. Using the different ways in which EMG median frequency parameters change as a function of contraction duration and muscle site, as well as the symmetry of activation during the early part of the contraction, these investigators have shown the surface EMG signal to perform significantly better than conventional clinical parameters at correctly classifying patients with and without lower back pain. EMG biofeedback in the treatment of asthma, however, has proven to be of limited effectiveness (Ritz et al., 2004).

Miscellaneous

Surface EMG is a noninvasive, precise way of measuring muscular contraction in an ongoing fashion in situations where observation is too imprecise, awkward, or costly. In addition to those uses we detailed above, surface EMG continues to be used profitably to: (a) quantify muscle tension in ergonomics (see Kumar & Mital, 1996,

for a review), such as evaluating computer "mouse" use (Harvey & Peper, 1997), evaluating the comfort of automobile head rests (Lamotte et al., 1996), or evaluating stress and pain responses among supermarket cashiers (Lundberg et al., 1999; Rissen et al., 2000); (b) assess photophobia by quantifying "squinting" (Stringham et al., 2003); (c) measure precisely the onset, magnitude, and offset of responses in reaction time tasks, including incipient responses that precede the overt response (e.g., McGarry & Franks, 1997; Allain et al., 2004); (d) discern the specific muscles that maintain posture, coordinate gait, and participate in highly skilled acts (e.g., Trepman et al., 1994); (e) evaluate the effectiveness of television commercials (e.g., Hazlett & Hazlett, 1999; cf. Detenber et al., 2000); and (f) enable the continuous discrimination of adequate vs. inadequate anesthesia during surgery (see Paloheimo, 1990, for a review).

With the decreasing expense of the instrumentation required for sensitive and precise EMG measurement, the availability of guidelines and standards, and the emergence of conceptual frameworks and paradigms to aid in the interpretation of EMG responses, surface EMG promises to continue to find even wider application.

CONCLUSION

Theories proposed over a century ago attempted to explain many psychological processes entirely in terms of peripheral skeletomotor actions. This resulted in an exciting and active period for psychophysiology, but the disconfirmation of categorical predictions made by these motor theories was inevitable given the simplicity of the theories and the newness of the technology. Consequently, this premature peak of activity was followed by a downturn in interest in transient or weak skeletomotor actions during the middle of the past century. Nonetheless, many interesting results from this early period have been replicated and extended. Coupled with advances in signal acquisition and analysis, these data are ever increasingly being incorporated into sophisticated theoretical frameworks based on a more complete understanding of the integrated actions of the central and peripheral nervous systems. Major directions we foresee in the coming decade include (a) further refinement of the spatial and temporal patterning that characterizes specific organismic-environmental transactions, (b) continuing research on incipient actions of the skeletomotor system and their dynamic relation to ongoing mind/brain processes, (c) the continuing broadening of the inferential paradigms to include noninvasive brain imaging and brain stimulation methods (e.g., Iwase et al., 2002; Wräse et al., 2003; see Jahanshahi & Rothwell, 2000), (d) the continued development of an "emotional wardrobe" (see Picard, 1997; Stead et al., 2004) to enable "co-located" collaborative environments (see Mandryk & Inkpen, 2004; cf., Rani et al., 2004), and (e) the continued diagnostic and therapeutic use of EMG in psychopathology and rehabilitative medicine.

ACKNOWLEDGMENTS

The chapter represents a revision and update of a previous chapter by Tassinary and Cacioppo (2000).

13 The Neuroendocrinology of Stress

GREGORY A. KALTSAS AND GEORGE P. CHROUSOS

ABSTRACT

The *stress system* is among the most important and highly preserved systems in the organism. It is located and functions in both the central nervous system (CNS) and the periphery. Several external or internal stressful stimuli or *stressors* in association with higher cortical functions integrate and act at the level of the hypothalamus and the brain stem to activate the stress system. The latter maintains a basal circadian tone and responds to stressors in an appropriate attempt to maintain *homeostasis*. The CNS components of the stress system are the corticotrophin-releasing hormone (CRH)/arginine-vasopressin (AVP) and locus ceruleus-noradrenaline (LC-NA)/autonomic, mainly sympathetic, neurons of the hypothalamus and brain stem, respectively. The main effectors of the stress system include CRH, AVP, propiomelanocortin-derived peptides, glucocorticoids, and the catecholamines norepinephrine and epinephrine. Adequate responsiveness of the stress system to stressors is responsible for attaining homeostasis and achieving a sense of well-being. The *adaptive* or *stress response* depends not only on the intensity of the stressor but also on the inherent ability of the stress system to achieve and maintain an appropriate level and duration of activity. The stress response is influenced by both genetic and developmental factors. Nosologic disorders of homeostasis develop when there is an inappropriate level or duration response of the stress system to stressors. Inadequate or excessive and/or too brief or prolonged stress responses can be deleterious to the organism. The state of achieving survival at the expense of the psychologic and somatic well-being of an individual is called *chronic dyshomeostasis* or *allostasis*, or, even more to the point, *cacostasis*. Cacostasis accounts for major endocrine, metabolic, autoimmune, and psychiatric disorders.

INTRODUCTION

The neuroendocrine system plays a major role in the adaptation of the organism to stress and, hence, its survival as an individual and species (Chrousos and Gold, 1992;

Habib et al., 2000). Under favorable conditions, functions that enhance growth, development, and reproduction, and thus survival of the self and species, are facilitated. Under threatening conditions, adaptations occur that help the individual survive the stressful environment, while searching for more favorable circumstances (Chrousos and Gold, 1992). Any potent enough *stressor*, that is, any real or perceived major threat to the stability of "*homeostasis*," or balances, places the organism in a *stress (threatened) state* and activates a "nonspecific, stereotypic," *adaptive response*, during which the brain interprets the stressor as threatening, thus responding in a progressively generalized and hence nonspecific way (Habib et al., 2000; Chrousos, 1998). Activation of the *stress system* leads to behavioral and peripheral changes that optimize the ability of the organism to adjust homeostasis and increases its chances of survival (Chrousos and Gold, 1992). The main central nervous system (CNS) components of this system are the corticotrophin-releasing hormone (CRH)/arginine-vasopressin (AVP) and locus ceruleus-noradrenaline (LC-NA)/autonomic (mainly sympathetic) neurons of the hypothalamus and brain stem (Chrousos, 1995). These respectively regulate the peripheral activities of the hypothalamic-pituitary-adrenal (HPA) axis and the systemic/adrenomedullary sympathetic nervous systems (SNS) (Chrousos and Gold, 1992). Activation of the HPA axis and LC-NA/autonomic system result in systemic elevations of glucocorticoids and catecholamines (Cas), which together with other products of the stress system, influence a variety of adaptive responses both at their baseline levels and/or at elevated levels which are encountered during the stress response (Elenkov et al., 1999).

During stress, cardiac output, and respiration are enhanced and blood flow is redirected to provide the highest perfusion to the brain and musculoskeletal system. The brain focuses on the perceived threat and stimulates behaviors that propel the organism to act accordingly (Habib et al., 2000). Endocrine programs of growth and reproduction are suppressed in order to save energy; catabolism is enhanced and fuel is used to supply the brain, heart, and muscles accompanied by increases in

glucose levels, heart rate, and blood pressure (Chrousos and Gold, 1992). In addition, stress induces a state of immunomodulation particularly inhibiting innate and cellular immunity and favoring humoral immunity. In certain tissues, activation of the sympathetic system and the peripheral CRH-mast-cell-histamine axis, induces early proinflammatory activity, which has been referred to as *neurogenic inflammation* (Elenkov and Chrousos, 2002). This new understanding helps explain some well-known, but often contradictory, effects of stress on a variety of infectious, autoimmune/inflammatory, allergic, metabolic, adaptive, and neoplastic diseases. In this overview, the current understanding of the neuroendocrine components of the stress system and its interactions with other systems is presented and the physiologic and pathophysiologic implications of these interactions are briefly discussed.

ORGANIZATION OF THE STRESS SYSTEM

The brain circuits that initiate and maintain the stress response are illustrated in Figure 13.1. The HPA axis and the SNS are the afferent limbs of the stress system, whose main function is to maintain basal and stress-related homeostasis (Chrousos and Gold, 1992; Chrousos, 1995). The central components of this system are located in the hypothalamus and the brain stem. They include the parvocellular neurons of the paraventricular nuclei (PVN) of the hypothalamus that release CRH and AVP, the CRH neurons of the paragigantocellular and parabrachial nuclei of the brain stem, and the A1, A2, A3, and A6 (locus ceruleus, LC) mostly noradrenergic (NE) cell groups of the pons and medulla (the LC-NE system) (Chrousos and Gold, 1992). Paraventricular CRH neurons project to and innervate proopiomelanocortin (POMC)-containing neurons of the central stress system in the arcuate nucleus of the hypothalamus, as well as neurons of pain control areas of the hind brain and spinal cord (Figures 13.1 and 13.2). Activation of the stress system leads to CRH-induced secretion of POMC-derived and other opioid peptides, which enhance analgesia (Chrousos, 1995). These peptides also simultaneously inhibit the activity of the stress system by suppressing CRH and NE secretion (Chrousos and Gold, 1992).

CRH and AVP synergistically stimulate the secretion of corticotrophin (ACTH) hormone by the corticotroph cells of the anterior pituitary. This in turn stimulates adrenal steroidogenesis (mainly cortisol and androgens). CRH and AVP may act synergistically on other target tissues as well, both in the CNS and the periphery (Chrousos and Gold, 1992). Every hour, the parvocellular neurons secrete two or three mostly synchronous pulses of CRH and AVP into the hypophysial portal system. In early morning, the amplitudes of these pulses are highest, increasing the amplitude and apparent frequency of ACTH and cortisol secretory episodes (Chrousos and Gold, 1992; Chrousos, 1995). During acute stress, the amplitude of CRH and AVP pulses also increases, resulting in increases in the

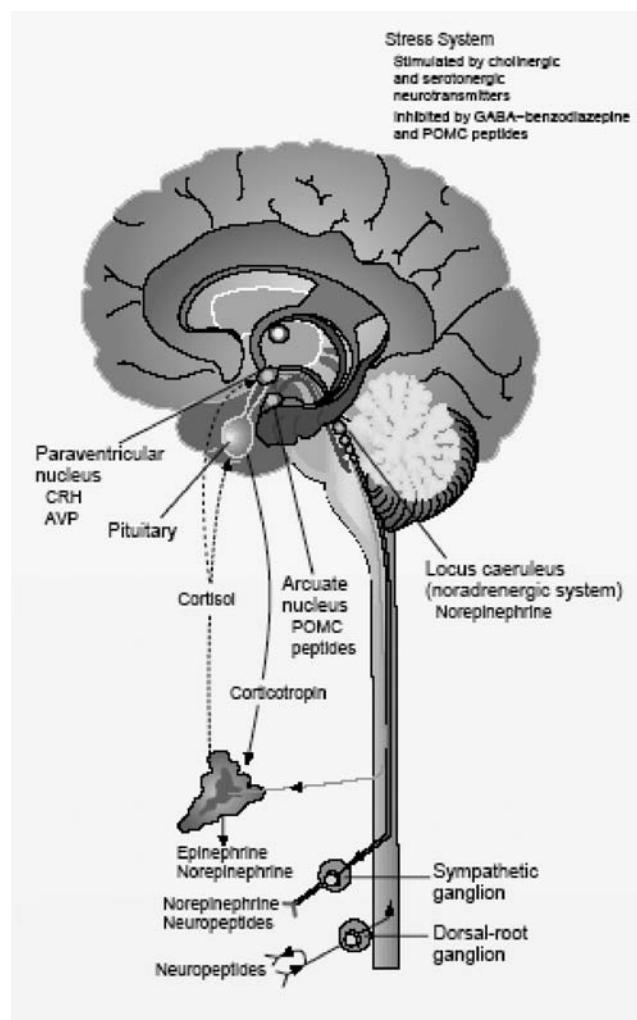

Figure 13.1. Major Components of the Central and Peripheral Stress System. The paraventricular nucleus and the locus ceruleus/noradrenergic system are shown along with their peripheral limbs, the pituitary-adrenal axis, and the adrenomedullary and systemic sympathetic systems. The hypothalamic corticotrophin-releasing hormone (CRH) and central noradrenergic neurons mutually innervate and activate each other, while they exert presynaptic autoinhibition through collateral fibers. Arginine vasopressin (AVP) from the paraventricular nucleus synergizes with CRH on stimulating corticotrophin (ACTH) secretion. The cholinergic and serotonergic neurotransmitter systems stimulate both components of the central stress system, while the gamma aminobutyric acid/benzodiazepine (GABA/BZD) and arcuate nucleus proopiomelanocortin (POMC) peptide systems inhibit it. The latter is directly activated by the stress system and is important in the enhancement of analgesia that takes place during stress (From Chrousos G. 1999. 1351–1362).

amplitude and apparent frequency of ACTH and cortisol pulses. In this case, the stress system recruits additional secretagogues of CRH, AVP, or ACTH, such as magnocellular AVP, and angiotensin II (Elenkov et al., 1999). Circulating ACTH of pituitary origin is the key regulator of glucocorticoid secretion from cells of the adrenal gland's *zona fasciculata*. Other hormones, including Cas, neuropeptide Y (NPY), and CRH are produced by the adrenal medulla and additional autonomic neural input to

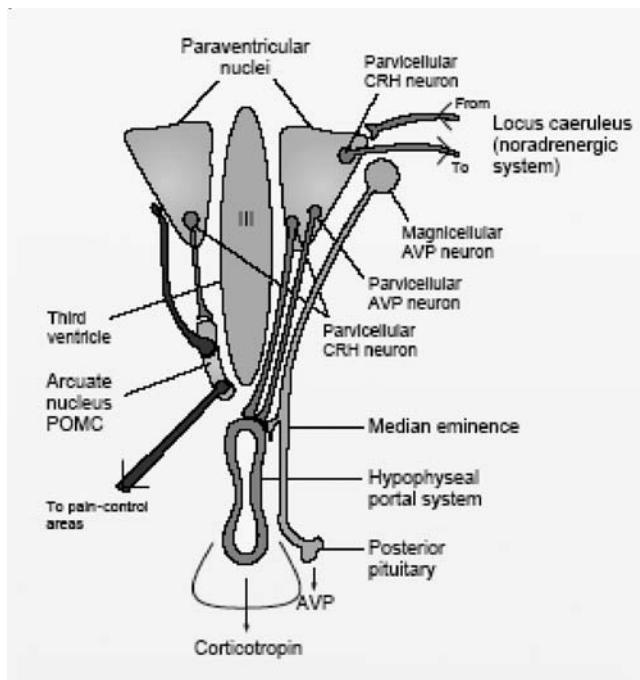

Figure 13.2. A Close-up View of the Paraventricular Nuclei of the Hypothalamus. Parvocellular CRH-and arginine vasopressin (AVP)-secreting neurons project to and secrete into the hypophysial portal system. Parvocellular CRH neurons also project to the brainstem to innervate neurons of the locus ceruleus/noradrenergic system. Magnocellular AVP-secreting neurons terminate at the posterior pituitary and secrete into the systemic circulation; however, they also have collateral terminals in the portal system. CRH is permissive for and stimulates pituitary corticotrophin (ACTH) secretion, while AVP has a major synergistic role with CRH in the secretion of ACTH. The arcuate proopiomelanocortin (POMC) nucleus is shown, along with the mutual innervations between CRH and POMC-peptide-secreting neurons (From Chrousos G., 1351–1362).

the adrenal cortex also influences glucocorticoid secretion (Elenkov et al., 1999).

The LC-NE system controls stress-induced stimulation of the arousal system as well as of the systemic sympathetic and sympathoadrenal nervous systems. The SNS, which originates in nuclei within the brain stem, gives rise to pre-ganglionic efferent fibers that leave the CNS through the thoracic and lumbar spinal nerves (“thoracolumbar system”). Although this review will not address the parasympathetic nervous system (PSNS), it should be noted that it also participates in the stress response. Thus, Barrington’s nucleus, the nucleus tractus solitarius, and the dorsal motor vagal nucleus, all components of the PSNS, control the differential activation of vagal and sacral parasympathetic efferent nerves that mediate gut responses to stress (Habib, Gold, and Chrousos, 2001). Furthermore the PSNS may facilitate or inhibit the effects of the SNS by respectively decreasing or increasing its activity.

The LC-NA system activates and is activated by the amygdala, which, acting in conjunction with the hippocampus and the anterior cingulate and prefrontal cortices, mediate focused attention of a perceived threat,

define the affective state of the individual and regulate fear-related behaviors (Brown et al., 1982). Most of the sympathetic preganglionic fibers terminate in ganglia located in the paravertebral chains that lie on either side of the spinal column; the remaining preganglionic sympathetic neurons terminate in prevertebral ganglia, which lie in front of the vertebrae (Chrousos and Gold, 1992). From these ganglia, postganglionic sympathetic fibers run to the tissues innervated by the SNS. Most postganglionic sympathetic fibers release NE. However, subpopulations of neurons also secrete other active substances including CRH, neuropeptide Y (NPY), somatostatin, and inflammatory mediators (Chrousos and Gold, 1992). In contrast to the SNS, the main neurotransmitter that mediates the action of the PSNS is acetylcholine (Habib, Gold, and Chrousos, 2001). The adrenal medulla contains chromaffin cells, embryologically and anatomically homologous to the sympathetic ganglia but unlike the postganglionic sympathetic nerve terminals, releases mainly epinephrine, and to a lesser extent NE in an approximate ratio of 4:1. Typical pre-ganglionic sympathetic nerve terminals, whose main neurotransmitter is acetylcholine, innervate the chromaffin cells of the adrenal medulla (Chrousos, 1998).

NEUROENDOCRINE ALTERATIONS DURING THE STRESS RESPONSE

Role of stress system in maintaining basal and stress-related homeostasis

The stress system has a baseline, circadian activity, but also responds on demand to physical and emotional stressors through CRH, glucocorticoids, and Cas (Chrousos and Gold, 1992; Chrousos, 1998). These substances are major regulators of behavior, metabolism, cardiovascular function and thermogenesis, and adjust these functions according to the needs of the organism. The stress system integrates and responds to a great diversity of distinct circadian, neurosensory, blood-borne, and limbic signals. Functionally, the CRH/AVP and LC-NE systems seem to participate in a positive, reverberating feedback loop, so that activation of one system tends to activate the others as well (Chrousos and Gold, 1992; Chrousos, 1998). This includes projections of CRH- and AVP-secreting neurons from the lateral PVN to the central sympathetic regions in the brainstem, and conversely, projections of catecholaminergic fibers from the LC-NE system, via the ascending noradrenergic bundle, to the PVN in the hypothalamus. Thus, CRH and AVP stimulate norepinephrine secretion through their specific receptors, while norepinephrine stimulates CRH and AVP secretion through primarily α_1 -noradrenergic receptors (Chrousos, 1995). Autoregulatory, ultrashort negative feedback loops are also present in these neurons, with CRH and norepinephrine collateral fibers acting in an inhibitory fashion on presynaptic CRH and α_2 -noradrenergic receptors, respectively (Chrousos and Gold, 1992).

Table 13.1. Behavioral and physical adaptation during acute stress

Behavioral adaptation: adaptive redirection of behavior	Physical adaptation: adaptive redirection of energy
Increased arousal and alertness	Oxygen and nutrients directed to the CNS and stressed body sites
Increased cognition, vigilance and focused attention	Altered cardiovascular tone, increased blood pressure and heart rate
Euphoria or dysphoria	Increased respiratory rate
Heightened analgesia	Increased gluconeogenesis and lipolysis
Increased temperature	Detoxification from toxic products
Suppression of appetite and feeding behavior	Inhibition of growth and reproduction
Containment of the stress response	Containment of the inflammatory/immune response

The CRH, AVP, and noradrenergic neurons receive stimulatory input from the serotonergic, cholinergic, and histaminergic systems and inhibitory input from the gamma-aminobutyric acid (GABA)/benzodiazepine and opioid peptide neuronal systems of the brain (Chrousos and Gold, 1992; Chrousos, 1998). Centrally secreted substance P (SP) has inhibitory actions on hypothalamic CRH but not AVP neurons and stimulatory effects on the central noradrenergic system. Activation of the stress system leads to adaptive behavioral and physical changes (McEwen, 2002). Centrally, the behavioral changes include enhanced arousal and accelerated motor reflexes, improved attention span and cognitive function, reduced feeding, and sexual behavior, and increased ability to withstand pain (Table 13.1) (Chrousos and Gold, 1992). Peripherally, activation of the stress system results in increased sympathetic output, i.e., increased release of NE from sympathetic nerve terminals and epinephrine/NE from the adrenal medulla, as well as in increased secretion of glucocorticoids by the adrenal cortex (Chrousos, 1995). These changes result in physical adaptation that include changes in cardiovascular function, intermediary metabolism, and modulation of the immune and inflammatory reaction (Habib, Gold, and Chrousos, 2001). Thus, mobilization of stored energy with inhibition of subsequent energy storage and gluconeogenesis, sharpened focused attention on the perceived threat, increased cerebral perfusion rates, and cerebral glucose use, enhanced cardiovascular output and respiration, enhanced delivery of energy substrates to the skeletal muscles, inhibition of reproductive function and behavior, modulation of immune function, and decreased feeding and appetite, are all consequences of the activation of

the stress system (Table 13.1) (Habib, Gold, and Chrousos, 2001).

The endocrine component of the stress system

Glucocorticoids. Glucocorticoids, the final products of HPA axis stimulation, are pleiotropic hormones and exert their effects via ubiquitously distributed intracellular receptors (Chrousos, 1995; Bamberger, Schulte, and Chrousos, 1996). The glucocorticoid receptor is a cytoplasmic protein with three major functional domains and several subdomains. The nonactivated glucocorticoid receptor resides in the cytosol in the form of a hetero-oligomer with heat shock proteins and immunophilins. The carboxyterminal region binds glucocorticoid and the middle portion domain binds to specific sequences of DNA in the regulatory regions of glucocorticoid-responsive genes (glucocorticoid-response elements) (Bamberger, Schulte, and Chrousos, 1996). The activated receptors also inhibit, by protein-protein interactions, several transcription factors, such as activator protein-1 (AP-1) which comprises c-jun/c-fos, and NF- κ B, which are positive regulators of the transcription of several genes involved in the function and growth of nonimmune and immune cells (van der Saag, Caldenhoven, and van de, 1996). They also change the stability of mRNAs and, hence, the translation rates of several glucocorticoid-responsive genes and proteins (Table 13.2).

Glucocorticoids influence the traffic of circulating leukocytes and inhibit many functions of leukocytes and immune accessory cells. They suppress the immune activation of these cells, inhibit the production of cytokines and other mediators of inflammation, and cause proinflammatory cytokine resistance. Furthermore, glucocorticoids influence the secretion rates of specific proteins and alter the electrical potential of neuronal cells through mechanisms and remain to be elucidated (Gower, 1993). Glucocorticoids exert an inhibitory feedback on pituitary ACTH secretion, thus limiting the duration of the total tissue exposure to glucocorticoids and minimizing their basic catabolic, lipogenic, antireproductive, and immunosuppressive effect (Table 13.3) (Habib, Gold, and Chrousos, 2001). It seems that a dual receptor system for glucocorticoids exists in the CNS, including the glucocorticoid receptor type I, or mineralocorticoid receptor, that responds positively to low levels of glucocorticoids, and the glucocorticoid receptor type II, which responds to basal and stress levels (Habib, Gold, and Chrousos, 2001). Only the type II receptor appears to participate in the negative control feedback of the HPA axis (Habib, Gold, and Chrousos, 2001; Charmandari, Tsigos, and Chrousos, 2005). Several circadian immune functions cause disease-associated diurnal changes that correspond to plasma glucocorticoid levels (Chrousos and Gold, 1992).

Corticotrophin releasing hormone (CRH). CRH is one of the most potent factors that initiate and perpetuate the stress response affecting overall arousal and autonomic

Table 13.2. Genes that are regulated by glucocorticoids or glucocorticoid receptors

activation (Habib, Gold, and Chrousos, 2001). Administration of CRH antagonists is associated with suppression of many aspects of the stress response and CRH type 1 receptor (CRH-R1) knockout mice have a markedly deficient ability to mount an effective stress response (Smith et al., 1998). The presence of CRH neurons in the cerebral cortex is important for the behavioral effect of this peptide, particularly in the prefrontal areas which may be related with its effect on cognitive processing (Habib, Gold, and

Chrousos, 2001). In addition, the projection of CRH neurons to the brain stem and spinal cord is related with its actions on autonomic nervous system function, modulation of sensory input via ascending projections to the thalamus and reticular formation function (Chrousos, 1998).

CRH exerts its actions following binding to two distinct CRH receptors. CRH-R1 is the most abundant subtype found in the anterior pituitary as well as in the adrenal gland, skin, ovary and testis (Bale and Vale, 2004), whereas

Table 13.3. The principal action of glucocorticoids in humans highlighting some of the consequences of glucocorticoid excess

System/organ	Effect
Brain/CNS	Depression Psychosis
Eye	Glaucoma
Endocrine System	Reduction of LH, FSH release Reduction of TSH release Reduction of GH secretion Increase of appetite
Gastrointestinal tract	Increase in acid secretion (peptic ulceration)
Carbohydrate/lipid metabolism	Increased hepatic glycogen deposition Increased peripheral insulin secretion Increased gluconeogenesis Increased fatty acid production Overall diabetogenic effect Promotion of visceral obesity
Cardiovascular/Renal	Salt and water retention Hypertension
Skin/muscle/Renal	Protein catabolism/collagen breakdown Thinning of the skin Muscular atrophy
Bone	Reduction of bone formation Reduction of bone mass and development of osteoporosis
Growth and development	Reduction of linear growth
Immune system	Anti-inflammatory action Immunosuppression

CNS, central nervous system; GI, gastrointestinal; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; TSH, thyroid stimulating hormone.

CRH-R2 is mainly expressed in the peripheral vasculature of the heart and subcortical structures of the brain (Habib, Gold, and Chrouzos, 2001). The diversity of CRH subtype and isoform expression is crucial in modifying the stress response through the actions of different ligands (CRH and CRH-related peptides) and intracellular signal systems (Bale and Vale, 2004). Central CRH administration produces a constellation behavioral effects including increased locomotor activity, increased sniffing, grooming and rearing in a familiar environment, assumption of a freeze posture, decreased feeding and sexual behavior and increased conflict behavior in an unfamiliar environment (Habib, Gold, and Chrouzos, 2001). CRH is also a major anorexiogenic peptide, whose secretion is stimulated by NPY, a very potent orexiogenic peptide which

can also inhibit the LC-NA sympathetic system (Oellerich, Schwartz, and Malik, 1994). Changes in NPY levels may be of particular relevance to alterations in the activity of the stress system in conditions such as malnutrition, anorexia neurosa, and/or obesity (Oellerich, Schwartz, and Malik, 1994). The majority of these effects are blocked following the administration of specific CRH antagonists (Habib, et al., 2000).

CRH acts in the brain to activate the SNS (leading to subsequent increment in Ca release) with increased mean arterial pressure and heart rate inhibition of PSNS output (Kregel et al. 1990). In addition, the function of several interrelated neuronal pathways is increased, particularly those related to locus ceruleus, hippocampus, cerebral cortex, and lumbar spine (Habib, Gold, and Chrouzos, 2001). Activation of the LC-NA system results in increased arousal and increased vigilance and its dysfunction may be related to the development of anxiety and depression (Habib, Gold, and Chrouzos, 2001). In addition to CRH, several other CRH receptor ligands exist, with homology to CRH, including urocortin (Ucn I), Ucn II, and Ucn III (Bale and Vale, 2004). Although CRH seems to exert a mainly a stimulatory role in stress via the CRH R1 receptor, specific actions of UcnII and/or UcnIII on CRH R2 may be extremely important in altering stress sensitivity. In addition, UcnI exhibits a high affinity for both receptors and may also exert a regulatory action (Bale and Vale, 2004).

GABA agonists and benzodiazepines exert an inhibitory effect on CRH neurons, whereas cholinergic and serotonergic neurons stimulate CRH release (Habib, Gold, and Chrouzos, 2001). Glucocorticoids exert a mainly inhibitory effect on the HPA axis, except on the CRH neurons in the amygdala and LC-NA, where their stimulatory effect is related in the perpetuation of the stress response (Spinedi, 1998).

CRH has also been localized in a variety of peripheral tissues including the adrenal medulla. Adrenomedullary CRH increases following autonomic nervous system stimulation and during stressful situation (Habib, Gold, and Chrouzos, 2001). CRH can also be found in other tissues such as the testis, ovaries, pancreas, stomach, small intestine, uterus and placenta (Aguilera et al., 1987). Similarly, CRH immunoreactivity and mRNA have been detected in lymphocytes, where it plays a role in immune regulation (Elenkov and Chrouzos, 2002). Systemic administration of specific CRH antiserum blocks the inflammatory exudate volume and cell number in carrageenin-induced inflammation, and inhibits stress-induced intracranial mast cell degranulation (Elenkov and Chrouzos, 2002).

In addition, CRH administration to humans or nonhuman primates causes major peripheral vasodilation manifested as flushing and increased blood flow and hypotension. An intradermal CRH injection induces a marked increase in vascular permeability and mast cell degranulation, which is blocked by a CRH type 1 receptor antagonist (Theoharides et al., 1998). It appears that CRH activates mast cells via a CRH receptor type 1-dependent mechanism, leading to release of histamine and other

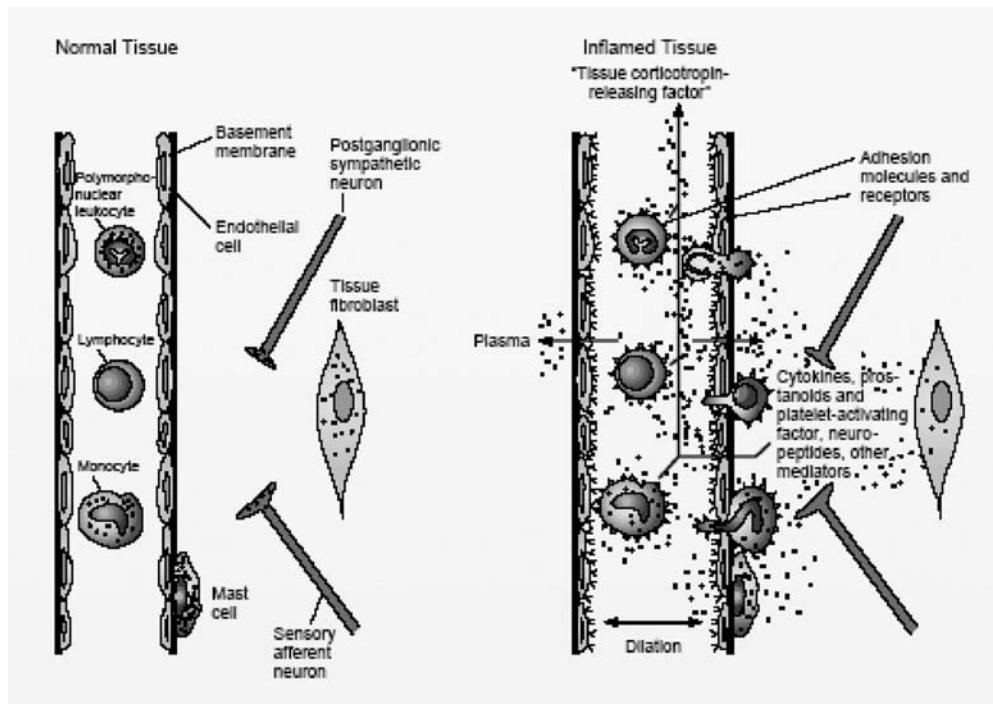

Figure 13.3. Major Components and Events of Inflammation. Quiescent circulating leukocytes, local immune accessory cells, and the terminals of peripheral postganglionic sympathetic and sensory afferent neurons are shown (left-hand panel). In inflamed tissue (right-hand panel), there is vasodilation, increased permeability of the vessel and exudation of plasma. Activated leukocytes and endothelial cells express adhesion molecules and adhesion-molecule receptors. Cells attach to the vessel wall and diapedesis takes place, with chemotaxis towards a chemokine gradient at the focus of inflammation. Activated circulating cells, migrant cells, local immune accessory cells, and peripheral nerves secrete cytokines, prostaglandins, platelet activating factor, neuropeptides, and other mediators of inflammation. Some of these substances, such as interleukin-6, leukotrienes, complement component 5α , corticotrophin-releasing hormone, and transforming growth factor- β have chemokinetic activity. Some substances, such as the inflammatory cytokines tumor necrosis factor α , interleukin-1 and interleukin-6, escape in the systemic circulation, causing systemic symptoms and activating the hypothalamic-pituitary-adrenal axis. Because of such effects, these substances were historically referred to as “tissue corticotrophin releasing factor (CRF)” (From Chrousos G., 1351–1362).

contents of the mast cell granules that subsequently cause vasodilatation, increased vascular permeability and other manifestations of inflammation (Figure 13.3). Central, hypothalamic CRH influences the immune system indirectly, through activation of the end-products of the peripheral stress response, i.e., glucocorticoids and Cas. Peripherally secreted CRH at inflammatory sites (*peripheral or immune CRH*) influences the immune system directly, through local modulatory actions (Chrousos and Gold, 1992). Immune CRH has been shown in inflamed tissues of animals with experimentally induced aseptic inflammation, and in human tissues from patients with various autoimmune/inflammatory diseases, including rheumatoid arthritis, autoimmune thyroid disease, and ulcerative colitis. The identification of CRH-like immunoreactivity in the dorsal horn of the spinal cord, dorsal root ganglia and sympathetic ganglia support the hypothesis that the majority of immune CRH in early inflammation is of peripheral nerve rather than of immune cell origin (Habib, Gold, and Chrousos, 2001).

Argininine-vasopressin. AVP parvocellular neurons of the PVN of the hypothalamus have an important co-secretory role, and are activated together with CRH neurons during stress to achieve maximum secretion of ACTH (Koob et al., 1985). The subset of PVN neurons that co-secrete both of these peptides increases significantly during stress (Habib, Gold, and Chrousos, 2001), and during chronic or prolonged stress, there may be a shift in control of ACTH from CRH to AVP (Hauger and Aguilera, 1993). PVN CRH and AVP neurons also project to POMC neurons in the arcuate nucleus, which in turn inhibit LC-NA system neurons and pain control neurons of the hind brain and spinal cord (Habib, Gold, and Chrousos, 2001). AVP derived from magnocellular neurons has a major role in conserving body fluids and controlling plasma osmolality, and during hypovolemic stress, AVP becomes the principal ACTH secretagogue (Habib, Gold, and Chrousos, 2001). In addition to its endocrine and metabolic roles AVP has been implicated in some of the behavioral responses to stress (Habib, Gold, and Chrousos, 2001).

Table 13.4. Adrenergic responses of selected tissues

Organ or tissue	Receptor	Effect
Heart (myocardium)	β_1	Increased force of contraction
		Increased rate of contraction
Blood vessels	α	Vasoconstriction
	β_2	Vasodilation
Kidney	β	Increased renin release
Gut	α, β	Decreased motility and increased sphincter tone
Pancreas	α	Decreased insulin release
	β	Decreased glucagons release
		Increased insulin release
		Increased glucagon release
Liver	α, β	Increased glycogenolysis
Adipose tissue	β	Increased lipolysis
Most tissue	β	Increased calorigenesis
Skin	α	Increased sweating
Bronchioles	β_2	Dilation
Uterus	α	Contraction
	β_2	Relaxation

The autonomic component of the stress response (LC-NA/Systemic Sympathetic and Adrenomedullary and Parasympathetic Systems)

The autonomic nervous system (ANS) (SNS and PSNS) responds rapidly to stressors and controls a wide range of systemic functions (Tsigos and Chrousos, 1994). The cardiovascular, respiratory, renal, endocrine and other systems, such as the gastrointestinal system, are regulated by either the SNS or PSNS, or both (Table 13.4) (Habib, Gold, and Chrousos, 2001). Reduction of parasympathetic nervous system activity results in removal of inhibition of the SNS, thus increasing sympathetic functions, while increased activity antagonizes the SNS (Charmandari, Tsigos, and Chrousos, 2005; Tsigos and Chrousos, 1994). Several immune functions are under the influence of SNS and catecholamines including lymphocyte traffic and circulation (Chrousos, 1995). Catecholamines appear to have both inhibitory and stimulatory effects on macrophage activity. In addition to the "classic" neurotransmitters, acetylcholine and norepinephrine, both sympathetic and parasympathetic subdivisions of the autonomic nervous system include several subpopulations of target-selective and neurochemically coded neurons that express a variety of neuropeptides and, in some cases, adenosine triphosphate (ATP), nitric oxide, or lipid mediators of inflammation (Elenkov et al., 1999). Thus, CRH, NPY, somatostatin, and galanin are found in postganglionic noradrenergic vasoconstrictive neurons, while vasoactive intestinal pep-

tide (IP), SP, and calcitonin gene-related peptide are found in cholinergic neurons (Habib, Gold, and Chrousos, 2001). Transmission in sympathetic ganglia is also modulated by neuropeptides released from preganglionic fibers and short interneurons, as well as by primary afferent nerve collaterals. These effects that underlie the characteristic phenomenology of behavioral, endocrine, visceral autonomic, and immune responses to stress are induced and maintained via the orchestrated interplay of several neurotransmitter systems in the brain (Figure 13.1) (Chrousos and Gold, 1992).

Other neuroendocrine systems that participate in the stress response

NPY, besides being a very potent stimulant of feeding behavior, exerts an important role in circadian rhythms and affects behavior, anterior pituitary hormone secretion, autonomic control, and other neurotransmitter systems (Habib, Gold, and Chrousos, 2001). Alteration of central NPY has been documented in stress and several mental disorders. Thus an inverse correlation has been shown between anxiety scores and NPY levels in depressed patients (Heilig and Widerlov, 1995). Several other systems, mainly including the dopaminergic system, also exert an effect on stress. Thus *mesocortical system* is involved in anticipatory phenomena and cognitive functions and is thought to exert a suppressive effect on the stress system (Chrousos and Gold, 1992). The *mesolimbic system* has a major role in motivation reinforcement and reward phenomena (Chrousos, 1998). Euphoria or dysphoria are also mediated through the mesocorticolimbic system and are affected by stress (Gold and Chrousos, 1999). Similarly, the *amygdala nuclei* are activated during stress mainly by catecholaminergic neurons and respond to emotional stressors that originate in cortical related areas. This is important for retrieval and emotional analysis of relevant information for any given stressor (Charmandari, Tsigos, and Chrousos, 2005).

Activation of the stress system also stimulates hypothalamic POMC-peptide secretion, such as α -MSH and β -endorphin. This reciprocally inhibits the activity of central components of the stress system and produces analgesia and, by stimulating the mesocorticolimbic system euphoria, may enhance dependence (Charmandari, Tsigos, and Chrousos, 2005). Activation of the stress system, either via the HPA-axis or the LC/NE system, elevates core temperature (Chrousos, 1998). In addition, CRH can mediate the pyrogenic effects of inflammatory cytokines, such as tumor necrosis factor α (TNF- α), interleukin-1, and -6 (IL-1 and IL-6) (Elenkov and Chrousos, 2002). Prolonged physical and psychological stress may also alter core temperature and suppress food intake (Habib, Gold, and Chrousos, 2001). This effect on appetite/satiety centers may be mediated via increased CRH or CRH-like peptides and/or decreased NPY levels and their actions on LC-NE/sympathetic system (Uehara et al., 1998). Furthermore,

leptin, a satiety-stimulating polypeptide secreted by the white adipose tissue, is also involved reciprocally in these changes by directly suppressing NPY secretion or stimulating α -MSH secretion, the latter being a very potent anorexiogen (Charmandari, Tsigos, and Chrousos, 2005).

The last 20 years have provided evidence that certain cytokines, and particularly the pro-inflammatory ones, including tumor necrosis factor (TNF)- α , interleukin (IL)-1 and IL-6, activate both the HPA axis and the LC-NE/SNS system (Chrousos, 1995; Papanicolaou et al., 1996). Moreover, these cytokines induce anorexia/nausea, fatigue and/or depressive affect, hyperalgesia with or without headache, somnolence, sleep disturbances, temperature elevation or fever and increases of the basal metabolic rate, changes collectively referred to as *sickness behavior*. These cytokines also activate hepatic and other tissue synthesis of acute phase proteins, such as C-reactive protein, serum amyloid A, cell adhesion molecules, fibrinogen and plasminogen activator inhibitor 1, a phenomenon referred to as the “acute phase reaction” (Cutolo et al., 1998). Stress that is associated with an immune challenge has been called *immune* or *inflammatory stress*, which in fact is a combination of the sickness and classic stress syndromes, together with their effects on the pain/affective neural systems and the acute phase reaction (Table 13.5) (Elenkov et al., 1999).

Emotions and psychological stress. Emotional responses are produced in the limbic system, which projects to several parts of the brain, including those involved in the initial activation and maintenance of the stress system thus explaining why emotional insults activate the stress system in humans (Chrousos and Gold, 1992). In humans the physiological responses to social pressures, information overload, and rapid cultural change resemble those that are produced during physical stress and/or danger and outright threats to survival (Chrousos and Gold, 1992).

Genetics, development, environment, and the stress response

Vulnerability to stress effects may be the result of genetic, developmental, and environmental factors (Charmandari, Tsigos, and Chrousos, 2005). Many factors that determine individual stress responses are inherited. It is thought that approximately one half of reliable variance in personality traits is related to genetic influences but a significant amount of variance of the stress responses of individuals is also related to environmental factors, particularly at periods of increased brain plasticity during development (Chrousos, 1998). Depending on the genetic background of the individual, polymorphisms, such as those of CRH, AVP, and their receptors and/or regulators, and exposure to adverse stimuli in prenatal and/or postnatal life (developmental influences), there may be a failure to initiate and propagate appropriate stress responses to various stressors leading to various chronic states of either

Table 13.5. Inflammatory stress syndrome as a compound of two major biological programs of adaptation

hyper- or hypoactivity of the stress system that can occur in any combination and degree of severity (Habib, Gold, and Chrousos, 2001). Excessive or sustained activation of the stress system during these critical periods may have profound effects on its function. These environmental triggers or stressors may have not a transient, but rather a permanent effect on the development of the HPA axis responses to stress, which may persist long after cessation of exposure to these hormones (Habib, Gold, and Chrousos, 2001; Charmandari, Tsigos, and Chrousos, 2005). In these early stages of development, exposure to psychological trauma sets into motion a cascade of mental changes that may result in long-term predisposition to anxiety, depression, or other stress related somatic illnesses (Maughan and McCarthy, 1997). Although no prospective studies exist, several observational studies have shown the presence of an association between the patterns of activity of the HPA-axis and the development of mood and/or anxiety disorders (Chrousos, 1998).

THE STRESS SYSTEM IN PHYSIOLOGY

Activation of the central CRH and LC-NE systems, and subsequent secretion of large amounts of glucocorticoids and Cas, affect virtually every cell of the body (Chrousos and Gold, 1992). This leads to extensive mobilization of energy stores in various systems. The heart's rate is accelerated and its force of contraction is grossly increased in an

attempt to provide optimal blood supply to various tissues. Respiratory rate increases, and the bronchi dilate, providing maximum oxygen supply to the tissues to ensure adequate fuel consumption. Significant changes in blood flow result in redistribution of nutrients and oxygen (Chrousos and Gold, 1992). Endocrine adaptations also occur and preserve energy by ceasing function of various hormonal dependent behaviors. Thus the reproductive and growth axis and, to a lesser extent the thyrotrophin axis are temporarily shut off (Habib, Gold, and Chrousos, 2001). Activation of the HPA axis exerts profound modulatory effects on the immune system (Table 13.1). All these adaptations are protective and help to maintain homeostasis in the short run but can be damaging in the long run if the mediators are overproduced, underproduced, or dysregulated chronically (McEwen, 2002).

THE STRESS SYSTEM IN PATHOPHYSIOLOGY

In general, an appropriate stress response is of limited duration. The time-limited nature of this process renders its accompanying anti-growth, anti-reproductive, catabolic, and immunosuppressive effects temporarily beneficial and/or of no adverse consequences to the individual (Chrousos and Gold, 1992). In principle, there are four situations that can be related to either the intensity of the stressor and/or the response of the stress system that may lead to dysregulation of the system (McEwen, 1998). This could be frequent exposure to stressful stimuli, lack of adaptation to repeated stressors, inability to shut off the stress response after the stressful stimulus is eliminated, and inadequate responses of the stress system to stressors (Figure 13.4) (McEwen, 1998). Chronic activation of the stress system may lead to a number of disorders, which are due to increased and/or prolonged secretion of stress mediators such as CRH, Cas, and/or glucocorticoids (Table 13.6).

SYSTEMIC EFFECTS DUE TO CHRONIC HYPERACTIVITY OF THE STRESS SYSTEM

Growth and development

During stress, the growth axis is inhibited at several levels. Prolonged activation of the HPA axis leads to suppression of GH secretion via CRH-induced increases in somatostatin secretion. Glucocorticoids also induce resistance in target tissues to the effects of both GH, insulin-like growth factor I (IGF-I) and other growth factors (Magiakou, Mastorakos, and Chrousos, 1994; Magiakou et al., 1994). The molecular mechanisms by which glucocorticoids suppress growth are complex, and involve both transcriptional and translational mechanisms that ultimately influence the GH receptor action (Bamberger, Schulte, and Chrousos, 1996). In several stress-related mood disorders accompanied by a hyperactive HPA axis, such as anxiety or melancholic depression, GH, and/or IGF-I concentrations

are significantly decreased, and the GH response to intravenously administered glucocorticoids is blunted. Children with anxiety disorders also may have short stature (Habib, Gold, and Chrousos, 2001). "Psychosocial short stature" is characterized by severely compromised height in children due to emotional deprivation. Such children display a significant decrease in GH secretion, which is fully restored within a few days following separation of the child from the adverse environment. Such children also exhibit a hyperactive HPA axis and amygdala (Skuse, 1996). Other consequences of hyperactive stress system include delayed growth and puberty; manifestations of the metabolic syndrome, such as premature adrenarche; visceral obesity, insulin resistance, and diabetes type II; hypertension; dyslipidemia; polycystic ovary syndrome (PCOS); sleep apnea; cardiovascular disease; and osteoporosis (Habib, Gold, and Chrousos, 2001).

Thyroid function

Thyroid function is also inhibited during stress. Activation of the HPA axis is associated with decreased production of thyroid-stimulating hormone (TSH), as well as inhibition of peripheral conversion of the relatively inactive thyroxine to the biologically active triiodothyronine (Benker et al., 1990). These alterations may be due to the increased concentrations of CRH-induced somatostatin and glucocorticoids. Somatostatin suppresses both TRH and TSH, while glucocorticoids inhibit the activity of the enzyme 5-deiodinase, which converts thyroxine to triiodothyronine. During inflammatory stress, inflammatory cytokines, such as TNF- α , IL-1, and IL-6, also activate CRH secretion and inhibit 5-deiodinase activity resulting in decreased T3 and increased rT3 levels (Chrousos and Gold, 1992; Tsigos and Chrousos, 2002).

Reproduction

The reproductive axis is inhibited at all levels by various components of the HPA axis. CRH suppresses the secretion of gonadotropin-releasing hormone (GnRH) either directly or indirectly, by stimulating arcuate POMC peptide-secreting neurons (Vamvakopoulos and Chrousos, 1994). Glucocorticoids also exert an inhibitory effect on GnRH neurons, pituitary gonadotrophs, and the gonads, and render target tissues of gonadal steroids resistant to these hormones (Tsigos and Chrousos, 2002; Chrousos, Torpy, and Gold, 1998). Suppression of gonadal function secondary to chronic activation of the HPA axis has been demonstrated in highly trained runners of both sexes and in ballet dancers (Habib, Gold, and Chrousos, 2001). The interaction between CRH and the hypothalamic-pituitary-gonadal axis is bi-directional, given that estrogen increases CRH gene expression via estrogen-response elements in the promoter region of the CRH gene (Vamvakopoulos and Chrousos, 1994). Therefore, the CRH gene is an important target of gonadal steroids and a potential mediator of

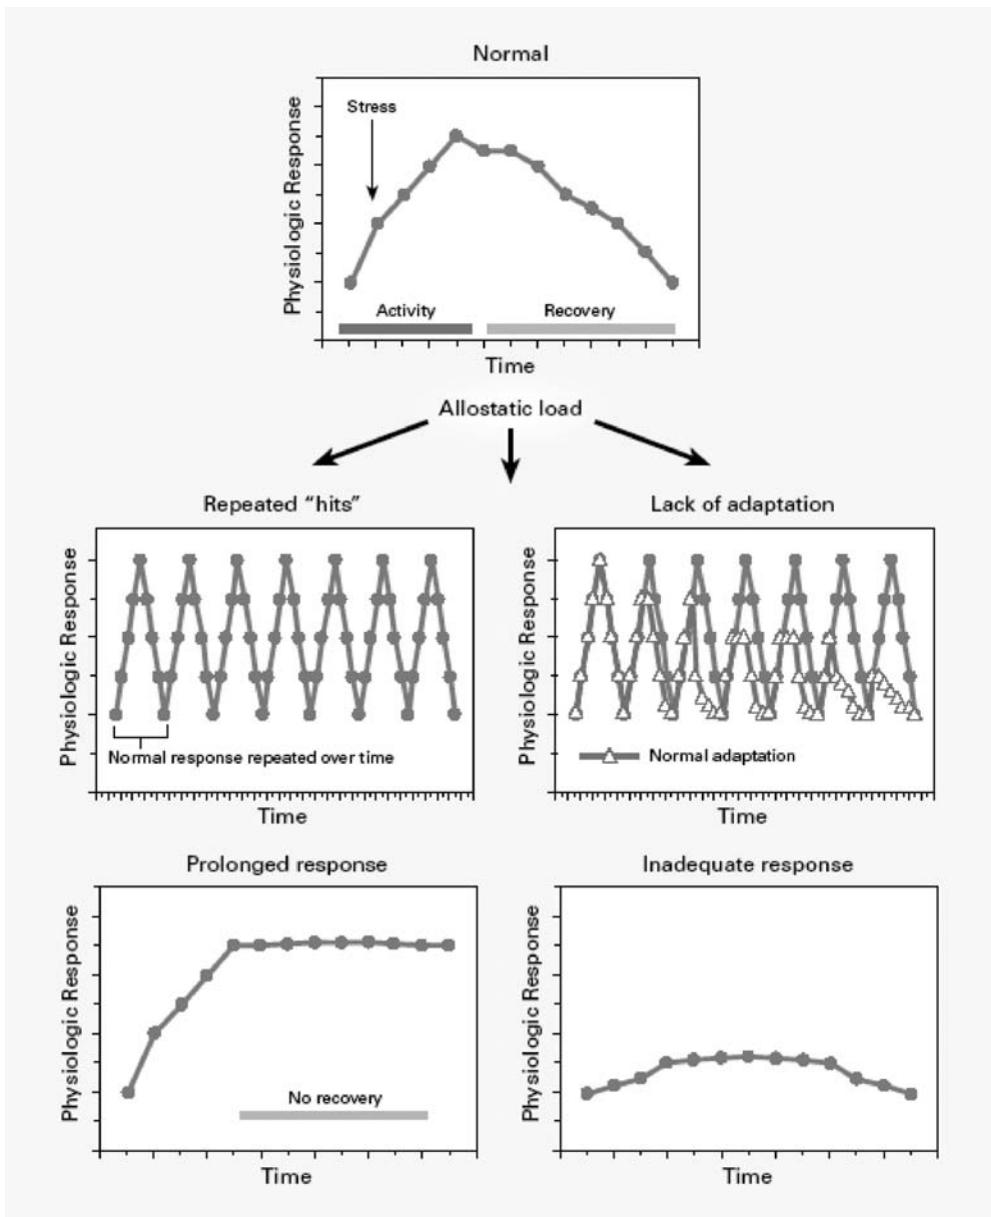

Figure 13.4. Types of allostatic (ability to handle stress) load. The top panel illustrates the normal allostatic response, in which a stressor initiates a response from the stress system and then is adequately turned off. The remaining panels illustrate four conditions that lead to allostatic load: repeated hits from multiple stressors, lack of adaptation, prolonged response due to delayed shutdown, and inadequate response that leads to compensatory hyperactivity of other mediators (From Mc Ewen B., 171–179).

sex-related differences in the stress-response and the activity of the HPA axis.

Metabolism

In addition to their direct catabolic effects, glucocorticoids also antagonize the actions of GH and sex steroids on fat tissue catabolism (lipolysis) and muscle and bone anabolism (Charmandari, Tsigos, and Chrousos, 2005; Tsigos and Chrousos, 2002). Chronic activation of the stress system is associated with increased visceral adiposity, decreased lean body (bone and muscle) mass, and

suppressed osteoblastic activity (a phenotype observed in patients with Cushing's syndrome). Some patients with melancholic depression, and patients with the metabolic syndrome (visceral obesity, insulin resistance, dyslipidemia, hypertension, hypercoagulation, atherosclerotic cardiovascular disease, sleep apnea), many of whom display increased HPA axis activity, exhibit similar clinical and biochemical manifestations (Gold and Chrousos, 1999; Tsigos and Chrousos, 2002; Pasquali et al., 1993). It has been shown that life-stress related hypersecretion of cortisol or tissue-limited hypersensitivity to glucocorticoids may deleteriously affect important physiologic

Table 13.6. States associated with hyperactivation or hypoactivation of the HPA axis

Increased HPA axis activity	Decreased HPA axis activity	Disrupted HPA axis activity
Severe chronic disease		
Melancholic depression	Atypical depression	Cushing syndrome
Anorexia neurosa	Seasonal depression	Glucocorticoid deficiency
Obsessive-compulsive disorders	Chronic fatigue syndrome	Glucocorticoid resistance
Panic disorders	Fibromyalgia	
Chronic excessive exercise	Adrenal suppression	
Malnutrition	Post glucocorticoid therapy	
Diabetes Mellitus	Post stress Drug withdrawal	
Central Obesity	Rheumatoid arthritis	
Childhood sexual abuse	Postpartum	
Pregnancy		

parameters, such as systemic blood pressure, lipid, and carbohydrate metabolism (Pasquali et al., 1993; Rosmond, Dallman, and Björntorp, 1998). Since increased gluconeogenesis is a cardinal feature of the stress response and glucocorticoids regulate insulin action and induce insulin resistance, activation of the HPA axis may also contribute to the poor control of diabetic patients with emotional stress or concurrent inflammatory or other diseases (Tsigos and Chrousos, 2002). Mild, chronic activation of the HPA axis has been shown in type I diabetic patients under moderate or poor glycemic control, and in type II diabetic patients who had developed diabetic neuropathy (Tsigos, Young, and White, 1993). Over time, progressive glucocorticoid-induced visceral adiposity and loss of lean body mass cause further insulin resistance and deterioration of glycemic control (Tsigos and Chrousos, 2002).

“Low turnover” osteoporosis is almost invariably seen in association with hypercortisolism and GH deficiency, and represents another example of the adverse effects of elevated cortisol concentrations and decreased GH/IGF-I concentrations on osteoblastic activity. Stress-induced hypogonadism and reduced concentrations of sex steroids may further contribute to the development of osteoporosis. Increased prevalence of osteoporosis has been demonstrated in young women with depression or a previous history of depression (Michelson et al., 1996).

Gastrointestinal function

PVN CRH induces inhibition of gastric acid secretion and emptying, while it stimulates colonic motor function (Tache et al., 1993). These effects are mediated by inhibition of the vagus nerve, which leads to selective inhibition of gastric motility, and by stimulation of the LC-NE-regulated sacral parasympathetic system, results

in selective stimulation of colonic motility. Therefore, CRH may be implicated in mediating the gastric stasis observed following surgery or during an inflammatory process, when central IL-1 concentrations are elevated (Suto, Kiraly, and Tache, 1994). CRH may also play a role in the stress-induced colonic hypermotility of patients with the irritable bowel syndrome. Colonic contraction and pain in these patients may activate LC-NE-sympathetic neurons, forming a vicious cycle, which may account for the chronicity of the condition. Chronic activation of the HPA axis and/or the LC-NE-sympathetic system due to depletion of the opioid-peptide system, which mediates stress-induced analgesia, may also account for the lower pain threshold for visceral sensation reported in patients with functional gastrointestinal disorders (Habib, Gold, and Chrousos, 2001).

Psychiatric disorders

The syndrome of adult melancholic depression represents a typical example of dysregulation of the generalized stress response, leading to chronic dysphoric hyperarousal, activation of the HPA axis and the SNS, and relative immunosuppression (Elenkov et al., 1996; Elenkov and Chrousos, 1999). Patients suffering from the condition exhibit hypersecretion of CRH, elevated concentrations of norepinephrine in the CSF, which remain elevated even during sleep, and a marked increase in the number of PVN CRH neurons on autopsy (Gold and Chrousos, 1999). Some developmental environmental exposures may predispose to such syndromes. Childhood sexual abuse is associated with an increased incidence of adult psychopathology, as well as with abnormalities in HPA function. Sexually abused girls have a greater incidence of suicidal ideation, suicide attempts, and dysthymia compared

to controls (De Bellis et al., 1994). In addition, they excrete significantly higher amounts of catecholamines and their metabolites, and display lower basal and CRH-stimulated ACTH concentrations compared to controls. However, the total and free basal and CRH-stimulated serum cortisol concentrations and 24h urinary free cortisol concentrations in these subjects are similar to those in controls. These findings reflect pituitary hyporesponsiveness to CRH, which may be corrected by the presence of intact glucocorticoid feedback regulatory mechanisms (De Bellis et al., 1994).

Other conditions may be associated with increased and prolonged activation of the HPA axis. These include anorexia nervosa (Ce Bellis et al., 1994), malnutrition, obsessive-compulsive disorder, panic anxiety, excessive exercise, chronic active alcoholism, alcohol and narcotic withdrawal, diabetes mellitus types I and II, visceral obesity, and perhaps, hyperthyroidism (Habib, Gold, and Chrousos, 2001). Both anorexia nervosa and malnutrition are characterized by a marked decrease in circulating leptin concentration and an increase in CSF NPY concentration, which could provide an explanation as to why the HPA axis in these subjects is activated in the presence of a profoundly hypoactive LC-NE-sympathetic system (Liu et al., 1994). Glucocorticoids, on the other hand, by stimulating NPY and by inhibiting the PVN CRH and the LC-NE-sympathetic systems may produce hyperphagia and obesity such as that observed in patients with Cushing's syndrome and many rodent models of obesity, including the Zucker rat (Charmandari, Tsigos, and Chrousos, 2005). Glucocorticoids have also been associated with leptin resistance, while Zucker rats are leptin receptor deficient with concurrent hypercorticotosteronism and decreased LC-NE-sympathetic system activity (Habib, Gold, and Chrousos, 2001).

SYSTEMIC EFFECTS DUE TO CHRONIC HYPERACTIVITY OF THE STRESS SYSTEM

Hypoactivity of the stress system is characterized by chronically reduced secretion of CRH and norepinephrine and may be associated with hypoarousal states (Table 13.6). As a consequence, the activity of other systems increases as a result of lack of counterregulation, i.e., if cortisol secretion does not increase in response to stress, secretion of inflammatory cytokines (which are counterregulated by cortisol) increases (McEwen, 1998). Thus, patients with a typical or seasonal depression and chronic fatigue syndrome show chronic hypoactivity of the HPA axis in the depressive state and during the period of fatigue respectively (Habib, Gold, and Chrousos, 2001). Similarly, patients with fibromyalgia have been shown to have decreased 24-hour urinary free cortisol excretion when they develop fatigue (Ehlert, Gaab, and Heinrichs, 2001). In such cases a suboptimal HPA axis response to inflammatory stimuli would be expected to reproduce the glucocorticoid-deficient state and lead to relative resistance to infections and neoplastic diseases but

Ageing

increased susceptibility to autoimmune inflammatory disease (Elenkov et al., 1999). This has been shown in Fischer and Lewis rats, inbred strains characterized by their relative hyper- and hypo-HPA axis responsiveness and resistance or susceptibility, respectively, to inflammatory disease (Elenkov and Chrousos, 1999).

Patients with depression or anxiety have been shown to be more vulnerable to tuberculosis, both in terms of prevalence and severity of the disease (Sternberg et al., 1989; Sternberg et al., 1989). Similarly, stress has been associated with increased vulnerability to the common cold virus. A compromised innate and T helper-1 driven immunity may predispose an individual to these conditions. Furthermore, patients with rheumatoid arthritis, a T-helper-1 driven pattern of inflammatory disease, have a mild form of central hypocortisolism, as indicated by the normal 24-hour cortisol excretion despite the major inflammatory stress and diminished HPA axis responses to surgical stress (Elenkov and Chrousos, 2002). Therefore, dysregulation of the HPA axis may play a role in the development and/or perpetuation of T helper-1-type of autoimmune disease. The same theoretical concept may explain the high incidence of T helper-1 autoimmune diseases, such as rheumatoid arthritis and multiple sclerosis, observed following correction of hypercortisolism, in the postpartum period and in patients with adrenal insufficiency, who do not receive adequate replacement therapy (Chikanza et al., 1992; Magiakou et al., 1996).

STRESS, SYSTEMIC INFLAMMATION AND WELL-BEING

Like the stress response, the inflammatory reaction of an individual is crucial for survival of the self and species (Chrousos, 1998). Be it an inflammatory focus with spillover of inflammatory effector molecules into the systemic circulation or a truly generalized, systemic inflammatory reaction, the biological programs that are activated during inflammation have both synergistic and antagonistic actions (Table 13.7). For instance, inflammatory cytokines stimulate CRP production by the liver and this effect is potentiated by glucocorticoids, which, however,

also inhibit the secretion of inflammatory cytokines (Chrousos and Gold, 1992). Most of the manifestations of sickness syndrome, including anorexia/nausea, fatigue and/or depressed affect, somnolence, hyperalgesia with or without headache, fever, and an increased metabolic rate, are all suppressed by glucocorticoids. Yet, peripheral neuronal CRH activated by stress or the inflammatory reaction, and substance P activated by the inflammatory reaction, both potentiate inflammation (Chrousos and Gold, 1992; Chrousos, 1995). Hypercytokinemia is not limited to conditions characterized by classic inflammatory stress, such as trauma and burns, infectious illnesses, autoimmune inflammatory diseases, and allergic inflammatory states (Table 13.4). Inflammatory phenomena in the CNS, such as Alzheimer's disease or schizophrenia, as well as noninflammatory stress, such as that of melancholic depression are associated with elevations of IL-6. Interestingly, obesity, especially the visceral type, is associated with chronic elevations of IL-6 in the circulation (see below).

The chronic pain and fatigue syndromes. Several chronic pain and fatigue syndromes, such as fibromyalgia and chronic fatigue syndrome, have been associated with chronic sickness syndrome manifestations, such as fatigue and hyperalgesia, and with hypoactivity of the stress system (Clauw and Chrousos, 1997) (Table 13.6). Interestingly, these clinical manifestations and the hypocortisolism of these patients are quite reminiscent of mild glucocorticoid deficiency (Addison's disease). Patients with glucocorticoid deficiency have elevated levels of proinflammatory cytokines such as IL-6 which may explain their typical sickness syndrome manifestations (Papanicolaou et al., 1996; Papanicolaou et al., 1998). It is tempting to speculate that patients with chronic pain and fatigue syndromes such as fibromyalgia and CFS suffer from an imbalance between the immune and inflammatory response and the stress response, which results in excessive sickness syndrome manifestations and diminished stress system counterregulation (Table 13.5).

Obesity as a chronic inflammatory state. Adipose tissue secretes large amounts of TNF- α and IL-6 in a neurally, hormonally and metabolically regulated fashion (Orban et al., 1999). The plasma levels of these cytokines are proportional to the body mass index (BMI) and are further elevated in patients with visceral obesity (Vgontzas et al., 1997). The secretion of inflammatory cytokines has a circadian pattern, with elevations in the evening and in the early morning hours (Vgontzas et al., 1999). This pattern is maintained in obese subjects, albeit at a higher level, is affected by the quality and quantity of sleep, and correlates with manifestations of the sickness syndrome. In obesity, hypercytokinemia is frequently associated with some manifestations of the sickness syndrome, such as fatigue and somnolence, and of the other biological programs that may be activated during the inflammatory reaction, especially

the acute phase reaction. Thus, obesity especially the visceral type, can be considered as a chronic inflammatory state, with many of the behavioral, immune, metabolic and cardiovascular sequel of such a state (Tables 13.6 and 13.7).

CONCLUSIONS

The stress system coordinates the adaptive response of the organism to stressors and plays an important role in maintenance of basal and stress-related homeostasis. Activation of the stress system leads to behavioral and physical changes that improve the ability of the organism to adapt and increase its chances for survival. However, an inadequate or excessive and prolonged response to stressors may impair growth and development, and may result in a variety of endocrine, metabolic, autoimmune, and psychiatric disorders. The development and severity of these conditions primarily depend on genetic, developmental and environmental factors. Medications that aim at antagonizing the central and peripheral activation of the stress system may be useful in states characterized by chronic hyperactivity of the stress system, whereas glucocorticoids may be useful in conditions characterized by chronic hypoactivity of the stress system.

14 Reproductive Hormones

CHARLES T. SNOWDON AND TONI E. ZIEGLER

HISTORICAL BACKGROUND

Critical to understanding reproduction is an understanding of hormones. Hormones keep our bodies in balance. They are our chemical messengers. Hormones are secreted into the blood stream to maintain homeostasis. Endocrine and ductless glands, located throughout the body, release hormones into the blood stream affecting tissues in other parts of the body. Only within the latter half of the twentieth century have we understood the connection between the endocrine and nervous systems in their regulation of body function. The nervous system was considered the high-speed information track transmitting by electric stimuli whereas the endocrine system worked at a much slower pace but enacted long-term changes in the body. However, the nervous system not only carries information by electrical impulses from one cell to another but nerve endings also release chemical transmitters which, under some circumstances, circulate in the blood and, thus, can be considered endocrine gland products or hormones (Moore, 1978). To study hormones, it is essential to understand both neuroscience and endocrinology. This chapter examines the interaction of neural and endocrine systems on behavior, immunity, and reproductive function.

The concept of hormones and the endocrine glands was so complex that it took until the middle of the twentieth century to understand endocrinology. To recognize a gland or group of tissue as part of the endocrine system, one needed: (1) an anatomical recognition of glandular tissue, (2) a method to detect secretions from the gland, (3) glandular extracts to test that these secretions influenced other parts of the body, and (4) isolation of the pure hormone, determining its structure and synthesis (Doisy, 1936).

Much of early human behavior was based upon hormonal therapy. In prehistoric times, men ate the organs of their enemies after battle, drank their blood, or devoured

extracts of their enemy's organs to obtain their bravery and, unknowingly, their hormones. The first deliberate use of hormone replacement occurred when French neurologist and physiologist, Charles Brown-Séquard (1817–1894), injected endocrine gland extracts from animals into humans to increase energy, or in the case of testicular injections, to rejuvenate “intellectual work and physical powers” (Brown-Séquard, 1889). These original experiments with animal testicular extracts were done by the physicians on themselves with reported increase in “strength, vigor and mental activity as well as increased contractility of the bladder” (Brown-Séquard, 1889). Within a few years, the procedure was called “organotherapy” and the techniques became an acceptable mode of therapeutics (Borell, 1976). Although interest in testicular extract injections faded, treatment with thyroid extracts was used to restore thyroid function in humans (Murray, 1891). Injections of adrenal extracts increased blood pressure (Abel & Crawford, 1897).

Infertility has long been a source of shame and worry. Anatomical description of the gonads and some understanding of their influence on the body were noted in antiquity. Many early societies had an understanding of the reproductive system (for review, see Medvei, 1982) and herbal and physical contraception was in use. Ovaries were described in Aristotle's time (384–322 B.C.) and his *History of Animals* described ovariotomy as a method to increase strength, endurance, and as a contraceptive device for animals. Ovariectomies may have been performed by the ancient Egyptians with the understanding that ovaries were necessary to conception. The importance of testicles was well known during antiquity. Early scholars debated the source of the genetic material, but many agreed with Aristotle that the testicles were the source of male genetic material and determined the sex of the child. Castration was practiced on a large scale, not only on slaves and defeated enemies, but also by the priesthood of various cults and on male attendants in harems. Castrated males, or eunuchs, were known to be sterile, and therefore, were sought after by women for love affairs because there was

no danger of pregnancy (Medvei, 1982). Hippocratic writings indicated that the menstrual cycle was known and that timing intercourse to the tenth day after the beginning of the period would increase one's chances for conception (Himes, 1936).

With the invention of microscopes in the seventeenth century, many advances in understanding the reproductive organs were made. The first descriptions of spermatozoa were made by van Leeuwenhoek and were referred to as "little animals of the sperm" or "animalcules" (Van Leeuwenhoek, 1678).

Isolation, purification and synthesis of hormones began in the early 1900s. Adrenaline (epinephrine) was the first hormone isolated (Aldrich, 1901) and synthesized. Estrogens, androgens, and corticosteroids were extracted, isolated, and synthesized in the 1920s and 1930s (Moore et al., 1929; Reichstein, 1936; Dodds et al., 1938). During this time, large quantities of estrogens were discovered in the urine of women, small amounts in the urine of men and tremendous amounts in the urine of pregnant mares. Extracts from pregnant mare urine have been the most popular hormone replacement for postmenopausal women (PREMARIN = PREgnant MARe urINE) until recently when long-term hormonal replacement has been considered risky.

In the 1950s, the neural connections to the endocrine system were beginning to be discovered. G. W. Harris suggested that the release of the pituitary hormones was controlled by humoral factors probably of hypothalamic origin (Harris, 1955). Extracts made from the hypothalamus were found to release some of the anterior pituitary hormones. After this, the race to isolate and identify the structure of the many releasing factors of the hypothalamus was begun by Schally and Guillemin, who worked independently of each other, to be the first to isolate and determine the structure of a releasing hormone. The structure of thyrotropin releasing hormone was first reported by Schally's lab. As reported in *Science*, "This race was monumental in that it lasted for 21 years, involved the creation of two rival teams of experts, and required investing time, money, and reputation in a venture seemed doomed to failure". The two scientists used techniques barely adequate for the job, faced skepticism from their colleagues, and were threatened with withdrawal of government funding if they didn't provide proof of a releasing hormone in a hurry (Wade, 1978). The two labs identified thyrotropin releasing hormone, gonadotropin releasing hormone, and somatostatin. For their perseverance, Schally and Guillemin shared the Nobel Prize in Physiology or Medicine in 1978.

The other large breakthrough was the development of methods to measure minute amounts of circulating and excreted hormones. The first methods were by bioassays. Bioassays measure the functional response of an organism, target organ, tissue, or group of cells to a hormone (Heist & Poland, 1992). For instance, the mouse Leydig cell bioassay for LH employs dispersed Leydig cells from

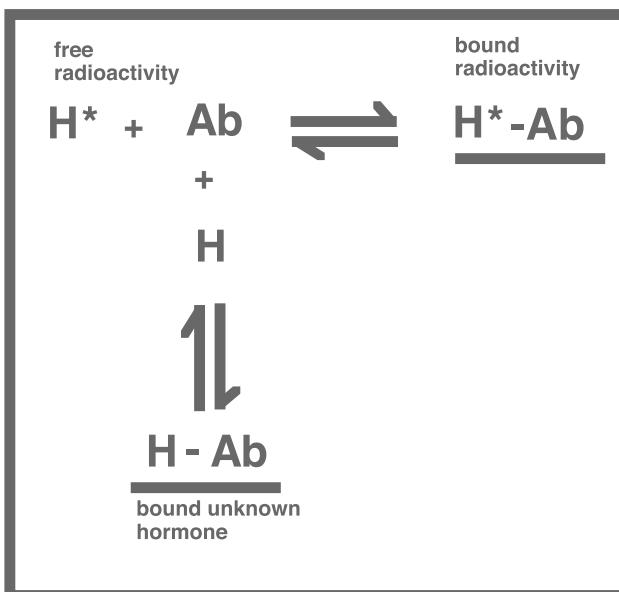

Figure 14.1. The principle of a competitive binding assay. Labeled hormone (H^*), either radioactive or enzymatic, is combined with a specific antibody (Ab) made against the hormone (H) to produce labeled-antigen-antibody complexes. Unlabeled hormone also binds with specific antibody and produces antigen-antibody complexes. By separating the bound from the free, a ratio can be set up that will determine the percent bound. Standard amounts of the hormone can be used to create a standard curve and thereby interpret the concentration of the hormone of interest in the sample. Figure adapted from Yalow, 1992, p. 123, *Textbook of Endocrinology*, Wilson, Foster (Eds).

postpubertal male mice testes. The dispersed cells are target cells stimulated by the gonadotropin molecules (LH or CG) present in the sample (blood or urine) and produce a dose-response related increase in testosterone production (Ellingwood & Resko, 1980). Another bioassay uses the steroid-primed uterus of the rat to study oxytocin-induced contraction of the uterus. There are many types of bioassays for determining the biological activity of hormones.

In most cases, however, bioassays were replaced by radioimmunoassays (RIA) except when a difference between the biological response and the immune response was expected. The RIA has provided for both an increase in sensitivity and an increase in specificity. RIA was first developed by Rosalyn Yalow and Seymour Berson 1959 to measure insulin in humans (Yalow & Berson, 1959). Hormones exhibit antigenic properties when the molecular weight of the molecule is high enough. Where the molecular weight is low, such as with steroids, the molecule is conjugated to a higher molecular weight molecule. The underlying principles of RIA consist of combining a radiolabeled hormone with an antibody made specifically for the hormone of interest. The labeled hormone and the antibody produce an antigen-antibody complex where the molecules are bound tightly to each other (Figure 14.1). When an unlabelled hormone (found in blood or any bodily fluid) is added to the system, it competes with the labeled hormone for binding to the antibody

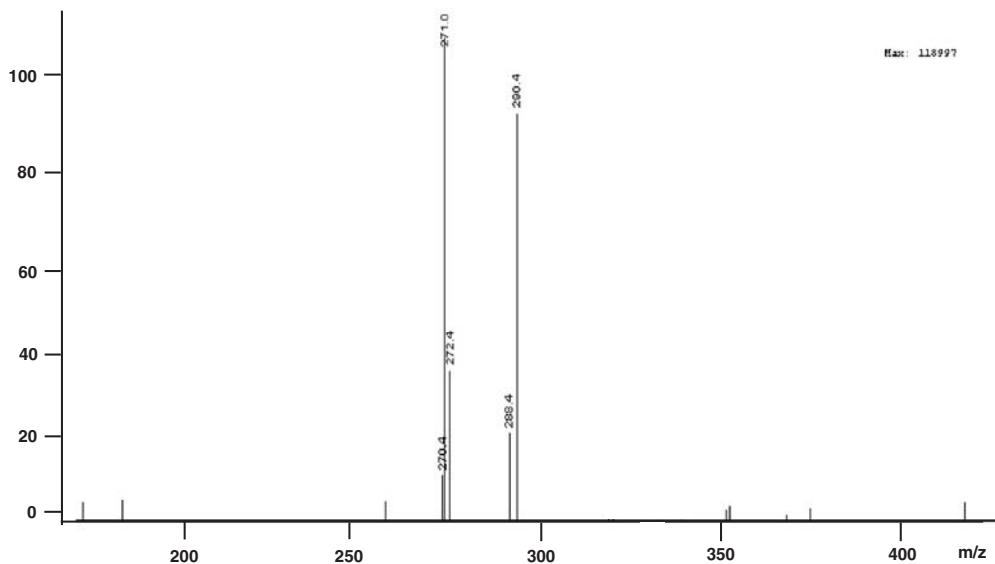

Figure 14.2. Mass spectrogram of estradiol and testosterone showing their mass-to-charge ratios.

and a displacement of radioactivity can be measured. Thus, a higher amount of radioactivity measured indicates less of the hormone of interest in the sample. RIAs have been used extensively since the 1960s to measure hormone concentration and can measure less than a picogram per milliliter of sample (10^{-12} gram per milliliter).

Recently, other methods of measuring hormones have been in use, which reduce the need to remove radioactive wastes. One of the more popular methods is an enzymeimmunoassay (EIA). EIAs have the same principle as RIAs except the hormone has an enzyme tag instead of a radioactive tag. The endpoint uses a color change measurable by spectrophotometry. EIAs have been shown to be as sensitive as RIAs, and in some cases, even more sensitive (Munro & Stabenfeldt, 1984). Other methods of measuring hormones make use of the chemical characteristics of the hormones. Chemical luminescence, fluorescence, chemical detection, and ultraviolet detection of High Pressure Liquid Chromatography (HPLC) separated hormones are all methods that are being used to identify or quantitate hormones.

Mass spectrometry via HPLC or Gas Chromatography encompasses techniques that have been available for many years but have only recently become a benchtop technique applicable to measurements of multiple hormones. These techniques, particularly LC/MS (liquid chromatography/mass spectrometry), can measure multiple hormones simultaneously at very low concentrations. Samples are separated by HPLC, usually using capillary columns that separate hormones to be measured in extremely low levels. The levels of steroid can be as low as subpicogram (femtogram) and can be measured in a volume as low as 1 microliter. Mass spectrometry measures the mass to charge ratio of an individual steroid. For instance, testosterone has a mass of 288 and depending upon the mobile phase (a mixture of buffers and solvents)

will take on electrons, such as hydrogen or sodium, and thereby will be identified at a mass of 289, 290, or 311. Once the mass and its charge are known, a steroid can be found readily and quantified by calibrating the steroid as a standard. All steroid or protein hormones can be measured this way as long as the chromatography method for separation of hormones is well developed. A mass spectral analysis of two steroids, estrone and testosterone, are shown as an on screen analyses in Figure 14.2. The two steroids have similar retention times using this particular method (estrone = 5.75, testosterone = 5.66 minutes) but different masses. Estrone, with a molecular weight of 270, is mainly ionized by hydrogen to yield a mass of 271. Testosterone, with a molecular weight of 288, is primarily ionized by two hydrogen ions to yield a mass of 290.4. These patterns of ionization provide the fingerprint of the individual steroids for identification. Through calibration, multiple steroids (or peptides) can be identified and quantified without the need for antibodies or concerns of cross-reactivities of RIAs or EIAs.

Hormones function by targeting specialized receptors that carry hormones into the cell nucleus where they bind to DNA and activate genes that transcribe proteins to activate enzymes that affect physiology and behavior. It has long been assumed that steroid receptors were activated only by binding with steroid ligands, but recent work has demonstrated ligand- or steroid-independent activation of steroid receptors is possible and that nuclear receptors bind co-regulatory proteins that can determine whether a particular gene is transcribed or not. Proteins enhancing receptor activation are co-activators and those that suppress activation are co-repressors (Auger, 2004). Steroid receptor co-activators have been found in many tissues – reproductive tract, mammary gland, and brain (Molenda et al., 2003) and at least one of these co-activators (SRC-1) can influence the development of sex-specific

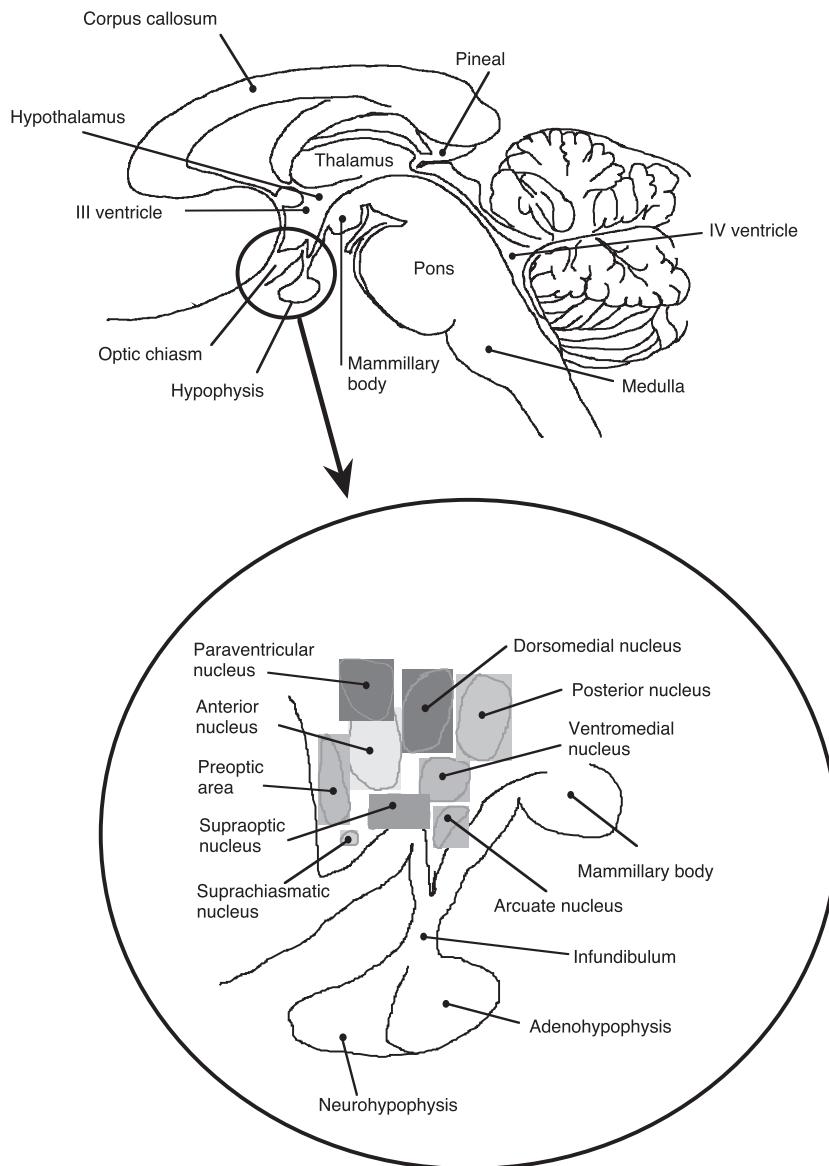

Figure 14.3. Drawing of the major parts of the brain. Circled part in the top diagram illustrates the position of the hypothalamus and pituitary. The hypothalamus and pituitary are shown in the enlarged circle. The hypothalamus is divided into nuclei named for their position. Nerve fibers extend from the hypothalamus into the infundibulum. Production and storage of LH, FSH, GH, TSH, ACTH, and prolactin occur in the adenohypophysis. Vasopressin and Oxytocin are produced in the hypothalamus and stored in the neurohypophysis.

brain morphology and behavior (Auger et al., 2000). Various neurotransmitters including dopamine, associated with motivational arousal and reward, can influence the expression of steroid receptors. What this means is that environmental events such as the behavior of a mate or various types of rewards may lead to expression of, for example, progestin receptors in females in the absence of progesterone. There are many implications of these findings for sexual differentiation and reproductive activation or inhibition (Auger, 2004).

PHYSICAL CONTEXT: ANATOMY AND PHYSIOLOGY OF THE NEUROENDOCRINE SYSTEM

Hypothalamus and pituitary

The brain influences the endocrine system through the hypothalamus (see Riskind & Martin, 1989). The hypothala-

lamus is an extension of the brain stem and is considered to be a phylogenetically ancient structure. The hypothalamus is below the thalamus and forms the walls and lower part of the third ventricle of the brain (Figure 14.3). The third ventricle is part of the fluid canal system that flows into the spinal cord. Links from other areas of the brain to the hypothalamus allow for social and behavioral, visceral, and autonomic controls. The hypothalamus is composed of areas referred to as the tuber cinereum, the infundibulum (also called the median eminence), and the mammillary bodies. Clusters of neurons are located here that secrete neurohormones for regulating the activity of the pituitary. The nerve clusters are named by position: supraoptic nucleus (SON), paraventricular nucleus (PVN), suprachiasmatic nucleus (SCN), ventromedial nucleus (VMN), dorsomedial nucleus (DMN), medial preoptic area (MPOA), arcuate nucleus (ARC), anterior nucleus, and the posterior nucleus. The

clusters of neurons contain cell bodies whose axons extend into the infundibulum. Some axons extend into the neural, or anterior pituitary, whereas other neurons produce regulatory hormones that are transported from the median eminence to the anterior pituitary by the hypothalamic-pituitary portal circulation. A rich vascular supply allows transport of the hypothalamic regulatory hormones, neuropeptides, and neurotransmitters to the anterior pituitary.

The pituitary is divided into the anterior and posterior pituitary (also called the adenohypophysis and neurohypophysis). The anterior lobe is composed of three divisions: pars distalis, pars intermedia, and pars tuberalis. The hormone-producing cells are located in the pars distalis. The pars intermedia is very small and rudimentary in humans. The pars tuberalis is the upward extension of the anterior lobe and its attachment to the pituitary stalk. The posterior pituitary is an extension of the hypothalamus consisting of the infundibulum, the infundibular stem and the neural lobe. Two hormones, arginine vasopressin (AVP) and oxytocin (OT), are synthesized in the SON and PVN area of the hypothalamus, transported through elongated axons, and stored in the posterior lobe and from there released into the peripheral circulation. The anterior pituitary synthesizes adrenocorticotropin hormone (ACTH), growth hormone (GH), prolactin (PRL), thyroid stimulating hormone (TSH), luteinizing hormone (LH), follicle stimulating hormone (FSH), and in the pars intermedia, melanocyte-stimulating hormone (MSH) is produced in many mammals but not in adult humans. These hormones, in turn, regulate the hormones produced in the endocrine glands located throughout the body. Table 14.1 shows the relationship between the hypothalamus, pituitary, and target gland hormones.

Hypothalamic control of pituitary hormones can cause a positive release or an inhibitory release of hormones, as occurs with dopamine's inhibition of prolactin release. The anterior pituitary releases hormones in a pulsatile fashion into the blood where they travel to their target glands and exert effect. The hormones in the target glands feed back to both the hypothalamus and the pituitary. In this way the hormonal production of the endocrine glands is continuously monitored and regulated by the brain. The control of pituitary hormones is more complex than demonstrated in Table 14.1. For example, TRH also can stimulate the release of PRL from the pituitary whereas dopamine causes an inhibition of PRL release. OT stored in the posterior pituitary can stimulate the release of PRL (Mori et al., 1990). Although GnRH (gonadotropin releasing hormone) stimulates the release of both LH and FSH, the quantity of release of both these pituitary hormones changes during the ovarian cycle so that at ovulation LH is released as a large surge but during menses and the onset of follicular growth, FSH is released while LH is maintained at basal levels in the blood. More than 16 different neurotransmitters contribute to regulating LH and PRL (see Kordon et al., 1994 for an extensive review).

Table 14.1. Hypothalamic and pituitary hormones and their feedback control

Hypothalamic hormone	Pituitary hormone	Target gland	Feedback hormone
TRH	TSH	Thyroid	T ₄ and T ₃
GnRH	LH	Gonads	E ₂ (women), T (men), P
	FSH	Gonads	Inhibin and (?) E ₂ and T
SS	GH	Multiple	IGF 1
GHRH	GH	Multiple	IGF 1
DA, OT, TRH	Prl	Breast Gonads + brain	?
CRH	ACTH	Adrenal	Cortisol
AVP	ACTH	Adrenal	Cortisol
DA, CRH, GABA	MSH	Skin, fetal adrenal	(?)

Key: ACTH, adrenocorticotropin hormone; AVP, arginine vasopressin; CRH, corticotropin releasing hormone; DA, dopamine; E₂, estradiol; FSH, follicle stimulating hormone; GABA, gamma-amino-butyric acid; GH, growth hormone; GHRH, Growth hormone releasing hormone; GnRH, gonadotropin releasing hormone; IGF, insulin-like growth factor; LH, luteinizing hormone; MSH, melanocyte stimulating hormone; OT, oxytocin; P, progesterone; Prl, prolactin; SS, somatostatin; T, testosterone; TRH, thyrotropin releasing hormone; TSH, thyroid stimulating hormone.

Source: Adapted from Thorner et al. (1992).

Neurotransmitters control the secretion of releasing hormones and are secreted from neurons, which may be linked, to other neuronal inputs or to sensory neurons receptive to endogenous and exogenous cues. Neurotransmitters may have an inhibitory or a stimulatory effect. Small-molecule neurotransmitters mediate rapid reactions, whereas neuropeptides tend to modulate slower, ongoing brain functions. Small-molecule neurotransmitters consist of: acetylcholine, the amino acids such as glutamate, aspartate, GABA, glycine, the catecholamines such as dopamine, norepinephrine, epinephrine, serotonin, and histamine (Purves et al., 1997). Neuropeptides include enkephalins, endorphins, cholecystokinin (CCK), vasoactive intestinal peptide (VIP), neuropeptide-Y, AVP, OT, and angiotensin-II.

The main feedback control of anterior pituitary hormones comes from the release of steroids from the target endocrine glands. These include the adrenal gland, the thyroid gland, the gonads (ovaries and testes), the pancreas, the pineal and the placenta. Steroids secreted from these glands are released into the bloodstream to exert their effect on many tissues in the body. They also reach the pituitary and the hypothalamus to exert the negative feedback loop to control their own secretion.

Neurohypophysis hormones: oxytocin and arginine vasopressin

The nonapeptides, OT and AVP, are structurally closely related while serving distinct physiological roles. Both hormones consist of nine amino acids folded into a ring through a disulfide bridge with a terminal tripeptide side chain. The hormones differ by only two amino acids. Classically, OT is known for its control of milk release from the mammary gland and the contractions of the uterus during labor whereas AVP (also referred to as antidiuretic hormone) is involved with water balance. Actually both hormones serve many other functions within the body. They are involved in the processes of learning and memory, especially in a social context (Engelmann et al., 1996; Heinrichs et al., 2004). OT and AVP are released from the posterior pituitary into the bloodstream but they also serve a role in interneuronal communication. Both substances are released synaptically from axon terminals, dendrites and somata of hypothalamic neurons. Central actions include a variety of autonomic, endocrine and behavioral effects (Engelmann et al., 1996). Concentration of AVP and OT in the extracellular fluid of discrete brain areas is several orders of magnitude higher than peripheral levels in the blood.

The role of OT as a maternal hormone is without doubt. OT is not only responsible for milk letdown during nursing but is known for induction of contractions during labor. OT facilitates mother-infant interactions and has an inhibitory effect on aggressive behavior in rats (Giovenardi et al., 1997). Pairbond formation in monogamous prairie voles appears to be influenced by OT released centrally in the brain (Carter, 1998). OT may facilitate both social contact and attachment and the regulation of the parasympathetic functions (see below). OT inhibits CRH-mediated ACTH secretion in men. OT regulates receptor-mediated mechanisms within the amygdala involved in passive stress-coping strategies, which might be mediated via inhibitory influence on the local release of excitatory amino acids during stress (Ebner et al., 2004). OT has effects on female sexual receptivity (lordosis in rodents), penile erection, and male mounting behavior (Rao, 1995).

AVP, on the other hand, is associated with regulating defensive behaviors such as arousal, attention, or vigilance – increased aggressive behavior with an increase in sympathetic functions (Carter & Altemus, 1997). In monogamous male prairie voles, however, AVP induces pair bond formation and promotes parental behavior (Wang et al., 1994). AVP induces the contraction or relaxation of certain types of smooth muscle and it promotes the movement of water and sodium across responsive epithelial tissues, especially the kidney (Hadley, 1992).

Interestingly, these two peptides might be synergistic in promoting parenting behavior (Bales et al., 2004). OT and AVP have been shown to be anxiolytic (Uvnas-Moberg, 1997; Appenrodt et al., 1998; Dharmadhikari et al., 1997). Reducing the phobic responses to newborn infants is crit-

ical to promoting parental behaviors ensuring the success of the offspring (Pryce, 1996).

The structure of the glands

The major glands secreting hormones are listed in Table 14.2, but many tissues in the body secrete chemical messengers. In the gastro-intestinal tract alone there are at least 10 hormones recognized. Other tissues that release chemical messengers are: skin, liver, kidney, heart, plasma, and various tissues releasing growth factors considered to be hormones. Here we briefly discuss the adrenal glands and then concentrate on the gonads with their communication to the brain and hypothalamus.

Adrenals

The adrenals are located directly above the kidneys and about one-tenth the size of kidneys. Each adrenal consists of two functionally distinct endocrine glands. The cortex is the steroid-secreting gland consisting of cells grouped into: the zona glomerulosa, zona fasciculata, and zona reticularis. The zona glomerulosa produces mineralocorticoids, such as aldosterone, which promotes sodium retention and potassium excretion, both regulating extracellular fluid volume (Bartter et al., 1956). The zona fasciculata and zona reticularis secrete glucocorticoids and androgens including dehydroepiandrosterone (DHEA) and androstenedione. The major human glucocorticoid is cortisol. The adrenal medulla is an endocrine gland derived from the neural crest. Epinephrine is the predominant catecholamine released from the medulla. The close anatomical coupling and functional interrelations between the adrenal cortex and medulla suggest that these two tissues may provide an integrated functional unit (Hadley, 1992).

Cortisol is well known for its role in the stress response and discussion of glucocorticoids can be found in other chapters. Both higher and lower amounts of cortisol than the physiological levels lead to disease states. Superphysiological levels can modulate mood, influence sleep patterns, cognition, and the reception of sensory input (McEwen, 1979). Cortisol has an inhibitory influence on the reproductive system. During prolonged stress, beta-endorphin, and CRH inhibit the release of GnRH. Stress causes the pituitary to be less sensitive to GnRH and glucocorticoids inhibit ovarian sensitivity to LH (Sapolsky, 1992), thus decreasing the likelihood of reproduction. Additionally, gonadal hormones influence the reactivity of the hypothalamic-pituitary-adrenal axis to stress. Estrogens enhance the HPA activity and androgens attenuate the response (Lund et al., 2004).

Epinephrine, synthesized and stored in the adrenal medulla is also released centrally from neurons, but is the primary catecholamine known to be released peripherally. The adrenal medulla is under the direct and exclusive control of the central nervous system. Functionally, catecholamines are neurochemical transducers that convert

Table 14.2. Endocrine glands in mammals and the major known hormones

Gland	Secreted hormone
Anterior pituitary	Growth Hormone Prolactin Melanophore stimulating hormone Adrenocorticotropin Luteinizing hormone Follicle stimulating hormone Thyroid stimulating hormone
Posterior pituitary	Arginine vasopressin Oxytocin
Thyroid gland	Thyroxin Calcitonin
Adrenal cortex	Glucocorticoids Corticosterone Cortisol Dihydroepiandrosterone Mineralocorticoids Aldosterone
Adrenal medulla	Epinephrine Norepinephrine Enkephalins Endorphins
Kidney	Renin Angiotensin
Liver	Preangiotensin
Pancreas	Insulin Glucagon
Stomach and intestines	Gastrin Secretin Cholecystokinin Gastric inhibitory peptide Vasoactive inhibitory peptide Chymotrypsin Motilin Neurotensin Substance P Gastrin releasing peptide
Pineal	Melatonin
Ovary	Estrogens Estradiol Estrone Progesterone Inhibin
Testes	Androgens Testosterone Dihydrotestosterone Androstenedione

electrical neural activity into physiological responses. Catecholamine effects are induced rapidly and dissipate quickly, unlike the slower, more prolonged effects of most hormones. The catecholamines maintain the constancy of the body's internal environment.

In summary, adrenal glands have both an endocrine and neural component. The main function of the adrenals is to maintain homeostasis. Through secretions of epinephrine by the adrenal medulla and glucocorticoids by the adrenal cortex, the body responds rapidly to a change in homeostasis with the release of neurally controlled epinephrine—or more slowly for a longer duration with release of the endocrine-controlled glucocorticoids.

Ovaries

The ovaries control reproduction in the female. Here ova are produced and the hormones that regulate the female sexual life are synthesized. Both the development of the ovum and the synthesis of steroid hormones are under the control of the hypothalamo-pituitary-ovarian axis. Figure 14.4 shows the reproductive organs of the human female. The ovaries lie laterally and posteriorly in the pelvic wall attached to the posterior surface of the broad ligament by a peritoneal fold termed the mesovarian. The ovary consists of three regions: the cortex containing the germinal epithelium and the follicles, the central medulla consisting of stroma and a hilum where the attachment of the ovary to the mesovarian ligament occurs (Carr, 1992). The primordial follicles lie near the periphery of the cortex and contain the primordial germ cells that give rise to the oocytes. The number of oocytes is fixed by birth in the female at about 1 million per ovary. The primordial follicles begin the process of meiosis within the embryo and became arrested in the prophase of mitosis by birth of the fetus. After puberty the endocrine system initiates the continued maturation of the follicles.

During each ovarian cycle six to 12 primary follicles develop into secondary follicles. The size of the oocyte and the number of layers of the granulosa cells that surround the ovum increase. A zona pellucida is formed and granulosa cells begin to develop. Usually only one or two follicles continue to develop beyond this stage and the others end in atresia. As a follicle develops, granulosa cells continue to mature and the interstitial tissue surrounding the follicle differentiates into two layers: theca externa and theca interna. As the follicle enlarges, a single large vesicle is formed. A mature follicle is called a Graafian follicle. The mechanisms controlling the rupture of the mature follicle involves the sequestering of leukocytes as part of the inflammatory process (Bonello et al., 2004) initiated by the release of LH from the pituitary. The LH causes rapid secretion of follicular steroid hormones and begins the conversion to secreting progesterone. At this time, the outside capsule of the follicle (theca externa) begins secreting proteolytic enzymes, weakening the capsular wall and increasing follicular swelling. New blood vessel growth occurs rapidly in the follicle wall and prostaglandins are secreted

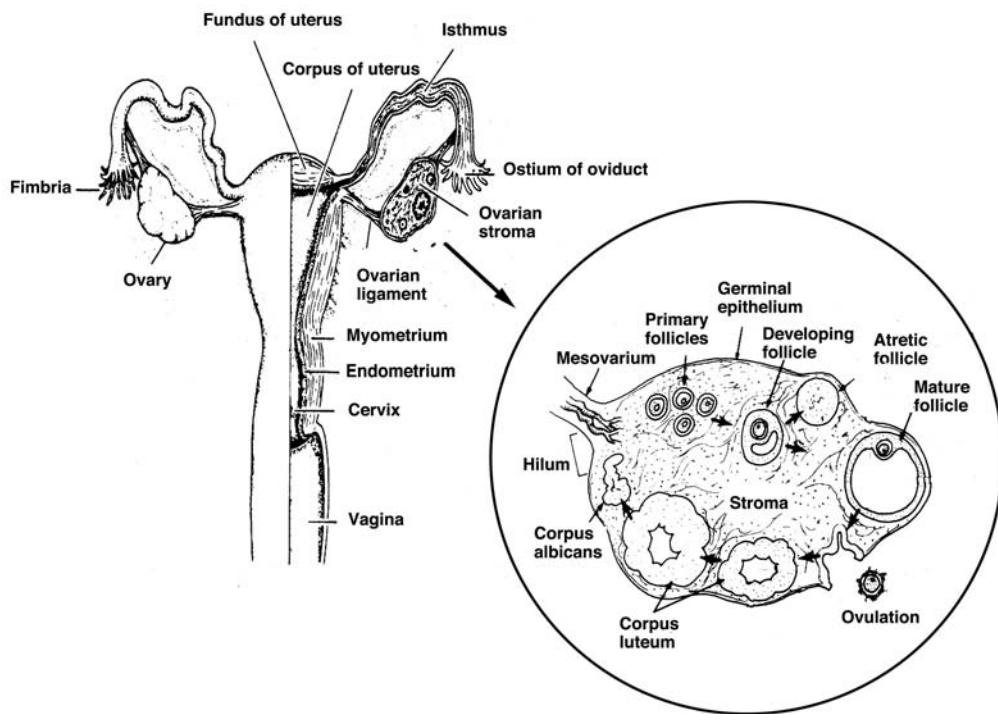

Figure 14.4. The reproductive organs of the human female. An enlargement of the ovary and the process of ovulation are shown in the circle. Parts of this figure were adapted from Niswender and Nett, 1988, p. 490, *The Physiology of Reproduction*, Knobil, Neill (Eds).

in the follicular tissues. The prostaglandins act as local hormones causing vasodilation of blood vessels (Guyton & Hall, 1996). Plasma flows into the follicle increasing the swelling, and the follicle ruptures. During ovulation, the fimbria of the uterine tubes (Fallopian tubes) spread over most of the medial surface of the ovary and provide wave-like movements to draw in the ovulated ova. The ovum moves down the Fallopian tubes where fertilization takes place. After fertilization the embryo moves into the fundus of the uterus where implantation and growth takes place. If fertilization does not take place, then prostaglandins secreted by the endometrium of the uterus initiate luteolysis of the corpus luteum. After the follicle ruptures, it fills with blood forming the corpus hemorrhagicum. Both granulosa cells and thecal cells begin increasing in number. The granulosa cells begin to accumulate large quantities of cholesterol in a process termed luteinization. The corpus luteum is now formed and will remain large for about 14 days before regression.

Ovarian steroids are derived from the follicle and corpus luteum. There are three types: estrogens, androgens, and progestogens. During the follicular phase, estrogens are the major steroids secreted from the ovary whereas during the luteal phase and pregnancy, progesterone is the major steroid hormone secreted. Ovarian steroids, like all steroids including cortisol, are derived from cholesterol. Estradiol is biosynthesized from cholesterol via steroidogenic pathways shown in Figure 14.5. The thecal cells synthesize androgens, androstenedione, and testosterone, from cholesterol via pregnenolone, primarily through

dihydroepiandrosterone. The androgens are transferred to the granulosa cells where they are aromatized to estrogens. During follicular maturation the ability of granulosa cells to aromatize androgens into estradiol increases. Low levels of estradiol exert a negative feedback on pituitary LH. Peak levels of estradiol feed back to the hypothalamus and pituitary to initiate the release of GnRH, which in turn releases LH and FSH. With the LH/FSH surge, progesterone biosynthesis begins in the granulosa cells. Progesterone acts on the hypothalamus to decrease LH and FSH secretion. As progesterone levels decline, pituitary gonadotropins begin secreting and initiate the next set of follicle growth. Other ovarian hormones help to regulate the pituitary's influence on the ovary such as follicular activin, which exerts a positive release on FSH and follicular inhibin and follistatin that exert an inhibitory effect on FSH release.

At puberty, estrogens stimulate the continued development of the vagina, uterus, and oviducts. Secondary sexual characteristics developed at this time are due to estrogen secretion. However, ovarian androgens are also responsible for some of the changes of puberty, such as pubic and axillary hair growth, acne, and sebaceous gland activity. Estrogen secretion also affects the distribution of fat and mammary growth and development typical to females.

Progesterone prepares and maintains the reproductive tract for the embryo during pregnancy. Progesterone inhibits uterine contractions, increases the viscosity of the cervical mucus, promotes glandular development of the breast, and increases body temperature. The sequence of

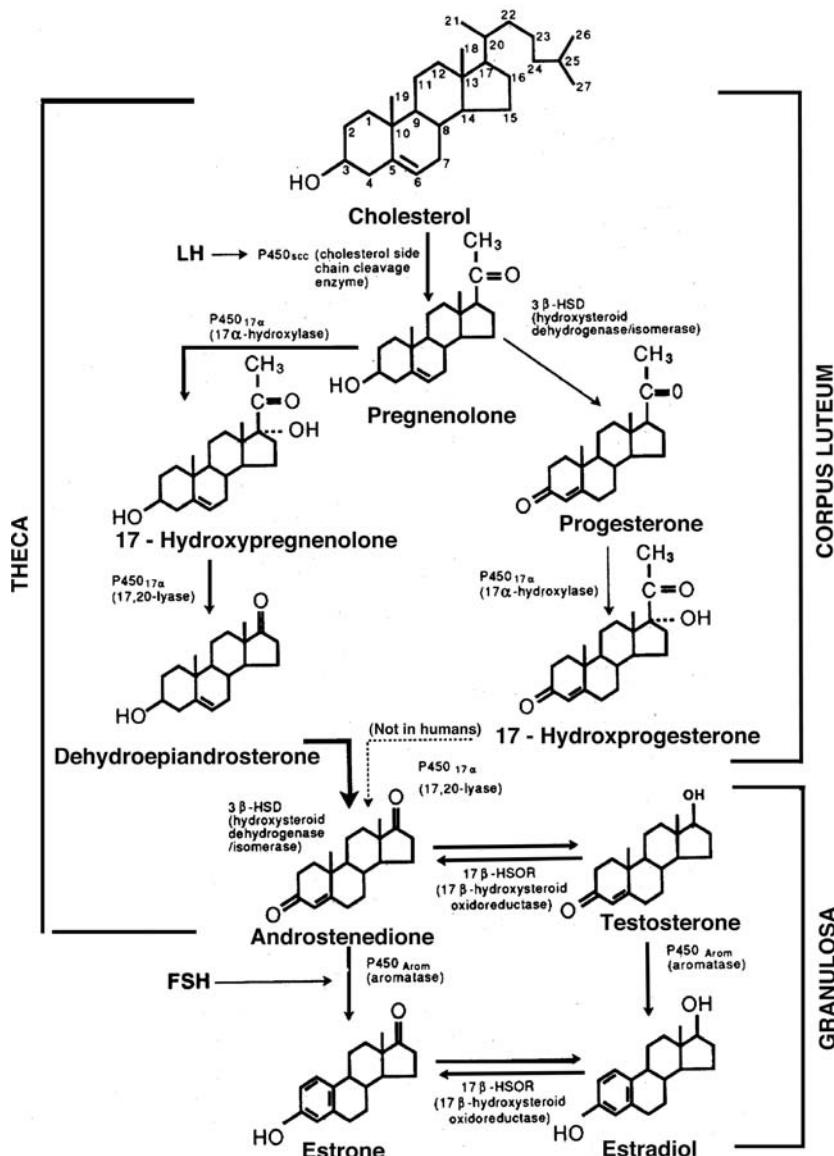

Figure 14.5. Steroidogenic pathway of ovarian steroids.

estrogen-primed tissue with increasing levels of progesterone has been implicated in triggering sexual behavior in many mammals.

Steroids and other hormones regulate specific target tissues by interacting with specific receptors. Hormone-specific receptors are located in plasma membranes, in the cell cytosol (cytoplasm) or in the nucleus. Estradiol receptors may bind with other substances that resemble estradiol. Many compounds, which bind to estrogen receptors, have estrogen-like effects on the body. Estrogen-like compounds, such as synthetic diethylstilbestrol or naturally occurring plant estrogens can mediate estrogen effects in the body producing physiological responses (Miksicek, 1993).

Ovulation occurs on average once every 28 days in the nonpregnant woman. However, many social and stressful events can influence cycle length or puberty onset. Olfactory cues from men can affect the length of ovarian cycles. The actual axillary secretions of men reduce the

variability in menstrual cycle lengths, whereas women's axillary secretions synchronize the onset of the menstrual cycle in recipient women (Prete et al., 1986; Cutler et al., 1986). Menstrual cycle synchrony has been demonstrated in women living in a college dormitory and among close friends (McClintock, 1971). Chemical signals from different times of a donor's cycle will either shorten (follicular cues) or lengthen (luteal cues) the recipient's cycle (Stern & McClintock, 1998). Factors of close bonding, or friendship, affect cycle synchrony (Goldman & Schneider, 1987; Weller & Weller, 1993, 1995). The presence of unrelated men in the home accelerate the timing of menarche in girls whereas the physical exposure of a related male may delay menarche (Surbey, 1990). (See subsequent sections for more details).

Testes

Testes produce both the sperm necessary for fertilization and the steroid hormones that regulate sperm production

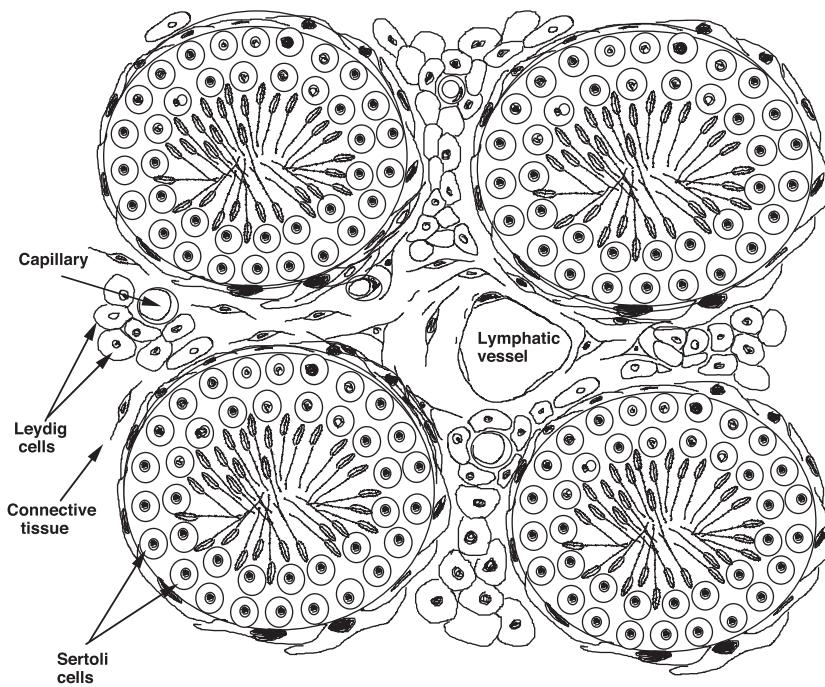

Figure 14.6. Diagram of the testicular tissue in man showing the arrangement of the Sertoli cells with spermatocytes and the interstitial tissue containing the Leydig cells where testosterone is produced.

and male sexual life (Griffin & Wilson, 1992). The testes lie outside the abdominal cavity within the scrotal sac. Descent of the testes from the abdominal cavity where development takes place occurs during the latter two thirds of gestation. In the adult male, the testes have two components necessary for sexual function. Figure 14.6 shows the structures of the seminiferous tubules and the steroid producing Leydig cells. The tubules produce and transport the sperm to the excretory-ejaculatory ducts. Steroid-producing Leydig cells are located outside the seminiferous tubules. They contain lipid droplets of cholesterol that serve as a substrate for testosterone synthesis. Testosterone is metabolized from cholesterol by conversion to pregnenolone with subsequent 17-hydroxylation synthesis through dehydroepiandrosterone and androstenedione to testosterone as occurs in the ovary (Figure 14.5). Dehydroepiandrosterone and androstenedione are also end products of the Leydig cells but in small amounts and with low physiological potencies. Little testosterone is stored within the Leydig cells because the newly synthesized testosterone diffuses quickly into the blood from nearby capillary cells (Hadley, 1992).

The seminiferous tubules are filled with Sertoli cells that give rise to the spermatocytes. FSH interacts with receptors on the Sertoli cells to induce the synthesis of an androgen-binding protein (ABP). ABP is secreted into the lumen of the seminiferous tubules. The Leydig cells respond to LH stimulation and produce testosterone. Testosterone is also actively transported into the seminiferous tubules where it becomes bound to ABP within the Sertoli cells. The spermatocytes begin the process of maturation under the influence of testosterone. Mature sperm are stored in the epididymis where they develop the potential for fertilization and motility.

GnRH is released in an episodic manner into the hypophyseal portal system causing LH and FSH release in a pulsatile manner. The rate of secretion of LH, however, is controlled by the feedback action of gonadal steroids on the hypothalamus and the pituitary. Both testosterone and estradiol exert a negative feedback on LH. Testosterone can be converted to estradiol in the brain and pituitary. The ratio of testosterone to estradiol appears to influence the release of FSH (Sherins et al., 1982). FSH is also controlled by negative feedback from inhibin produced by the Sertoli cells under the influence of FSH.

Although testosterone is the main steroid secreted by the testes, it actually serves as a precursor for two types of active metabolites that have a higher biological activity than testosterone and provide the androgen effects on the body. Testosterone (T) can be reduced by 5-alpha-reductase to dihydrotestosterone (DHT). The conversion can take place in the prostate and seminal vesicles or in peripheral tissues. DHT mediates the growth promotion, differentiation, and functional aspects of male sexual development. The ratio of DHT to testosterone levels changes rapidly at the onset of puberty to favor the more potent DHT (Ginther et al., 2002). Alternatively, testosterone can be aromatized to estrogens in extraglandular tissues. Estrogens can act in concert with the androgens but more often estrogens have the opposite effect from androgens. Androgens can act directly on the brain to affect the male's behavior. Acting on other androgen-sensitive tissues, including accessory sex organs, androgens may affect behavior indirectly.

Sexual development into male or female proceeds from the establishment of genetic sex at the time of conception. Genetic sex governs the development of gonadal sex, which in turn, regulates the development of phenotypic

sex, which is the differentiation of internal and external sex organs and the attainment of adult secondary sexual characteristics. In mammals the gonads and accessory glands develop toward the female unless influenced by the Y chromosome (Roberts, 1988). The Y chromosome triggers the genital ridges in the embryo to develop into testes rather than ovaries. The differentiation toward the male gonadal and body phenotype requires the inductive actions of gonadal androgens. Female ovarian and genital development may be considered an autonomous process requiring no hormonally active inductive substances. Removal of the gonads from indifferent embryos of either sex results in development of a female genotype (Bardin & Catterall, 1981). The timing of androgen exposure to the brain is important for physiological and behavioral processes. Deprivation of testosterone in the male animal during his species-specific critical time of brain differentiation will result in a female pattern of sexual dimorphic behavior (see below).

REPRODUCTIVE HORMONES AND IMMUNE DISEASES

Many autoimmune and rheumatic diseases occur at different rates in men and women suggesting a potential role for reproductive hormones in these disorders. For example, rheumatoid arthritis, Sjogren's (or dry-eye syndrome), systematic lupus erythematosus (lupus), scleroderma, and multiple sclerosis all occur much more often in women than in men and ankylosing spondylitis occurs much more often in men. Furthermore rheumatoid arthritis, lupus, and multiple sclerosis have typical onset during the peak reproductive years when estrogen and progestin levels are high whereas dry-eye syndrome appears to correlate with the onset of menopause (Butts & Sternberg, 2004). Despite the correlational evidence direct involvement of reproductive hormones is known for only a few of these diseases. Lupus can arise early in puberty and has decreased severity during menses, suggesting direct hormonal involvement. Oral contraceptives exacerbate symptoms, and women have high levels of estrogen and low levels of androgens. Experimental studies show that estradiol can block B-cell tolerance and induce a lupus-like syndrome in mice (Bynoe et al., 2000). High prolactin concentrations are associated with lupus and early death was induced with prolactin in an animal model of lupus (Walker et al., 1998).

Although the major steroid influences on rheumatoid arthritis are adrenal glucocorticoids, experimental animal studies suggest that long-term androgen treatment may protect cartilage from inflammatory breakdown. Estrogen may also be critical because symptoms are reduced during early pregnancy when estrogen levels are high (Cutolo, 1998). Dry-eye syndrome develops at the time of menopause suggesting that the reduction of gonadal steroids might influence the disease, but women with estrogen replacement therapy have a higher incidence of dry-eye syndrome and estradiol and progesterone treat-

ment of mice have significant effects on the expression of many genes regulating the lachrymal gland (Suzuki et al., 2002).

SOCIAL CONTEXT

Introduction

Many of the most interesting behavioral phenomena of life (behavioral sex differences, courtship, sex, parental care, aggression, cognition) are to some degree influenced by reproductive hormones, and psychophysiological research plays an important role in discovering the relative role of the hormones versus environmental and social factors influencing these phenomena.

We review seven broad areas here: What is the role of genes, hormones, and social environment on the development of sex differences? What is the interaction of hormones and social environment on puberty and reproductive maturation? How do hormones influence affiliative behavior, courtship, and pair bonding? Do hormones influence behavior across the ovarian cycle, and how do social interactions influence ovarian function? What is the relative role of hormones and social behavior on parental care? Are there sex differences in aggression and do these differences result from hormonal differences? Finally, how do reproductive hormones influence memory and cognition?

Development of behavioral sex differences

There is great diversity in how sex is determined biologically, and within mammals there are many places where sex determination can go awry. In mammals, the ovum always contains an X chromosome and sperm can be either X or Y, meaning that the father's sperm determines the sex of the offspring. In birds, however, males are homogametic (with two Z chromosomes) and ova contain either W or Z chromosomes, meaning that mothers determine the sex of their offspring (Breedlove, 1992). In some reptiles there are no sex chromosomes, and sex is determined by the temperature at which the eggs are incubated (Bull & Vogt, 1979). Some species of fish are sequentially hermaphroditic (female then male or male then female) – changing sex in response to the social structure of the group – or simultaneously hermaphroditic (trading sex roles and gametes during a sexual interaction (Demski, 1987). Postmaturational sex changes are influenced by social cues such as dominance interactions with larger individuals dominating. In some species sex is determined by relative size as a juvenile (Francis & Barlow, 1993).

In mammals, the Y chromosome contains a gene that stimulates fetal testes development, and secretions from the fetal testes lead to differentiation of male external genitalia and internal accessory organs. In the absence of testicular hormones or their receptors, female external genitalia and internal accessory organs develop. Thus, being

female is the default value in mammalian fetal development (Eve had to precede Adam).

Research on rodents demonstrated that manipulation of fetal or perinatal hormone levels influenced the development of sex-typical behavior. Injections of testosterone to fetal females produced male-like behavior in adults. Subsequently, female rats injected with estrogen also displayed masculine behavior. How could this happen? Testosterone may be converted to estrogen by the aromatase enzyme found in the hypothalamus. In rodents, alpha-feto-protein binds plasma estrogen in female fetuses, preventing exposure of the female brain to maternal estrogen. Testosterone is not bound to alpha-feto-protein in the brain, where it is aromatized into estrogen and masculinizes neural structures (Breedlove, 1992). However, in spotted hyenas where females dominate males and have an extremely enlarged clitoris, infant females have very high levels of androgens although adult females do not exhibit high androgen levels (Van Jaarsveld & Skinner, 1991; Glickman et al., 1992).

Hormonal manipulations in nonhuman primates have used (a) injection of testosterone to females at various stages of fetal development and (b) administration of drugs to block testosterone secretion in males. Injections of testosterone to fetal females masculinized the expression of rough-and-tumble play and double-foot clasp mounts (Goy, 1970; Goy & Resko, 1972). Goy, Bercovitch, and McBrair (1988) used short-term doses of testosterone that did not masculinize genitalia and still reported increases in rough play and mounting behavior. Injections of diethylstilbestrol, a synthetic estrogen that often has masculinizing effects on human females, had little effect on male behavior but had a limited masculinizing effect on female macaques (Goy & Deputte, 1996). Wallen et al. (1995) injected fetal male monkeys with a gonadotropin releasing hormone antagonist to block testosterone secretion and found no effects on male behavior development.

Environment may influence sexual differentiation. Intrauterine position can affect sex-typical behavior and in hamsters females gestating between two male fetuses will give birth themselves to a higher proportion of male offspring than females gestated between two female fetuses (Clark & Galef, 1995). Postnatal social environments are also important. Goldfoot and associates (1984) reared rhesus macaques in isosexual groups and found aspects of behavior typical to each sex within the isosexual groups. In all-female groups, some showed male-like mounting and reduced female-like presenting; the opposite was found in all-male groups. Dimorphic behavior in rhesus macaques can be modulated by social experience and group composition.

In humans there are several hormonal disorders that provide analogs to the experiments with monkeys. Androgen-insensitive males have normal testes that secrete testosterone, but the receptor tissues are insensitive to testosterone. As a result, the internal accessory organs and external genitalia are female. Because the testes and adrenal glands secrete small amounts of estrogen, these

androgen-insensitive males develop breasts and other female secondary sex characteristics at puberty. Generally, they discover they are genetic males only when they fail to menstruate. These genetic males identify themselves as female, suggesting the importance of sexual anatomy on sexual identification. (Breedlove, 1992).

A second disorder occurs when the enzyme needed to convert testosterone to dihydrotestosterone (5-alpha-reductase) is missing. Dihydrotestosterone is needed for the masculinization of external genitalia. A genetic male is born with testes inside the labia and an enlarged clitoris instead of a penis. In the Dominican Republic there is a population where this genetic disorder is relatively common. Children are typically reared as girls, but with the surge of testosterone at puberty leading to secondary sex characteristics, the children start taking on male roles and wearing men's clothes (Imperator-McGinley et al., 1979). The culture appears to support the social transition from girlhood to young manhood.

Fetal females can be exposed to exceptional levels of testosterone through congenital adrenal hyperplasia (CAH) where the adrenal gland lacks the enzyme needed to convert androstenedione to cortisol. Cortisol is not sufficient to stop production of ACTH, and thus the adrenal gland produces high levels of androgens. Some synthetic progestins and estrogens (e.g., diethylstilbestrol, used to sustain pregnancies in women with a history of hormonal insufficiency) also have androgenic effects.

The results are that genitals are often ambiguous at birth, with an enlarged clitoris that may resemble a penis and fused labia that resemble a scrotum. Ehrhardt and Money (1967) described the androgenized girls as becoming more tomboyish and athletic, preferring male playmates and male clothes and preferring career to marriage. But these tomboys of the 1960s sound like ideal feminist girls of the 2000s. More recent work (Berenbaum & Hines, 1992) also reports that girls with CAH prefer to play with male typical toys. Zucker and colleagues (1996) found that women with CAH recalled more cross-gender role behavior and expressed less comfort with their sense of "femininity" than unaffected cousins or sisters of similar age. Adult CAH women had lower rates of heterosexual fantasy and fewer heterosexual relationships. However, there were no differences between CAH women and controls in relationship status or sexual relations with women. Three women lived in a male gender role, two having been reared as boys and one having switched gender role during adolescence.

Meyer-Bahlburg and associates (1996) studied four CAH women who lived as men. Each had masculine childhood gender-role behavior, each was sexually attracted only to females, and each had changed gender gradually. A combination of gender-atypical behavioral image, a gender-atypical body image, and sexual attraction to women was involved in the gender change.

The work on ligand-independent activation and co-activation of nuclear steroid receptors by a variety of

mechanisms including neurotransmitters described above (Auger, 2004) suggests that future research may discover many other mechanisms that influence sex-role determination and gender identity.

In summary, there is no simple role for reproductive hormones in sociosexual development. The social structure of rearing groups, the responses of parents to genital development, and individual difference appear to play important roles. The prenatal hormonal environment predisposes responses by caretakers toward infants and influences development. As Wallen concluded "Social context and biological predispositions are indispensable components in the development of behavioral sex differences" (1996, p. 377).

Influences on puberty and fertility

The social regulation of puberty has been well studied in rodents, where pheromonal control of reproductive maturation is clear (Vandenbergh, 1987). A female mouse exposed to the odor of an adult male reaches puberty sooner than expected, and a young female exposed to the odors of cycling females reaches puberty later than expected. In areas with high population density, female mice reach puberty at a much later age than do mice in low-density populations (Vandenbergh, 1987). Thus the social regulation of puberty has direct effects on regulating population density.

Social regulation of fertility is common in cooperatively breeding mammals, where only one or two females breed while the other females do not (canids, Moehlman & Hofer, 1997; voles, Carter et al., 1986; dwarf mongoose, Creel et al., 1992; naked mole rats, Faulkes & Abbott, 1997, Clarke & Faulkes, 1998; marmosets and tamarins, Snowdon, 1996; French, 1997). We followed the reproductive hormones of 31 postpubertal cotton-top tamarin females housed with mothers in intact families and found no evidence of ovulation (Snowdon, 1996), yet in golden lion tamarins French and Sibley (1987) demonstrated synchronous estrogen cycles between mothers and daughters. In both captive common marmosets (Saltzman et al., 1997) and pygmy marmosets (Carlson et al., 1997), some females ovulate within the natal family but do not become pregnant. Transfer of scents from the mother to a daughter newly paired with a novel male delayed the onset of ovulation compared with control females (Barrett et al., 1990; Savage et al., 1988). Stimulation by a novel male is also important (Widowski et al., 1990). Females removed from their mother and housed with a brother failed to ovulate, but the mere sight, sound, or smell of a novel male induced ovulation (Widowski et al., 1992). Clark and Galef (2001) report reproductive inhibition in female gerbils occurring between sisters but this is accentuated when an older, dominant female is present, so that reproduction is less likely with familiar males compared with novel males. Recent fathers had a higher latency of impregnating young females than other males.

There is little evidence of reproductive suppression in males in marmosets and tamarins (Ginther et al., 2001, 2002), but in spotted hyenas natal adult males had lower testosterone levels than immigrant males whose T levels directly correlated with social rank (Holekamp & Smale, 1998). The mechanism of reproductive inhibition in a cichlid fish is directly related to changes in size of gonadotropin-releasing hormone cells in the brain which become larger as males switch from subordinate to territorial and decrease as males switch from territorial to subordinate (Francis et al., 1993).

Puberty acceleration and delay in rodents, reproductive inhibition in cooperatively breeding mammals and dominance effects on fertility may seem to have little relevance to human reproduction, but social influences do affect human reproductive functioning.

Surbey (1990) found that girls experiencing the absence of father or of both parents prior to menarche reached puberty 4–5 months sooner than girls in biparental families. Family size, birth order, socioeconomic status, body weight, and height were similar between girls in biparental families and girls in father-absent families. Girls with stepfathers matured two months sooner than other girls, supporting the novel-male result with tamarins and gerbils. Mothers and daughters were highly correlated in age of menarche. Maternal age of menarche, years of contact with father, and stressful life events each affected the age of puberty in girls. Gerra et al. (1993) reported lower basal levels of luteinizing hormone in adolescent girls from divorced families compared with girls in intact families. Intense physical training or low body fat can lead to a delay in menarche or to anovulatory cycles in women already past menarche (Frisch, 2002). After exercise stress, girls from divorced families had lower responses of growth hormone and prolactin, suggesting other hormonal disorders in children of single-parent families.

Affiliation, bonding, and courtship

Although sexual behavior and parental care have been well studied, the precursors of courtship and pair bonding have been studied less (however, see Carter, 1998). In many species sexual contact is relatively brief, but in humans (and in many other socially monogamous or cooperatively breeding species) a long-term relationship involving non-conceptive sexual and affiliative behavior is established between mates. Such bonds can be evaluated by several methods: brief separations and reunions to see if affiliation is increased on reunions, intruder challenges when same-sex intruders are presented, and tests to choose between one's mate and another individual. These tests have been used to evaluate a mother-infant bond but less often to study the relationships between adults.

Recently, there has been increased interest in the hormonal correlates of pair bonding and affiliation. Female prairie voles, a monogamous species showing strong pair

bonds, have increased oxytocin levels following the extensive vaginal cervical stimulation resulting from initial mating. After a prolonged mating bout, females form strong partner preferences. Intracerebral injections of oxytocin can facilitate pair-bond formation in female voles, and administration of oxytocin inhibitors can block pair formation (Carter, 1998).

In male voles, vasopressin administration influences partner choice and also leads to increased levels of territory defense and mate guarding. Increased levels of vasopressin may influence parental care in male prairie voles (Wang & Insel, 1996). The distribution of vasopressin receptor sites in the brain differs between monogamous and polygynous species of voles, and parallel differences as a function of breeding system are found in the distribution of oxytocin receptors in female voles (Wang & Insel, 1996). The vasopressin receptor, V1a, can be transferred from a male prairie vole (biparental) to a male meadow vole (promiscuous) inducing male meadow voles to mate for life. These genetically modified meadow voles have dopaminergic motivational circuits activated by vasopressin (Konner, 2004). Dopaminergic neural circuits are known to be active in the cravings expressed in addiction and substance abuse as well, suggesting that social attachment or pair bonds might be considered as a form of addictive disorder (Insel, 2003). However, oxytocin inhibits the development of tolerance to morphine and cocaine and attenuates symptoms of withdrawal (Kovacs et al., 1998). How can oxytocin related attachment be addictive if oxytocin blocks addictions?

Recent studies on both masturbatory and coital sex in men and women have reported an increase in prolactin at the time of orgasm (Exton et al., 2001; Krueger et al., 2003). Prolactin and dopamine have mutual inhibitory influences, and prolactin-releasing peptides can activate oxytocin cells (Zhu & Onaka, 2003). If we view the dopamine system as mediating arousal and the prolactin-oxytocin system as mediating arousal reduction or reward, then prolactin and oxytocin may have their major effects as "reward" hormones in positive social settings that can be conditioned to aspects of the mate (voice, appearance, odor) that serve to form and maintain a pair bond.

Adrenal steroids (corticosterone) are higher in monogamous voles than in polygynous voles (Carter, 1998), and oxytocin reduces levels of adrenal steroids in both rodents and humans (Carter & Altemus, 1997). Thus, one consequence of pair bonding may be reduction of stress hormones (Carter, 1998). Little is known about the hormonal basis of pair bonding in nonhuman and human primates. However, in the monogamous titi monkey, Mendoza and Mason (1997) found that (1) pairs spend much time in physical contact and (2) adrenal hormones rise to very high levels when mates are separated and return to normal levels at pair reunion. Wang et al. (1997) found fibers in the brains of common marmosets – monogamous primates – that had distributions of reactivity to vasopressin and oxytocin similar to those in monogamous voles. Future

research using minimally invasive methods is needed to evaluate the importance of oxytocin and vasopressin on pair bonding in primates.

Sexual behavior and changes over the menstrual cycle

Role of hormones in sexual behavior

Reproductive hormones appear to be important for copulatory behavior in many species. Removal of gonads prior to puberty may produce a failure to express sexual behavior, and removal of gonads after puberty can also reduce or eliminate sexual activity. Yet in primates (both human and nonhuman), sexual arousal and sexual behavior may continue for years after castration. Although testes size decreases and testosterone levels decline in men over 60, men over 80 can be sexually active. Correlations between testosterone and sexual activity are weak (Carter, 1992). Males who are hypogonadal due to Kallman's syndrome (a deficiency of gonadotropin-releasing hormone) have very low testosterone levels and do not experience puberty without hormonal supplementation. They also show low interest in sex, low sexual activity, and few nocturnal erections or emissions. When testosterone is administered, sexual interest does not appear within a year of injections. Although testosterone is not essential for sexual activity or interest, reduced testosterone levels generally correlate with lower sexual activity. Both surgical castration and administration of the antiandrogen-cyproterone acetate (CPA) can reduce sexually directed aggression in male sex offenders (Bradford, 1988) and low rates of recidivism occur after CPA administration. Bradford (1988) argued that consensual adult heterosexual relations are not affected by CPA.

Removal of ovaries or onset of menopause can reduce sexual activity, but the effects may be indirect because estrogen influences vaginal lubrication. In general, little is known about the effects of reproductive steroids on female sexuality (Carter, 1992).

Carter (1992) suggested that oxytocin be considered in studies of sexual behavior. Oxytocin is released during the contractions of the orgasmic response in humans of both sexes and during ejaculation in other species. Steroids, particularly estrogen and testosterone, can modulate oxytocin binding and release in the brain. Stimulation of breasts and other parts of the body during foreplay also releases oxytocin. Oxytocin may play a role in sexual satiation, in sperm transport into the uterus, and in promoting social bond formation in humans as it does in other species (Carter, 1998).

Prolactin may also be important. Prolactin levels increase at orgasm both coitus-induced and masturbation-induced in both men and women (Exton et al., 2001; Krueger et al., 2003). Prolactin is a dopamine antagonist and orgasm-released prolactin may provide a negative feedback loop to dopamine based sexual arousal (Krueger et al., 2002).

Changes in behavior over the ovarian cycle

Females of many species communicate ovulatory status by showing swellings of the genitals (chimpanzees, baboons) or marked changes in behavior (hamsters, rats, cats). However, in most pair-bonded species – including humans – physical or behavioral evidence of ovulation is not evident. This “concealed ovulation” has been described as adaptive for females to co-opt fathers for infant care-taking (Burley, 1979). Traditional theory holds that male mammals will have greatest reproductive success by mating with as many females as possible and deserting them before infants are born. Female mammals with greater parental certainty and the obligatory costs for gestation and lactation are obliged to provide infant care – so long as mothers can successfully rear infants alone (see Snowdon, 1997 for a summary and an alternative view). Biparental and cooperatively breeding species require helpers in addition to mothers to rear infants successfully, and concealed ovulation represents a method to “trick” males into staying long enough to engage in infant care. If the female is continuously receptive to copulation and conceals ovulation, males never know when a female becomes pregnant.

Several lines of evidence counter the idea of concealed ovulation. First, ovulation may be concealed from scientists but not from males of the species involved. In the cotton-top tamarin, Ziegler et al. (1993) transferred odors from ovulating females to recipient pairs each day. On the day of the donor female’s ovulation, her scent induced higher rates of male erection and mounting of his own partner than did the donor female’s scent from the remaining days of her cycle. Converse and colleagues (1995) showed elevated rates of male olfactory interest in females at the time of ovulation in pygmy marmosets. Ovulatory scents from a novel female common marmoset increased both sexual and investigative behaviors and testosterone levels in males in only 30 minutes (Ziegler et al., 2005). These same ovulatory odors induced activation of the anterior hypothalamus and medial preoptic areas as well as the hippocampus, temporal cortex, cerebellum, putamen, and anterior cingulate cortex using functional magnetic resonance imaging of awake conscious marmosets (Ferris et al., 2001, 2004). Cotton-top tamarin males exhibited increased levels of T and DHT during their mates’ follicular phase suggesting some communication of female ovulatory state to prepare males for mating (Ziegler et al., 2004b).

In polygynous (Polygynous meaning one male mates with more than one female, not necessarily that female mates with more than one male which we would call polygamy) species copulations occur throughout the female cycle. However, successful mating depends on whether the female can control or pace sexual behavior. When captive monkeys and apes are paired within a small area, rates of copulation are higher than seen in the wild, and copulation occurs throughout the ovulatory cycle. When females are given control over whether to allow

sexual access by males, copulation rates are much lower and more tightly linked to the time of ovulation (Graham & Nadler, 1990). Wallen (1990) reported lower levels of mating as well as mating more tightly linked to ovulation in large environments, where presumably the female has more control over mating. In rats, female-paced mating behavior differs from that where females cannot control mating (McClintock, 1984).

Female hormonal state is critical for sexual behavior and for social integration of rhesus monkey males into a group. Wallen and Tannenbaum (1997) found that females initiated proximity to males and groomed males only during the time of peak estradiol levels, times when ejaculations were most likely. They introduced ten adolescent males to a group of ovariectomized adult females and found, over a period of 2.5 years, no social interactions between males and females. Females were then injected with estradiol and within two days they were grooming and mating with the males. Affiliation with males remained high even after hormonal therapy was stopped. Tannenbaum and Wallen (1997) subsequently reported that novel males were more easily integrated into a female group during the breeding season (when female estrogen levels are high) than in the nonbreeding season. Elevated estrogen facilitates social interactions and social integration of males into macaque groups.

Wallen (1990) and Pfau (1996) distinguished between desire and ability. The consummatory act of copulation must be carefully distinguished from the appetitive phase, and the appetitive phase must be clearly differentiated according to which partner initiates. Do humans have concealed ovulation and does sexual initiation or enjoyment change with the ovarian cycle? There are several problems have been identified in conducting such studies. Women who were told the purpose of a study – examining changes in sexual behavior over the cycle – reported high levels of arousal shortly before menstruation, whereas those uninformed about the goals of the study reported greater enjoyment close to ovulation (Englander-Golden et al., 1980).

A careful study of human sexual behavior over the ovulatory cycle must: (1) eliminate subjects using oral contraception, because oral contraceptives inhibit the cyclic fluctuations of ovarian hormones; (2) be aware that fear of pregnancy due to contraceptive failure may alter sexual patterns; and (3) distinguish clearly between which partner initiated sex and between initiation and acceptance of copulation. Furthermore, initiation (representing the appetitive or desire phase) must be clearly distinguished from enjoyment (the consummatory phase). Mateo and Rissman (1984) avoided some of these problems by studying lesbians. They found a significant increase in sexual initiations and orgasms by both partners at midcycle, although ovulation was not determined physiologically.

Testosterone may be important in female sexual responses. Morris and associates (1987) reported a mid-cycle increase in testosterone that correlated with the

frequency of sexual initiation. Sherwin, Gelfand, and Brender (1985) studying premenopausal women with ovariectomies – found that administration of testosterone increased sexual desire, arousal, and frequency of sexual fantasies, whereas administration of estrogen and progesterone did not.

Many interesting questions remain concerning the role of reproductive hormones on sexual desire and responsiveness. Careful attention to the conceptual distinctions raised in the animal literature, coupled with use of hormonal assays to determine when ovulation really occurs (rather than simply inferring ovulation from menstruation), is critical for future research on human sexual behavior.

Menstrual synchrony

Menstrual cycle synchrony has been demonstrated in women who are close friends living in a college dormitory (McClintock, 1971). More recent studies have implicated the factors of close bonding or friendship, as well as time spent together, as affecting cycle synchrony (Goldman & Schneider, 1987; Weller & Weller, 1993, 1995).

Looking at menstrual synchrony under optimal conditions, Weller and Weller (1997) studied Bedouin women living in Israel. Bedouin women live together in close proximity and often share sleeping quarters. Society is sexually segregated, with little contact between sexes. Housing conditions are similar across all subjects with little use of oral contraceptives. Under these conditions, menstrual synchrony was found among all women in a family, among sisters who shared the same sleeping quarters, and among those who were close friends. However, no correlation existed between the degree of synchrony and either time spent together or degree of friendship.

McClintock (1971, 1984) suggested that olfactory cues provide the most plausible mechanisms for menstrual synchrony. Axillary secretions from men reduce the variability in menstrual cycle lengths in women. Stern and McClintock (1998) collected axillary secretions from women at different stages of ovulation and placed them above the lips of other women. Odors from women in the luteal phase (post-ovulation) decreased cycle length in recipients whereas odors from women in the follicular phase (pre-ovulatory) increased cycle length in recipients. These results support an olfactory mechanism, for menstrual synchrony.

The effects found even in an optimal study (like that of the Bedouin women) are small: a 20–25% shift toward synchrony from random expectations. Menstruation is easy to document, and it is used as a proxy for ovulation. But because ovulation has not been measured directly and because there is likely to be variation among women in when they ovulate relative to menstruation, the next generation of studies should measure ovulatory rather than menstrual synchrony. Functional explanations for synchrony are based on polygamous mating in species like rats, sheep, other ungulates, and polygynous pri-

mates where females can control mate choice through synchronous ovulation, but these explanations do not seem useful for explaining synchrony within families (Weller & Weller, 1997). Menstrual synchrony in humans remains an intriguing phenomenon in search of a function.

Ovarian hormones and stress

Ovarian hormones modulate physiological responses to stress. Postmenopausal middle-aged women showed heart rate increases during three stress tasks as well as increased systolic blood pressure in one of the tasks (Saab et al., 1989). Pregnant women had reduced diastolic blood pressure in response to serial subtraction, mirror image tracing and isotonic hand-grip tasks compared with their pre-pregnant responses and compared with a nonpregnant control group (Matthews & Rodin, 1992). The increased ovarian hormones of pregnancy and of pre-menopausal compared with postmenopausal women modulate the stress response. However, a study of performance in stress tests over the menstrual cycle found no effects of menstrual cycle on heart rate or blood pressure responses (Stoney et al., 1990).

Parental care

Maternal care

There is an extensive literature on the mechanisms of maternal care in a variety of species (Rosenblatt, 1992; Rosenblatt & Snowdon, 1996). Conceptually, it is important to distinguish between the onset and the maintenance of maternal care. The onset of maternal care appears to be influenced by the hormones of pregnancy and parturition. Thus, progesterone and estrogen are present at high levels through pregnancy and progesterone declines just before parturition, leading to increased levels of prolactin (to prepare the mammary tissue) and oxytocin, which stimulates uterine contractions and the milk letdown response from the nipple. Each of these hormones is involved in controlling the onset of maternal behavior, though the patterns and effects vary greatly across species.

Because estrogen and progesterone levels drop at parturition, maternal behavior must be maintained by stimuli from the infant rather than by any hormonal mechanism. Olfactory, auditory, and visual cues, nipple stimulation, and tactile contact with infants are all important stimuli for maintaining maternal care. Rabbits nurse infants only once a day, but even this brief nursing contact appears essential early in lactation to maintain maternal behavior. In sheep, where infants must follow mothers, oxytocin levels producing uterine contractions at parturition appear critical for forming a bond between mother and infant and facilitating maternal recognition of her infant based on its odors.

Surprisingly little evidence is available on the mechanisms influencing maternal behavior in primates. Pryce and colleagues (1988) showed in red-bellied tamarins that the quality of infant care shown by first-time mothers

was dependent upon the levels of estrogen in late pregnancy. Females showing the normal pattern of elevated estrogen through the end of pregnancy displayed adequate maternal care, but first-time mothers with low levels of estrogen prior to birth had poor maternal care. Mothers with extensive infant care experience demonstrated no effect of estrogen levels in late pregnancy and maternal quality. Ziegler and colleagues (in preparation) found no relationship between maternal hormones late in gestation and infant survival in cotton-top tamarins, but found that estrogen levels predicted the sex ratio of the twins. Pryce, Doebeli, and Martin (1993) treated nulliparous common marmosets with the hormones of late pregnancy (progesterone and estrogen) and found increased motivation toward infant care. Marmosets and tamarins often require experience with caring for someone else's infants in order to be competent parents, but there is still a high level of poor parental care, especially with first-born infants (see Snowdon, 1996 for review).

Pryce (1996) developed a motivational model that integrates social learning, maternal experience, hormonal changes, and infant stimuli as factors in maternal care. Infant stimuli can elicit attraction, aversion, anxiety, and neophobia, with negative motivational states being high in females without prior infant experience. Preadult infant care experience changes the valence of infant stimuli toward more positive motivational states. Hormonal changes in late pregnancy (e.g., high levels of progesterone, estrogen, and prolactin) also lead to increased attraction to infant stimuli coupled with increased anxiety responses to infant crying. With the reinforcement that results from direct contact with infants and with learning which behaviors reduce crying, long-term memories are formed that make a mother less dependent on hormonal stimuli with successive infants.

This model, coupled with cognition about one's own infant, may apply to human mothers (Corter & Fleming, 1990). Pregnancy does not make women more interested in other people's babies, and first-time mothers report less responsiveness to their own fetus – especially early in pregnancy – compared with experienced mothers. Many first-time mothers showed the greatest responsiveness to infant stimuli and learned to discriminate their infant from others within a short period after parturition, suggesting that the hormones of late pregnancy play only an indirect role. Experienced mothers were more responsive to infant cries than first-time mothers, but only after the period of postpartum hormonal changes (Corter & Fleming, 1990). Fleming and associates (1997) found in both longitudinal and cross-sectional studies that feelings of nurturance grew during pregnancy and increased after parturition. The estrogen/progesterone ratio in late pregnancy predicted postpartum attachment. Women with low attachment had higher estrogen/progesterone ratios during weeks 20–35 of pregnancy than did women with high infant attachment, although there were no hormonal differences between these two groups at the end of pregnancy

or postpartum. Both estrogen and progesterone prime prolactin secretion. Fleming (1990) reported a significant positive correlation between cortisol levels and the amount of affectionate interactions with infants. She speculated that cortisol may arouse the mother, making her more attentive to cues from the infant, and that cortisol may lead mothers to recognize infant odors and vocalizations more readily, leading to stronger bonding.

One hormone that logically should be important in maternal behavior is prolactin, but there are few studies of prolactin levels and maternal care in human or nonhuman primates. Fleming (1990) reported that breast-feeding mothers (who should have higher prolactin levels) showed more affection toward infants, left the infants alone less often, and responded more contingently to infants than did mothers who bottle-fed infants. Warren and Shortle (1990) reported an increase in maternal responsiveness correlated with prolactin levels, and they found that prolactin levels in women increased with successive births. Tamarin mothers can control the time of their next ovulation through how they nurse. Mothers who tended to nurse both twins simultaneously ovulated significantly sooner after parturition than mothers who tended to nurse their twins sequentially (Ziegler et al., 1990).

Nonmaternal infant care

In many socially monogamous species, fathers and older siblings play important roles in infant care and often are necessary for the survival of infants (Savage et al., 1997; Snowdon, 1996). Biparental care or cooperative breeding is thought to result when maternal effort alone is not sufficient to rear infants successfully, especially during extreme variations in temperature or food availability. The structure of many human families is socially monogamous, so examination of the mechanisms leading to infant care by nonmaternal group members in socially monogamous birds and mammals has direct relevance to human parental care systems.

Ziegler (2000) reviewed studies on nonmaternal infant care in socially monogamous and cooperatively breeding birds, rodents, and primates, and found several common themes. Prolactin levels are elevated in caregivers, both biological parents and nonreproductive helpers, in cooperatively breeding birds and primates. In female mammals, maternal hormones and stimuli from the infant influence maternal care and prolactin levels, whereas in males stimuli from the pregnant female and from infants appear to be important.

Dixson and George (1982) reported that common marmoset males had elevated prolactin levels when caring for infants. Ziegler et al. (1996b) measured urinary prolactin before and after the birth of infants in male cotton-top tamarins. Fathers had significantly higher prolactin levels than nonfathers, and experienced fathers had higher prolactin levels than first-time fathers or sons who assist in infant care. The number of births a father had experienced and his prolactin levels were highly correlated.

Nursing mothers had postpartum prolactin levels similar to fathers, whereas mothers with miscarriages or infant deaths showed declining prolactin levels by the third week postpartum. Surprisingly, both first-time and experienced fathers had elevated prolactin levels in the weeks before their mates gave birth, suggesting that some communication between mates occurs during pregnancy to prepare males for infant care (Ziegler et al., 1996b; Ziegler, 2000).

Experienced cotton-top tamarin fathers had an elevated prolactin level in the last three months of pregnancy whereas less experienced fathers demonstrated an elevation of prolactin only in the last month before parturition (Ziegler & Snowdon, 2000). Subsequently, Ziegler et al. (2004a) found significant increases of androgens, estrogen, prolactin, and cortisol in the last two months before birth. Males displayed a significant increase in glucocorticoids exactly a week after the onset of glucocorticoid production by the adrenals of the fetus as seen in maternal urinary glucocorticoids, suggesting that fetus communicates to its father through the mother. This response was not consistent in less experienced parents, but less experienced pairs showed increased affiliative behavior in the last month of pregnancy.

In many species there is a reciprocal relationship between testosterone and prolactin (Ziegler, 2000). Males that care for infants have low testosterone levels while prolactin levels are elevated. In black tufted eared marmosets (Nunez et al., 2001) and Mongolian gerbils (Clark & Galef, 1999) testosterone levels are decreased during the time of infant care. However, other studies have found an important role for testosterone in parenting. In the biparental California mouse, Trainor and Marler (2001a) found that castrated males were actually more aggressive and less paternal than gonadally intact males. Trainor and Marler (2001b) found that paternal care was mediated by the reduction of testosterone to estrogen by the aromatase enzyme. When aromatase was blocked, males displayed poor parental care. Fathers had increased aromatase activity in the medial preoptic area, and there was a negative correlation between aromatase and progesterone (Trainor et al., 2003). Ziegler et al. (2000, 2004b) reported high levels of testosterone before and after birth in cotton-top tamarin fathers with an increase in both T and DHT in the five days prior to the mate's post-partum ovulation. In species where males must parent, defend a territory and mate with a female shortly after parturition, prolactin and testosterone are both present and may be equally important.

In human fathers those with lower testosterone and those with higher prolactin responded more to infant cries, but fathers hearing cries showed an increase in testosterone. Experienced fathers showed greater prolactin responsiveness to infant cries than first time fathers (Fleming et al., 2002). In a cross-sectional study fathers three weeks after infant birth had lower T levels than expectant fathers sampled 3 weeks before birth (Storey et al., 2000). In another study (Berg & Wynne-Edwards,

2001) fathers had lower T, lower cortisol and more samples with detectable estrogen than nonfathers. Much remains to be learned about the role of prolactin and testosterone in parental care in men and males of other species.

Aggression and dominance

Aggression and dominance behaviors are commonly thought to be more typical of males than females and thus under the influence of testosterone. However, the importance and role of testosterone in human aggression is controversial. Several typologies distinguish among different functional aspects of aggression, with the broadest distinction being between offensive aggression or dominance (thought to be under the control of testosterone) and defensive aggression (not linked with testosterone).

Albert, Walsh, and Jonik (1993) argued that testosterone is directly involved with offensive aggression in nonhumans, yet after reviewing several hundred studies they concluded that there are no consistent differences in testosterone levels between men who exhibit high versus low aggressiveness. Abnormal states such as hypogonadism or castration in men or hirsutism in females (where testosterone levels may be 200% above normal female levels) show neither increases of offensive aggression with increased testosterone nor decreased aggression with decreased testosterone. Albert et al. (1993) concluded that there are similarities between defensive aggression in humans and that displayed by nonhuman species, where mechanisms other than testosterone appear to be similar across species.

However, studies have rarely been long term. Recent studies covering longer time periods do show effects of hormone levels on aggression. Users of anabolic androgenic steroids showed higher levels of verbal aggression, indirect aggression, and impulsiveness than controls (Galligani et al., 1996). Although this study contradicts Albert et al. (1993), there were no data on these users prior to steroid use. Those likely to use steroids may already be more aggressive and impulsive.

Mazur and Booth (1998) reached the opposite conclusion. They argued that a single measure of testosterone could predict dominant or antisocial aggressive behaviors. The anticipation of competition leads to increases in testosterone, and after competition testosterone increases in winners and decreases in losers. Mazur and Booth (1998) developed a reciprocal model where testosterone levels vary as a function of the cumulative dominance interactions a man experiences along with his history of winning and losing, with testosterone being both a cause and a consequence of dominance interactions. This is an intriguing model that can only be evaluated by longitudinal studies with adequate sample sizes. One longitudinal study of more than 4,000 U. S. Air Force veterans found small, but statistically significant, negative correlations between testosterone and both education and income. Men with higher testosterone levels were more likely to be arrested

for traffic violations and theft. Most interesting was an increase in testosterone just before and after a divorce and a decrease in testosterone with marriage (Mazur & Booth, 1998). Even though the correlations were significant, they were quite low and explained only a small amount of variance.

Stronger evidence comes from research on the “winner-effect” in animals. Hsu and Wolf (1999) tested a hermaphroditic fish where both the last and last but one experience in fighting affected the success in a subsequent contest. A winner effect lasted at least 48 hours. Trainor, Bird, and Marler (2004) injected castrated male California mice with testosterone (T) following an aggressive encounter. Males were more aggressive the following day than control males with the same fighting experience. Blocking the conversion of T to estradiol by injecting an aromatase inhibitor increased the aggression displayed. Oyegbile and Marler (2005) provided California mice with between zero and three winning experiences and found that three prior wins led to increased fighting success independent of intrinsic fighting ability and that winning at least two fights was associated with increased T levels. Thus, T increases the probability of winning and the experience of winning increases the levels of T.

Two sources of evidence question a simple model relating testosterone to offensive aggression. First, several studies of nonhuman species indicate that aggression is influenced by social, environmental, and cognitive variables. Second, there is increasing evidence (with human and non-human species) of dominance and offensive aggression by females that cannot easily be explained by testosterone.

Testing conditions often influence the outcome of contests. Castrated male wood rats fight as vigorously as intact males when tested in neutral arenas (Caldwell et al., 1984); castrated mice with no previous fighting experience do poorly, but males castrated after experiencing fights show normal levels of aggression (Scott & Fredericson, 1951). Wallen (1996) concluded that most aggressive behaviors (with the exception of rough-and-tumble play, which is under androgenic influence) are primarily influenced by social variables. Bester-Meredith and Marler (2001) cross fostered nonaggressive white-footed mice with territorially aggressive California mouse parents. Cross fostered pups displayed levels of territorial aggression similar to foster parents and also had high levels of arginine vasopressin in the bed nucleus of the stria terminalis, as did the California mouse foster parents. California mice are biparental and interestingly, the cross-fostering effects were observed only when fathers were present. Thus, even in nonhuman males, social and environmental variables are at least as important as hormones.

Recent data question the common assumptions about sex differences in offensive aggression. Because it has been assumed that there was little variance in female reproductive success but high variance in male success, offensive aggression was thought to benefit males more than females. In species of cooperatively breeding mam-

mals only one or two females reproduce whereas the remaining females do not. In the golden lion tamarin, two independent studies have found high levels of sex-specific aggression. Male-male aggression was as common as female-female aggression, but the latter was often lethal whereas the former was not (Inglett et al., 1989; Kleiman, 1979). Field studies of a related species, the common marmoset have observed that when reproductive suppression fails and two females give birth at about the same time, one female attacks the offspring of the other often killing the infants (Lazaro-Perea et al., 2000). Because the two females are often related, this means that often a female is killing her nieces and nephews.

De Waal (1982) described sex differences in aggression among chimpanzees. Males frequently engaged in dominance interactions but were readily reconciled after fighting. Females engaged in aggressive interactions much less often, but when they did fight, females were less likely to reconcile and more likely to harm each other. Long-term field data show that dominant female chimpanzees have greater lifetime reproductive success – with more total offspring and with daughters reaching reproductive age earlier than daughters of subordinate females (Pusey et al., 1997). Thus, for marmoset and chimpanzee females, dominance contests are of critical importance. In other species, females are dominant to males (hamsters, Floody, 1983; spotted hyenas, Frank, 1986).

An epidemiological study of human couples found that women were more likely to initiate aggression than men. Magdol et al. (1997) studied all members of the 1972 birth cohort in a city in New Zealand at age 21. Of the women, 37% reported initiating aggression in the home compared with 22% of the men. Severe aggression was initiated by 18.6% of the women but by only 5.7% of the men. Men who committed severe aggression were more likely to be deviant on social and mental health measures, whereas highly aggressive women were psychologically normal. This study contradicts popular beliefs about human aggression. It is unbiased – sampling an entire birth cohort in a population rather than using court or hospital records. The authors explained the results in terms of social norms. Men are reared to avoid being aggressive toward females and know they are more likely to be prosecuted if they do act aggressively. Women have fewer constraints on aggression and will be held less accountable by society. Although this study suggests that aggression is an “equal opportunity” behavior within the home that cannot be explained simply by testosterone, there is little evidence that women are as aggressive as men outside the family. In general, aggressive behavior is most likely the product of social, developmental, environmental, and cognitive variables interacting with hormones.

Hormonal effects on cognition

Much controversy concerns the degree to which there are gender differences in cognition, with meta-analyses of a

large number of studies generally reporting small effect sizes for both verbal ability (Hyde & Linn, 1988) and mathematical ability (Hyde et al., 1990). Nonetheless, there are some specific sex differences where the effects, though small, appear to be consistent (Hampson & Kimura, 1992). Women tend to do better in tests of verbal abilities, perceptual speed and accuracy, and fine motor tasks, whereas males do better on spatial abilities, quantitative abilities, and tests of physical strength. Left-hemisphere brain damage has a more devastating effect on verbal IQ in men than in women, suggesting possible sex differences in lateralization (Hampson & Kimura, 1992). Women performed better on tests of spatial ability at menstruation, when estrogen and progesterone levels are low, compared with performance at the time of ovulation, when hormonal levels are high (Hampson & Kimura, 1992). Verbal tasks that involve reading lists, counting, or repeating syllables tend to show higher levels of performance at ovulation than at other times in the cycle. Hausmann et al. (2000) tested women at menstruation and in the luteal phase and reported significant differences on a mental rotation task but not on other spatial tasks. They measured steroid hormones and found a significant correlation between a woman's T levels and performance on the mental rotation task. McCormick and Teillon (2001) used a mental rotation task with women at different parts of the menstrual cycle and compared them with men. Men performed better than women at all stages of the cycle except at menstruation when there were no performance differences. Liben et al. (2002) experimentally manipulated steroid levels in adolescents being treated for delayed puberty and found sex differences in spatial performance but no relationship between administration of steroids or steroid levels and performance. The sex difference appeared to be independent of steroid levels.

What might account for these differences if steroid levels do not? Kimball (1989) noted that although boys perform better on standardized tests of math ability, girls receive better math grades in school. Either boys have greater experience with math, sex differences in learning styles are involved, or boys do better in novel testing situations than girls. Saucier et al. (2002) studied sex differences in navigational ability and found men did best using Euclidean information whereas women did best using landmark cues and the authors relate this to differences in experience. Finally, Lubinski et al. (2001) in a study of world-class math and science graduate students concluded that there were minimal sex differences and that the development of exceptional scientific expertise requires special educational experiences similar for both sexes.

Studies of variation over the menstrual cycle and in response to administration of steroids test the activational effects of hormones on performance but do not evaluate possible organizational effects. Hines and Sandberg (1996) studied women exposed to diethylstilbestrol during fetal development and found no differences between them and their untreated sisters on measures of verbal fluency, perceptual speed, or associative memory. Wegesin (1998) and

Hall and Kimura (1995) assume that organizational effects underlie homosexuality. Wegesin (1998) reported that gay men performed like heterosexual women on both verbal and spatial tasks, whereas Hall and Kimura (1995) found gay men could not be easily categorized with either heterosexual men or women but that lesbians were more similar to heterosexual men than to any other group. The disparate results and the tenuous causal links between homosexuality and organizing effects suggest caution in interpreting such data.

Estrogen levels influence synaptic connections in the hippocampus, the brain area associated with formation of memory. Sherwin (see Wickelgren 1997) found that women treated with an estrogen blocker to suppress fibroid tumors decreased in verbal intelligence and also found improvement in women treated with estrogen compared with those taking a placebo. A few early trials with Alzheimer's patients showed improvements in verbal memory and attention with estrogen administration (Wickelgren, 1997). Studies of postmenopausal women with or without estrogen replacement therapy have shown that estrogen facilitates verbal memory but has no effect on visuospatial memory (Sherwin, 1997). Resnick and Maki (2001) compared a large sample of women receiving estrogen replacement therapy (ERT) compared with a sample matched for age and education. ERT women had higher visual retention scores, and increased skills in encoding, consolidation and recall on verbal learning tasks than untreated women. Furthermore, women starting ERT during the longitudinal study showed no cognitive decline over years compared with never-treated controls. fMRI measurements found women on ERT had greater blood flow to the hippocampus and mesial temporal lobe structures involved in memory. Together these studies that estrogen may facilitate visual and verbal memory and that ERT might be therapeutic in preventing or delaying the effects of cognitive aging.

INFERENTIAL CONTEXT

Many methods can be used to determine hormone concentrations. Likewise several types of samples can be collected from participants. Any bodily fluid will contain hormones, although not all hormones will be found in every body fluid. Hormones are released from the glands into the circulatory system where they can contact any tissue in the body. Hormones may be measured in blood, saliva, and ventricles of the brain, cerebral spinal fluid, secretions, ejaculates, urine, and feces. Selecting the type of body fluid to collect depends on the nature of the questions to be addressed, the amount of invasiveness that is permissible, the location of the individual (such as in primitive areas or in hospitals), and how frequently samples are needed (daily versus weekly). There are advantages and disadvantages to each type of body fluid used. For example, steroids are very small molecules and therefore can be found in most body fluids. Steroids can diffuse through

cellular membranes and through tight junctions between cells provided they are unconjugated. Protein hormones, however, are much larger molecules that cannot diffuse between cells. Therefore, measurements of protein hormones are limited to blood and urine or in central nervous system fluids where they are released. The advantages and disadvantages of different sources will be described next.

Blood

Advantages. Measurement of hormone levels in the blood of animals and humans has been the most routine method used. Normative blood values for humans are known for most reproductive hormones. Samples can be collected throughout the day if there is a need to understand the changes in circulating hormones. Circulating hormones will show immediate changes in hormones in response to a stimulus, whereas measurements in other media may be delayed relative to timing in the blood. For instance, circulating cortisol will increase within minutes in response to an acute stressor.

Disadvantages. Measurement of circulating hormones requires venipuncture, which may cause pain and stress. Furthermore, blood samples provide information on the level of the hormone only at the time of sample collection, thus not accurately reflecting fluctuations in the blood levels due to pulsatile release or diurnal rhythms. For example, prolactin levels in the blood are known to change within minutes in response to factors such as sleep, exercise, stress and sexual stimulation. A more accurate measure of cortisol responses to social stressors, which influence cortisol changes over time, may best be seen in samples (e.g., urine or feces) that likewise accumulate the steroid over time. In small organisms repeated blood sampling depletes red blood cells, limiting the number of samples possible.

Saliva

Advantages. Saliva samples can be collected noninvasively from humans and from cooperating animals without restraint. Noninvasive sampling eliminates some ethical issues relating to studies directed at various age groups, such as infants and the elderly, and the physically and mentally handicapped. The concentrations of steroids in saliva correlate directly with the free levels of circulating steroids. Samples can be taken daily or more frequently without physical effects on the subject. Circulating steroids appear quickly in saliva.

Disadvantages. Protein hormones generally are not found in saliva, which limits measurement to steroid hormones. Most salivary steroid levels represent the free portion of circulating steroids and not total levels (a proportion of circulating steroids are bound to specific or nonspecific blood proteins and therefore are not available for binding to receptors). Enzymes within the saliva can metabolize

steroids and therefore change their structure and the ability to measure them. Additionally, bacteria within the oral cavity can metabolize the steroids. False high values may occur if a small amount of blood enters the oral cavity due to lesions in the mouth. Conjugated steroids such as DHEAS cannot be measured in saliva because the conjugates will not filter into the saliva. Salivary steroid levels, like single venipuncture sampling, reflect the steroid level present in the blood only at that point in time. For chronic or longer term sampling, multiple salivary samples must be collected, or other bodily fluids must be used.

Urine

Advantages. Steroids, protein hormones, catecholamines, and neuropeptides can be found in the urine. These levels reflect an accumulation over time because hormones are filtered by the kidneys and stored in the bladder until urination. First morning void urine provides a concentrated sample that represents an overnight accumulation. Collection procedures can be performed daily. Indexing with creatinine (a metabolite that is excreted into the urine at a constant rate) can control for variability in urine concentration. Disease-related alterations in hormone metabolism can be monitored in the urine. Steroid hormones are usually found in very high amounts in urine due to the accumulation over time.

Disadvantages. Many hormones may be metabolized by the liver prior to excretion into the urine and therefore the specific metabolites that accurately reflect circulating hormones must be determined. Many steroid hormones are conjugated to glucuronides and sulfates prior to excretion (Ziegler et al., 1989). In this form, the steroids cannot be measured by most antibodies and conjugated molecules must be liberated prior to analysis. Some protein hormones have a short half-life and therefore low levels may appear in the urine. For example prolactin, has a half-life of 12 minutes whereas LH has a half-life of 45 minutes (Yen and Jaffe, 1978). A lag may occur between peak blood levels of a hormone and appearance in urine. Thus, the LH peak found in the blood may be found the following day in the urine.

Feces

Advantages. Feces may be collected freely from free-ranging organisms where close contact is not possible. Steroid levels are found in large amounts in the feces. The fecal excretion of steroids reflects an accumulation over time and therefore adjusts for fluctuations in the hormones throughout the day.

Disadvantages. Most steroids are metabolized into many different steroid metabolites prior to excretion into the feces. The liver conjugates many steroids prior to release into the intestines. Some steroids, such as estradiol, are highly conjugated and may re-circulate before being fully excreted (Ziegler et al., 1996a). No protein hormones,

neuropeptides, or catecholamines can be measured in the feces.

Metabolism of steroids

The measurement of steroids in blood has been thought to be fairly straightforward, and should represent the pure steroids released from the endocrine glands. However, some steroids, such as estradiol and estrone, can be conjugated quickly after release into the circulation and interconvert (Ruoff and Dziuk, 1994). A majority of estradiol can be converted to estrone and its conjugates within 5 minutes of its release (Ruoff and Dziuk, 1994). Therefore, the measurement of pure steroids in circulation may not always assess accurately the total amount of steroid unless one measures conjugated steroids as well. Human females and some primate species, such as common marmosets, have very high levels of estrone sulfate in circulation throughout the ovarian cycle (Nuñez et al., 1977; Harlow et al., 1984).

Steroid metabolites are a result of conversion of circulating steroids in the liver, although the stomach, intestines and some peripheral tissues also can metabolize steroids. The liver filters steroids from the blood and inactivates them by conjugation. Conjugation is the processes by which sulfate esters or glucuronates are attached to the steroid primarily by reduction of the A ring double bond and the 3-keto groups. The addition of sulfate or glucuronide acids makes the steroids water-soluble where they can then be removed from circulation by kidney filtration or released into the intestines by bile. Conjugation can be simple such as monoconjugates or complex such as di- or tri-conjugates consisting of both glucuronides and sulfates. When measuring steroids by an immune reaction as in RIA or EIA, the antibody does not always recognize the steroid in its conjugated form (Hodges and Eastman, 1984).

SUMMARY

Despite a fascination with reproductive processes that dates to antiquity, the modern study of reproductive hormones is barely five decades old. The development of assay methods to detect small amounts of hormones and the determination of hormonal structure and synthesis was needed to advance experimental research. We know that the regulation of hormones in the body is based on an intricate set of positive and negative feedback mechanisms involving multiple brain structures, the pituitary gland as well as peripheral glands. Current research on hormone receptor expression and the role of ligand-independent mechanisms of receptor expression promise an exciting future in understanding physical and behavioral sex differences. Reproductive hormones play an obvious role in sexual differentiation, in the control of puberty, in modulating behavior over the ovarian cycle and controlling courtship and sexual behavior. In a less obvious role

reproductive hormones are critical in preparing mothers for parental care and, in biparental species, including humans, preparing fathers as well. The hormones that function to maintain a parent-infant bond also appear to play an important role in pair bonding between adults. Reproductive hormones may also play an important role in dominance and aggressive behavior and may have some influence on spatial and verbal memory especially in aging. Reproductive hormones also play an important role in regulating immunological reactions and are increasingly being implicated in certain autoimmune disorders. At the same time, we have summarized in this review the important influences of early experience and social environment on hormonal function. Social relationships can affect the timing of menstrual cycles, the onset of puberty, the expression of competent parental behavior, the expression of dominance or aggressive behaviors and the maintenance of cognitive skills. It is the close interaction between social and physical environment and hormonal function that makes research on reproductive hormones exciting not just for endocrinologists, but also for psychophysiolologists. Novel methods for noninvasive monitoring of hormonal function promise an exciting future for research with human participants.

Innate and Cell-Mediated Immunity: Basic Principles and Psychophysiological Influences

FIRDAUS S. DHABHAR

HISTORICAL CONTEXT

Throughout the history of medicine, physicians and philosophers have grappled with the question of whether and how different mental and emotional states affect health. Approximately 4,000 years ago, the *Nei Ching*, an ancient Chinese classic on internal medicine, laid out nine groups of disease-causing agents among which they listed “worry and imagination” (stress) as being able to upset the functioning of the spleen (immune system). Around the second century A.D., the Greek physician Galen observed that melancholic women were more susceptible to breast cancer than those who were sanguine. Closer to our times, there has been a tremendous interest from society and the scientific community in applying the principles and techniques of modern science towards understanding the age-old question of how states of mind might affect states of body and health. Solomon and Moos (1964) coined the term psychoimmunology to describe the field that examines interactions between psychological states and immune function (Solomon & Moos, 1964) and Ader and Cohen (1981) introduced the term psychoneuroimmunology that also represents the neuroendocrine connections between psychological states and immune function (Ader & Cohen, 1981). The history of the field is reviewed in Uchino, Kiecolt-Glaser, & Glaser, 2000. The past few decades have seen a tremendous increase in the number of scientific studies designed to examine how psychophysiology can influence immunology and vice versa (Steinman, 2004). Numerous different dimensions of immune function have been included in these investigations are discussed in excellent comprehensive reviews (e.g., Blalock, 1984; Dantzer & Kelley, 1989; Rabin et al., 1989; Bovbjerg, 1991; Dunn, 1995; Anisman et al., 1996a; Anisman et al., 1996b; Maier & Watkins, 1997; McEwen et al., 1997; Bucala, 1998;

Felten et al., 1998; Heijnen & Kavelaars, 1999; Vedhara, Fox, & Wang 1999; Pruett, 2001; Webster, Tonelli, & Sternberg, 2002; Irwin, 2002; Kiecolt-Glaser et al., 2002; Sanders & Straub, 2002; Straub & Besedovsky, 2003; Kelley, 2004) and books (e.g., Rabin, 1999; Schedlowski & Tewes, 1999; Sternberg, 2000; Ader, Felten, & Cohen, 2001) that have provided an updated integration of the field almost every year for the past two decades. Interestingly, the interactions between psychophysiological and immune factors are not unidirectional but are reciprocal in nature. It has also been shown that changes in immune function can have profound reciprocal psychological, behavioral, and physiological effects (for review see Black 1994; Miller 1998; Dunn 2000; Dantzer 2001; Capuron & Dantzer 2003; Harbuz 2003; Maier & Watkins 2003; Raison & Miller 2003; Straub 2004). Some scientifically based books that are written for a more general audience also make excellent and informative reading: (e.g., Sternberg, 2000; McEwen, 2002; Sapolsky, 2004). This chapter will focus on the mechanisms mediating innate and cell-mediated immunity and discuss relevant issues in the larger context of psychophysiological effects on immune function.

FACTORS MEDIATING INNATE & CELL-MEDIATED IMMUNITY

The major cellular and molecular components that make up innate and cell-mediated immune responses are discussed in the following sections. The reader is encouraged to keep in mind that each of the parameters discussed in the following sections can be measured and many of these parameters can be measured in peripheral blood, which is the most accessible and widely used compartment for studies involving human subjects. The interpretation of information obtained from such measurements depends on many factors such as the context, compartment, time point, and manner in which these measurements are made. These factors will be discussed later in this chapter.

Preparation of this chapter was supported by grants from the National Institutes of Health (AI48995) and The Dana Foundation Clinical Hypotheses Program in Mind Body Medicine.

INNATE IMMUNITY

Innate immunity is also known as native or natural immunity because components of the innate immune system are always present and ready to defend the organism (Abbas, Lichtman, & Pober, 2000; Roitt, Brostoff, & Male, 2001). Although innate immunity is sometimes considered primarily reactive against microbial pathogens, components of the innate immune system can also be involved in foreign antigen/body reactions and immunopathological reactions to self tissue. Innate immunity constitutes an effective mechanism for responding to and often eliminating pathogens early during an immune response. Therefore, components of innate immunity form the body's first line of defense and elements of the innate immune system can be activated within minutes of an immunological challenge. Components of the innate immune system include the following players:

Epithelial barriers. The only interfaces through which pathogens can enter the body are the skin, and the gastrointestinal, respiratory, and urinary genital tracts. Each of these interfaces has a specialized layer of continuous epithelial cells and associated mucosal tissues that form formidable innate defenses. In addition to acting as physical barriers, epithelial cells secrete and are covered by a host of anti-microbial peptides and enzymes that also confer protection. Each specialized epithelial barrier also has a host of other cellular components. For example, keratinocytes, mast cells and intra-epithelial or $\gamma\delta$ -T cells are all present in skin and have important functions in host defense.

The complement system. The complement system is an important humoral component of innate immunity. It consists of critical circulating and membrane bound proteins that once triggered, participate in self-driven anti-microbial cascades. The complement cascade can be triggered by three major pathways: The classical pathway involves activation by antibodies bound on the microbial surface and as such is an example of the often-observed interplay between the innate and adaptive immune systems (discussed further in the [following section](#)). The alternative pathway is launched when specific complement proteins directly bind the microbial surface in the absence of counter-regulatory proteins (that are present to protect host cells). The lectin pathway is triggered when mannose-binding lectin (MBL, that is present in plasma) binds terminal mannose residues on microbial surface glycoproteins. Once activated, complement-mediated microbe destruction involves punching osmotic holes into the microbial surface, opsonization of the microbe by complement factor C3b which facilitates removal by phagocytes that express C3b receptors, and chemoattraction, activation, and targeting of additional leukocytes to the site of microbial invasion.

Neutrophils & macrophages. Neutrophils and macrophages form the critical cellular phagocytic component of innate immunity. They arise from progenitor stem cells within the bone marrow that are of the myeloid lineage. The production of these leukocyte subpopulations is controlled by cytokines that are known as colony stimulating factors like IL-1, IL-3, IL7, and granulocyte macrophage colony stimulating factor (GMCSF). Circulating macrophages are known as monocytes. Monocytes mature into macrophages when they leave the circulation to enter tissues where they may undergo further activation and differentiation.

Neutrophils are among the first cells to enter tissue from the circulation following immune activation. They are critical for defense against bacterial and fungal infections and for the initial phases of wound healing. Although they are present in high proportions particularly in human blood, neutrophils have a short half-life and may die within hours after extravasating into tissues. Controlled neutrophil death occurs via the process of apoptosis although necrotic cell death is also observed during immunopathology. Neutrophils eliminate pathogens via phagocytosis followed by internal enzymatic destruction.

Macrophages closely follow neutrophils into sites of immune activation. They phagocytose and destroy antigens, pathogens, dead neutrophils, and damaged cells and tissues. In addition to phagocytosis, macrophages perform important functions like antigen presentation to T cells and therefore form a critical nexus between the innate and the adaptive immune systems. Macrophages are different from neutrophils in that they are capable of long-term survival after extravasation. In addition to macrophages that are recruited as monocytes from the blood, there are resident macrophages that are stationed in most tissues of the body. Macrophage differentiation can lead to the formation of specialized tissue specific forms like microglia in the CNS, Kupffer cells in liver, alveolar macrophages in lung, and osteoclasts in bone.

Neutrophils and macrophages have receptors that enable them to recognize microbes and specific microbial products. These receptors are thought to enable phagocytes to distinguish pathogens from self-antigens because they recognize molecules that are specific to microbes and generally not expressed by healthy self-tissue. Such receptors include mannose receptors that bind terminal mannose residues on microbial surface glycoproteins, N-formyl methionine peptide (FMLP) receptors, and receptors that specifically recognize acetylated low density lipoproteins specific for certain pathogens. In addition, macrophages bear toll-like receptors (TLRs) that are specific for certain fungi and gram negative and gram positive bacteria. These receptors are so named because they are homologous to the Toll protein which is critical for protecting *Drosophila* from microbial pathogens. These cells may also express receptors for other microbe-specific products such as unmethylated bacterial DNA and double stranded

viral RNA. In addition to an array of receptor mechanisms serving the innate immune functions performed by neutrophils and macrophages, these phagocytic cells also bear receptors that enable them to harness complement (complement receptors) and antibody (Fc receptors) mediated protective mechanisms.

The process of phagocytosis involves capturing extracellular pathogens into intracellular phagosomes. The phagocyte does this by extending a portion of its cell membrane all the way around the pathogen(s) until the membrane closes up and pinches off into the cytoplasm of the phagocyte. Phagosomes then combine with cytoplasmic lysosomes to form phagolysosomes. Pathogens are killed within phagolysosomes by several mechanisms which include the activation of anti-microbial systems consisting of lysosomal proteases, phagocyte oxidase which generates superoxide anions and free radicals, and inducible nitric oxide synthase, which generates NO, all of which have potent microbicidal effects.

Therefore, neutrophils and monocytes are extremely important cells of the innate immune system because they have the ability to recognize, phagocytose, and internally destroy an array of pathogens.

NK cells. NK cells are derived from lymphoid progenitor stem cells in the bone marrow, but do not express antigen-specific receptors that are seen on T and B cells. They form an important component of the innate immune system. They are not phagocytic cells, but kill cells that are infected by intracellular pathogens via lytic mechanisms which involve punching holes in the plasma membrane with the help of proteins like perforin followed by introducing other molecules into the target cell that activate enzymes that induce apoptosis of the infected cell. NK cells also secrete IFN- γ , that is a critical cytokine for macrophage activation. Interestingly, macrophages in turn produce cytokines like IL-12 which are potent activators of NK cells.

NK cells are thought to recognize infected cells through receptors for specific molecules that are only expressed on cells carrying intracellular pathogens. NK cells also express Fc receptors which enable them to play a role in antibody-dependent cytotoxicity. Another class of NK cell surface receptors is the family of killer inhibitory receptors which prevent NK cells from destroying self tissue. Killer inhibitory receptors recognize molecules like MHC I which is present on all healthy nucleated cells of the body. MHC I recognition prevents further NK activity. However, many microbes have evolved to induce cells to stop expressing MHC I after they are infected. This gives the pathogen a survival advantage by preventing recognition and elimination of the infected cell by cytolytic T cells (CTL). However, infected cells are now recognized by NK cells because they no longer express MHC I and thus fail to activate killer inhibitory receptors and this facilitates their elimination by NK cells.

Primary cytokines of innate immunity. Macrophages, NK cells, and other leukocytes of innate immunity secrete cytokines upon stimulation. These cytokines often act on the cells that produce them (autocrine effects) and on other target cells that may be adjacent (paracrine effects) or at a distance (endocrine effects). It is important to appreciate that many cytokines are secreted by different types of leukocytes and act on different target cells and therefore may be involved in mediating aspects of innate as well as adaptive immunity. TNF- α and IL-1 are perhaps the most important cytokine drivers of innate immunity. They recruit and activate neutrophils, macrophages and other leukocytes to the site of an innate immune reaction.

The principal cellular sources of TNF- α are macrophages and T cells. TNF α can exert a variety of effects on numerous different cells and tissues which include activation of endothelial cells and promotion of inflammatory and hemostatic cascades, neutrophil activation, fever production through central nervous system actions, stimulation of acute phase protein synthesis and secretion by the liver, breakdown of muscle and adipose tissue (cachexia), and stimulation of apoptosis of different cell types. Excess of TNF- α can also lead to clinically important and devastating effects. For example, TNF- α mediates toxic shock that occurs when macrophages produce systemically high levels of TNF- α , following activation of their lipopolysaccharide (LPS) receptors by endotoxin (LPS) released from severe gram negative bacterial infections. Metabolic dysregulation, widespread intravascular coagulation and low blood pressure are hallmarks of toxic shock and are the result of high systemic levels of TNF- α .

The principal cellular sources of IL-1 are macrophages, keratinocytes, endothelial cells and some epithelial cells. IL-1 also activates endothelial cells, generates fever, and stimulates hepatic synthesis of acute phase proteins and can exert immuno-protective as well as immuno-pathological effects. In addition to these two cytokines, other components of the innate immune system like NK cells produce IFN- γ that is also produced by T cells and is a potent activator of macrophage function and also stimulates some classes of antibody responses. IFN- α and IFN- β that are critical for anti-viral immunity, are also produced by macrophages and other cells of the innate immune system. Other cytokines that are traditionally thought of as being mediators of adaptive immunity (e.g., IL-6, IL-10, IL-12, IL-15, and IL-18) are also secreted by macrophages in addition to T cells and act on various components of the innate immune system.

Acute phase proteins. Acute phase proteins are a family of proteins whose circulating levels increase sharply after infection. Plasma mannose-binding lectin (MBL) and C-reactive protein (CRP) are examples of acute phase proteins that also represent humoral components of innate immunity. MBL plays critical role by coating microbes

through binding terminal mannose residues on microbial surface glycoproteins this enables microbial elimination via activating the complement system and by promoting phagocytosis. CRP similarly binds phosphorylcholine on the microbial surface and also promotes phagocytosis of coated microbes via binding the macrophage CRP receptor.

Innate immunity summary. The innate immune system is critical for rapid elimination of pathogens and are often the only line of available defense in case of primary encounters with pathogens to which the immune system has not been previously exposed. Specific responses to different types of microbial pathogens vary and are evolutionarily selected to best protect against these microbes. In general, extracellular pathogens are eliminated by the acute phase and complement systems and phagocytes. Intracellular pathogens are eliminated by NK cells and phagocytes. Components of the innate immune system are not only the body's first defenders, but also play the crucial role of activating the adaptive immune system (e.g., antigen presentation and activation of helper T cells by macrophages) and forming a crucial part of the effector mechanisms that are enlisted by an adaptive immune response (e.g., antibody-dependent cell-mediated cytotoxicity, Th1 cytokine stimulated activation of macrophage phagocytosis). Cytokines provide the critical links in communication between the cellular components of innate and adaptive immunity.

CELL-MEDIATED IMMUNITY (CMI)

CMI represents one arm of the adaptive immune system; the other arm being humoral immunity that is discussed in Chapter 16 (Humoral Immunity, V. Sanders). Traditionally, CMI reactions were defined as antigen-specific reactions that could be transferred from one organism to another only by the transfer of cells (later identified as T cells) and not by antibodies (Abbas et al., 2000; Roitt et al., 2001). Immune reactions orchestrated by helper T (Th) cells and effected by cytolytic T cells (CTLs), macrophages, and NK cells are known as CMI reactions. CMI reactions are critical for eliminating infections by intracellular pathogens because antibodies that mediate humoral immunity are ineffective for intracellular pathogens. Antigen specificity of these reactions is conferred by T cells whereas macrophages are among the most important effector cells either as directly activated phagocytes or as the cells that ultimately clear up CTL and NK cell-mediated destruction.

Antigen presenting cell and T cell interactions. Extracellular pathogens that are specifically phagocytosed by APCs and processed within vesicles are presented by MHC II molecules. Intracellular pathogens that are present in the cytoplasm are processed into peptides that are presented by MHC I molecules. APCs that present antigen in conjunction with MHC II molecules are also known as pro-

fessional APCs. T cell activation occurs following specific cascades of interactions between the T cell and antigen presenting cell (APC) which involve antigen recognition in the context of MHC molecule presentation, cell-cell adhesion, and co-stimulation: (1) The T cell receptor complex interacts with MHC molecules on the APC to recognize antigen for which they are specific. (2) Integrins like LFA-1 on the T cell interact with ICAM-1 on the APC to stabilize cell-cell interactions that are crucial for T cell activation. (3) Co-stimulatory molecules like CD28 on T cells interact with B7-1 and B7-2 on APCs, and CD40L (CD154) on T cells interacts with CD40 on APCs to provide additional signals that are required for effective T cell activation.

Naïve, effector, & memory T cells. CMI involves antigen recognition by naïve and memory T cells at two largely distinct locations. Naïve T cells form within the thymus and are released into the circulation following positive and negative selection processes. Naïve T cells are activated when they encounter and recognize specific antigen in sentinel lymph nodes. Upon activation, naïve T cells proliferate and differentiate into effector and memory T cells. Effector T cells are responsible for elimination of pathogen whereas memory T cells are long-lived cells that are critical for mounting faster and more robust immune responses upon subsequent exposure to the same antigen. Once differentiated in sentinel lymph nodes, effector T cells can recognize the same antigen if detected anywhere in the body. These cells are again activated upon recognizing antigen under the appropriate antigen-presenting conditions. Activation of effector cells at sites of infection results in changes in phenotype that retain these cells at those sites. Cytokines, chemokines, and adhesion molecule cascades play a critical role in attracting, activating, and retaining antigen-specific effector T cells at sites of pathogen entry.

The adhesion molecule repertoire on the plasma membrane is particularly suited to maximize the probability that T cells in their different stages of differentiation will be exposed to antigen under the appropriate conditions. Therefore, naïve T cells express CD62L which enables them to attach to high endothelial venules within lymph nodes and increases the probability of their encountering APCs that may have trafficked to sentinel nodes following antigen entry. Activated effector and memory T cells on the other hand express ligands for E and P selectin which enable leukocyte rolling on activated endothelium and facilitate migration into tertiary immune tissues (skin, gut, etc.) that are often the sites of infection by intracellular pathogens. Effector and memory T cells also show increased expression of lymphocyte function-associated antigen-1 (LFA-1 a $\beta 2$ integrin) and very late activation antigen-4 (VLA-4, a $\beta 1$ integrin) which enable stronger adhesion to activated endothelium and transmigration into sites of infection. If an effector T cell encounters specific antigen, the cell is further activated at the tertiary site and retained at that site to stimulate or execute pathogen clearance. Effector cells that do not encounter specific

antigen exit tissues through lymphatic vessels and re-enter the circulation. Memory T cells persist for long periods of time and constantly patrol tissues following surveillance trafficking patterns designed to maximize the probability of encounter with specific antigens for which they have memory.

Effector responses of CMI. Effector CMI responses can be divided into two broad categories: CD4+ Th cells activate phagocytes to destroy ingested pathogens that are contained within vesicles and CD8+ CTLs destroy all cells (phagocytic and nonphagocytic) that harbor cytoplasmic pathogens that are not contained within vesicles. This distinction is useful and important but not absolute as some CD4 T cells kill infected phagocytes and some CD8 T cells can activate phagocytes for destruction of pathogens within phagolysosomes.

Macrophage effector function. Upon recognition of antigens presented by macrophage MHC II molecules, effector CD4 T cells secrete Th1 cytokines like IFN- γ and stimulate CD40L-CD40 interactions that activate macrophages. Macrophage activation results in the production of transcription factors that in turn activate gene expression of nitric oxide synthase, proteases, and enzymes that generate reactive oxygen species all of which exert potent antimicrobial effects that were discussed earlier under “innate immunity.” The requirement for activation by IFN- γ in addition to CD40L-CD40 interactions ensures that macrophages that are in close proximity to the Th cell (those that contain and are therefore able to present antigen) are mainly the ones that are activated. T cell stimulated macrophage effector function is especially important in cases where microbes have evolved to escape destruction in phagolysosomes and where additional T cell help enables macrophages to effectively eliminate such pathogens. In addition to eliminating pathogens, activated macrophages play several other important roles in CMI. They secrete cytokines like TNF- α and IL-1 and chemokines which activate endothelial cells and recruit additional leukocytes to the site of the CMI reaction. Macrophages are also critical for the clearance of apoptotic cells (e.g., neutrophils) and debris and hence pave the way for the resolution of inflammation.

CTL effector function. CD8+ cytolytic T cells (CTLs) are thus named because they kill infected cells and certain types of tumor cells by lysing as opposed to phagocytosing them. The classical method of CTL activation involves these cells recognizing antigen being presented in the context of MHC I molecules on the plasma membrane of an infected cell. CTLs can be activated by infected cells that present the antigen for which the CTL bears specificity. This specificity is expressed through the CTL T cell receptor. Adhesion molecules present on the CTL surface and interact with ligands (and vice versa) on the infected cell's plasma membrane and stabilize interactions between the

two cells. This enables the CTL to be activated and also enables the cell to go on to perform its effector function which is to lyse the infected target cell.

A single CTL can successively kill many infected or target cells one after the other. Target cell lysis is accomplished by directed exocytosis of the CTLs granule contents at the site of closest approximation with its target cell. The products that are exocytosed consist of perforin which gets polymerized and embedded within the target cell plasma membrane to form pores through the membrane, and enzymes that induce DNA fragmentation and target cell apoptosis which travel into the target cell through perforin channels. CTL granule enzymes are called granzymes. Upon entry into the target cell, granzymes activate target cell caspases which then induce controlled cell death or apoptosis of the target cell. Fas ligand which is expressed by activated CTLs is thought to induce target cell apoptosis by activating target cell Fas (CD95) in some instances.

Importantly, phagocytes play an crucial role following CTL effector actions because it is these cells that ultimately clear up damaged and dead infected target cells that have been destroyed by CTL action. CTLs secrete IFN- γ at sites of activation. This further activates macrophages at sites of immune activation and enables them to more effectively process and destroy phagocytosed pathogens.

Cytokine regulators of cell-mediated immunity. Several different cytokines play important and specific roles in regulating different aspects of CMI. These functions are briefly described here. IL-12 is secreted by macrophages and professional APCs like dendritic cells. IL-12 is one of the most important initial drivers of CMI because it stimulates the differentiation of naïve Th cells to activated effector Th1 cells. It also stimulates both Th cells and CTLs to secrete IFN- γ , that as discussed earlier, is a potent macrophage activator and therefore a critical driver of the effector phase of CMI. IL-2 is produced by T cells. It promotes clonal expansion of antigen-activated T cells because it is a powerful autocrine T cell growth factor. TNF- α is secreted by macrophages and T cells at the site of antigen or pathogen detection. TNF- α is a potent initiator of the inflammatory cascade that launches the effector phase of CMI. It acts on endothelial cells to activate adhesion molecules which help recruit circulating leukocytes to the site of immune activation. TNF- α also helps activate leukocytes that are thus recruited to the site of immune activation. Thus, the prototypical Th1 cytokines, IL-12, IL-2, and IFN- γ play are crucial cytokine drives of CMI. In contrast, the Th2 cytokines, IL-4, IL-13, and IL-10 are important counter-regulatory factors that are thought to dampen CMI responses by inhibiting macrophage and Th1 cell activation and function. In contrast to Th1 cytokines that promote CMI, Th2 cytokines promote humoral immunity.

CMI reactions and the delayed type hypersensitivity (DTH) skin test. The CMI reactions described above can be

modeled and measured by an *in vivo* immunological assay known as the DTH skin test. In this case, CMI reactions are elicited by injecting minute quantities of antigen into the skin of individuals to be tested. Healthy individuals who have been previously immunized or exposed to the antigen generally develop a positive immune response that is manifest as an increase in erythema and induration at the site of antigen injection. The name “Delayed Type Hypersensitivity” comes from the fact that it takes 24 to 48 hours for circulating antigen-specific T cells to be recruited to the site of antigen administration, to be activated, and to subsequently activate effector cells that mediate the CMI reactions that result in detectable signs of a DTH response. The magnitude of erythema can be subjectively graded and the diameters of the area of induration recorded in millimeters. DTH is an example of Type IV hypersensitivity and involves a longer time course (24–48 h) for development of a detectable immune response compared to those seen with Type I (within minutes) or Types II and III (5–12 h) hypersensitivity reactions. DTH tests may be used clinically to gauge whether an individual has been previously exposed to an antigen or pathogen (e.g., the tuberculin skin test that tests for prior exposure to mycobacterium tuberculosis). DTH tests may also be used to examine whether an individual has developed effective immunity following vaccination. Such tests have been used to elucidate the extent of immunodeficiency (e.g., AIDS patients may progressively lose their ability to mount DTH reactions to commonly encountered antigens which may indicate a progressive loss of immunity to certain pathogens) (Birx et al., 1993).

Immune responses work in synchrony *in vivo*. It is helpful to categorize different aspects of the immune system into different categories such as innate versus adaptive, Th1 versus Th2 and so on. However, it is extremely important to bear in mind that most components of the immune system participate in most *in vivo* immune responses. Therefore, any given immune response will consist of cellular and molecular components of innate and adaptive immunity and Th1 as well as Th2 cellular and cytokine driver and regulatory systems. For example, some reactions, such as CMI reactions, are categorized as being an example of adaptive immunity. They consist more of CTL and macrophage driven responses that are predominantly stimulated by the Th1 family of cytokines. Other responses involve a greater contribution from B cell driven antibody or humoral responses and are stimulated by the Th2 family of cytokines. However, as discussed earlier, Th1 and Th2 cytokines play important counter-regulatory roles in most adaptive immune responses, and importantly, neutrophils, macrophages and NK cells, of the “innate” immune system often serve as critical effector cells for cellular and humoral immune responses.

Importance of leukocyte distribution & trafficking. The appropriate distribution of immune cells between organs

in the body is crucial for the performance of the surveillance as well as effector functions of the immune system and is critical for supporting all types of immune responses. Rapid leukocyte trafficking into sites of immune activation is critical for effective immunoprotection (Sprent & Tough, 1994). Rapid and targeted leukocyte distribution also enables different components of the immune system to work together as discussed in the preceding section. The blood is an important conduit by which leukocytes travel from one body compartment to another and the blood is also perhaps the most important compartment that is sampled and studied especially for neuro-endocrine-immune studies involving human subjects. Therefore, it is important to understand the basic processes by which leukocytes traffic from body compartment to another.

Leukocytes travel from one area of the body to another by a combination of passive as well as active processes. Blood flow passively carries leukocytes throughout the circulatory system. Active processes triggered by cytokines and chemokines and mediated by changes in adhesion molecule expression or affinity, selectively retain specific leukocyte subpopulations at sites of immune activation. These active processes involve cascades of interactions between families of adhesion molecules and their ligands that may be present either on leukocytes or endothelial cells. The selectin family of adhesion molecules, consisting of L-selectin (CD62L), E-selectin (CD62E), and P-selectin (CD62P) and their respective ligands, are responsible for slowing leukocytes down by inducing leukocyte rolling on high endothelial venules within lymph node vasculature (CD62L) or on activated endothelial cells (CD62E and CD62P). Chemokines released by leukocytes, endothelial cells, and other cells at the site of immune activation are captured and presented by glycosaminoglycans on endothelial cells and they activate rolling leukocytes which begin to activate their cell surface integrins. Leukocyte surface integrins (e.g., CD18, CD11b) interact with endothelial ICAMs (e.g., CD54) to form stronger bonds that arrest leukocytes on the activated endothelium. Further activation cascades of integrins, ICAMS, and their respective ligands enable the activated leukocyte to transmigrate to leave the lumen of the blood vessel and enter extravascular tissue. Enzymes like matrix metalloproteases (MMPs) enable leukocytes to make their way through extracellular matrix to reach the site of immune activation.

PSYCHOPHYSIOLOGICAL INFLUENCES ON IMMUNE FUNCTION

Although it was traditionally thought that the immune system functioned largely autonomously from other physiological systems, a large body of evidence now shows that psychological and physiological factors can influence different immune parameters (For review see Ader et al., 2001). Solomon and Moos (1964) coined the term psychoimmunology to describe the field that examines

interactions between psychological states and immune function (Solomon & Moos, 1964) and Ader and Cohen (1981) introduced the term psychoneuroimmunology that also represents the neuroendocrine connections between psychological states and immune function (Ader & Cohen, 1981).

Several key scientific findings have provided convincing and intriguing evidence for the number of molecular, cellular, and systems level pathways through which psychophysiology can influence the immune system. These findings and selected references and reviews describing them, are listed in the following section.

Immune cells and organs bear receptors for hormones and neurotransmitters and respond to ligands for these receptors. Such ligand-receptor effects (Weigent & Blalock, 1987) include those reported for catecholamines (Benschop et al., 1993; Madden & Felten, 1995; Heijnen and Kavelaars, 1999; Rouppe van der Voort, et al., 1999; Rouppe van der Voort et al., 2000; Sanders and Straub, 2002), glucocorticoids (Munck, Crabtree, & Smith, 1979; Miller et al., 1990; Munck & Naray-Fejes-Toth, 1992; Dhabhar et al., 1996; McEwen et al., 1997), opioid peptides (Faith et al., 1984; Weber & Pert, 1989; Adler et al., 1993; Carr et al., 1995; Carr, Rogers, & Weber, 1996; Jessop, 1998), growth hormone (Arkins, Dantzer, & Kelley, 1993; Malarkey et al., 2002), melatonin (Maestroni & Conti, 1996), leptin (La cava & Mataresse, 2004), calcitonin gene-related peptide (Asahina et al., 1995; Bulloch et al., 1995), neurotrophic factors (Torii et al., 1997), vasoactive intestinal peptide (Bellinger et al., 1996), neuropeptide Y (Jessop et al., 1992; Lambert & Granstein, 1998; Straub et al., 2000), prolactin (Arkins et al., 1993; Berczi, 1997; Clevenger, Freier, & Kline, 1998), oxytocin and vasopressin (Geenen et al., 1989), and androgens and estrogens (Draca, 1995; Da Silva, 1999; Ben-Eliyahu et al., 2000; Cutolo et al., 2004; Obendorf & Patchev, 2004).

Immune cells and organs have also been shown to synthesize various hormones and neurotransmitters that were traditionally thought to be the "property" of the nervous and endocrine systems (Jessop, 2002). Examples include proopiomelanocortin (POMC) peptides (Blalock, Harbour-McMenamin, & Smith, 1985; Jessop, Jukes, & Lightman, 1994; Blalock, 1999), adrenocortotropic hormone (ACTH) (Jessop et al., 1995), endomorphins (Jessop et al., 2000), prolactin (Sabharwal et al., 1992), corticotrophin releasing factor (CRF) (Stephanou et al., 1990), corticosteroids (Vacchio, Papadopoulos, & Ashwell, 1994; Vacchio, Lee, & Ashwell 1999), and vasopressin (Jessop et al., 1995; Jessop, Murphy, & Larsen, 1995).

Elements of the nervous and endocrine systems have been shown to produce factors that were traditionally thought to belong exclusively to the immune system. For example, the pituitary has been shown to produce macrophage migration inhibition factor (MIF) that acts as an impor-

tant glucocorticoid counter-regulator (Bucala, 1998) and IL-18 has been shown to be produced by the adrenal cortex (Conti et al., 2000).

Different branches of the nervous system innervate specific immune organs. These innervations include those emanating from the sympathetic nervous system (Felten et al., 1987; Felten, 1993; Felten et al., 1993), the autonomic nervous system (Bulloch & Pomerantz, 1984; Tracey, 2002; Pavlov & Tracey, 2004), and from peptidergic nerves (Romano et al., 1991; Asahina et al., 1995; Kodali et al., 2004). Recently, the concept of the immunological reflex has been proposed that suggests that the nervous system, through cholinergic neurons may dampen immune responses as they occur (Tracey, 2002).

Immune responses can be behaviorally conditioned. A fundamental finding that in many ways launched modern field of psychoneuroimmunology came from seminal studies by Ader and Cohen (1975) that showed that immune responses can be behaviorally conditioned (Ader & Cohen, 1975; Bovbjerg, Ader, & Cohen, 1982; Ader & Cohen, 1991). In addition to showing the critical and intriguing link between the nervous and immune systems these conditioning studies have significant clinical implications for example for regulating the course of autoimmune diseases (Ader and Cohen, 1991). Importantly, conditioning studies have also been extended to human subjects which shows the significant clinical potential of behaviorally conditioning immune responses (Buske-Kirschbaum et al., 1992; Buske-Kirschbaum et al., 1994; Goebel et al., 2002).

Psychophysiological stressors affect immune function. The effects of stress on different parameters and aspects of immune function is perhaps the most widely studied connection between psychophysiological changes and immune function. Numerous groups of investigators have investigated this connection from different angles. The following reviews examine different aspects of the effects of stress on immune function (Zwilling, 1992; Herbert & Cohen, 1993; McEwen et al., 1997; Sheridan, 1998; Kiecolt-Glaser, 1999; Yang & Glaser, 2002; Cohen & Hamrick, 2003; Sephton & Spiegel, 2003; Hawkley & Cacioppo, 2004; Glaser, 2005). Specific examples include demonstrated relationships between stress reactivity and changes in immune parameters (Benschop et al., 1998; Cacioppo et al., 2002), chronic stress-induced suppression of wound healing (Kiecolt-Glaser et al., 2004), stress-induced suppression of recovery from surgery (Kiecolt-Glaser et al., 1998), chronic stress and susceptibility to infection (Glaser et al., 1987; Bonneau et al., 1991; Cohen, Tyrrell, & Smith, 1991; Sheridan et al., 1991; Bonneau, 1996; Cole & Kemeny, 1997; Sheridan et al., 1998; Sheridan et al., 2000; Buske-Kirschbaum et al., 2001), chronic stress-induced suppression of vaccine uptake (Kiecolt-Glaser et al., 1996; Glaser et al., 1998; Glaser et al., 2000), and the suggested

relationships between stress and cancer susceptibility (Shavit et al., 1985; Brenner et al., 1990; Ben-Eliyahu et al., 1991; Bryla, 1996; Andersen et al., 1998; Kiecolt-Glaser & Glaser 1999; Ben-Eliyahu, 2003; Lutgendorf et al., 2003; Pereira et al., 2003).

Exercise has also been shown to affect different immune parameters through physiological systems that are similar to those activated during stress (Pedersen & Hoffman-Goetz, 2000). In a recent paper, Epel et al. (2004) have shown that chronic perceived stress is correlated with accelerated telomere shortening in peripheral blood leukocytes (Epel et al., 2004). At first pass, a plausible explanation for such telomere shortening in immune cells was that the chronically stressed subjects may have experienced more infections. As a result, their immune cells may have been more activated by greater numbers of immune challenges, and may have gone through significantly higher numbers of cell divisions resulting in shorter telomeres. However, the relationship between stress and telomere shortening does not appear to be related to greater numbers of immune activating challenges experienced by high stress subjects. Thus, the high and low stress subjects did not show differences in proportions of naïve versus memory T cells, a ratio that reflects the “immunological experience” of an individual. Although much work remains to be done, this study is an important example of how clues obtained from different psychophysiological, immune, cellular, and molecular parameters can be pieced together to begin an understanding of an important phenomenon, namely accelerated cellular aging in the immune system that is related to psychological stress.

Although stress may be categorized in many ways, it is useful to classify stressors as being acute (lasting for minutes to hours) or chronic (lasting for weeks to months to years) (Dhabhar & McEwen, 1997; Dhabhar & McEwen, 2001). While working with these categories, it is also important to distinguish between single versus repeated stressors and recognize that repeated acute stressor may contribute significantly to chronic stress (Dhabhar, McEwen, & Spencer 1997). Dhabhar and McEwen have proposed a “stress spectrum model” that attempts to explain the bi-directional effects of acute versus chronic stress on immune function (Dhabhar & McEwen, 1997; Dhabhar & McEwen, 2001). The model also discusses the concept of resilience that biological organisms show in response to the transition from acute to chronic stress. It has been proposed that in healthy individuals acute stressors generally activate salubrious or health promoting aspects of psychophysiology whereas chronic stressors generally have maladaptive effects (Dhabhar, Miller, McEwen, & Spencer 1995; Dhabhar, 1998; Dhabhar and McEwen, 2001). The term “allostatic load” defines a useful concept for understanding the progressive “wear and tear” experienced by biological organisms as they attempt to maintain allostasis (homeostatic range of psychophysiological set points) in response to chronic stress exposure (McEwen, 1998; McEwen, 2002).

Decreased reactivity of the stress axes increases susceptibility to autoimmune disease. Interestingly, although most studies examining the effects of stress on immune function have shown stress to be immunosuppressive, an impressive body of work has clearly laid out the yin-yang relationships between physiological stress responses and regulation of immune function. These studies have shown that dysregulated stress reactivity can also have harmful consequences resulting in increased susceptibility to autoimmune and pro-inflammatory disorders (Mason, MacPhee, & Antoni 1990; Sternberg et al., 1992; Harbuz et al., 1997; Sternberg, 2001; Harbuz, Chover-Gonzalez, & Jessop 2003). In a series of seminal studies, Sternberg et al. (1989) showed that decreased HPA axis reactivity to inflammatory stimuli results in increased susceptibility to experimental arthritis (Sternberg et al., 1989; Sternberg et al., 1989; Sternberg et al., 1992). A similar role for HPA axis mediated endogenous immunoregulation has been shown for development of autoimmune thyroiditis, lupus erythematosus, and avian scleroderma in Obese strain (OS) chickens (Wick, Sgonc, & Lechner, 1998) and experimental autoimmune encephalomyelitis in rats (Whitacre, Dowdell, & Griffin, 1998). Complementing these pre-clinical studies, a series of elegantly conducted clinical studies (Buske-Kirschbaum & Hellhammer, 2003) have shown that patients with atopic dermatitis (Buske-Kirschbaum et al., 1997; Buske-Kirschbaum, Jobst, & Hellhammer, 1998; Buske-Kirschbaum, Geib, & Hellhammer, 2001), and asthma (Buske-Kirschbaum et al., 2003) show decreased reactivity of their HPA axes. Studies of pediatric rheumatic diseases suggest a similar HPA axis deficiency coupled with other pro-inflammatory hormonal biases (Chikanza, Kuis, & Heijnen, 2000). Differences in NK cell stress reactivity and beta(2)-adrenoreceptor upregulation on PBMC have been observed in patients with systemic lupus erythematosus (Pawlak et al., 1999). A more complex role for sympathetic nervous system involvement in autoimmune disease has also been proposed (Kuis et al., 1996; Kavelaars et al., 1998).

Psychosocial interventions influence aspects of disease progression that may be mediated through immunological factors. (Kiecolt-Glaser & Glaser, 1992; Fawzy, 1995; van der Pompe et al., 1996; Blake-Mortimer et al., 1999; Miller & Cohen, 2001). Examples include psychosocial intervention involving weekly supportive group therapy and self-hypnosis for pain that increased survival of patients with metastatic breast cancer (Spiegel et al., 1989) and similar interventions that have been shown to decrease anxiety and stress and enhance immune function in women surgically treated for breast cancer (Andersen et al., 2004), cognitive behavioral stress management (CMSM) interventions for breast cancer (McGregor et al., 2004) and HIV+ patients (Antoni et al., 1990; Antoni et al., 2000; Antoni, 2003), exercise-related interventions for HIV+ patients (LaPerriere et al., 1994), and mindfulness-based stress reduction interventions for early stage breast and prostate cancer patients (Carlson et al., 2004). These studies suggest

that psychosocial interventions may have clinically important benefits that affect stress status, immune function, and health or patients.

Other psychophysiological factors have been shown to affect immune parameters and health. Social support is an important factor that is positively correlated with immune function and health (Cohen, 1988; McGough, 1990; Lekander et al., 1996; Uchino, Cacioppo, & Kiecolt-Glaser 1996; Spiegel et al., 1998). The “physiology of marriage” has been suggested to exert both positive and negative effects on immune function and health depending on the quality of the marriage (Robles & Kiecolt-Glaser, 2003). Anxiety was shown to affect anticipatory immune reactions in women receiving adjuvant chemotherapy for breast cancer (Fredrikson et al., 1993). Self-rated health is related to levels of circulating cytokines (Lekander et al., 2004). Prenatal stress (Coe et al., 2002) and early rearing conditions (Coe et al., 1992) have been shown to induce long-lasting effects on behavior (Roughton et al., 1998) and immune responses (Boccia et al., 1997) in adulthood in nonhuman primates (Coe, Lubach, & W. B. 1989; Gorman, Mathew, & Coplan 2002). Negative emotions (Kiecolt-Glaser et al., 2002) and behavior (Kiecolt-Glaser et al., 1993) have also been shown to affect endocrine and immune function. It has also been suggested that personality-related factors may affect immune responses (Segerstrom, 2000) and susceptibility to disease (Segerstrom, 2003). Studies have shown that psychological and mood disorders like depression (Herbert & Cohen, 1993; Maes, 1993; Maes, 1995; Irwin, 1999; Kiecolt-Glaser & Glaser, 2002), anxiety disorders (Koh & Lee, 1998), and post traumatic stress disorder (PTSD) (Watson et al., 1993; Ironson et al., 1997) have significant effects on endocrine and immune function. Recent studies have also shown that dysregulated circadian rhythms may have profound deleterious effects on immune function and health (Sephton, Sapolsky, Kraemer, & Spiegel, 2000; Sephton and Spiegel, 2003). The role of pain and the associated role of opioids in modulating immune function has been the subject of numerous studies (Page, Ben-Eliyahu, Yirmiya, & Liebeskind, 1993; Page & Ben-Eliyahu, 1997). Sleep dysregulation has been shown to have negative effects on immune function and health (Toth & Rehg, 1998; Van Cauter & Spiegel, 1999; Irwin, 2002; Irwin & Rinetti, 2004).

Changes within the immune system can affect the nervous and endocrine systems and have short- and long-term psychological effects. Interestingly, the interactions between psychophysiological and immune factors are not unidirectional but are reciprocal in nature. It has been suggested the immune system can act as a sensory organ for communicating information about changes in immune activation to the CNS (Blalock, 1984). Numerous studies have shown that changes in immune function can have profound reciprocal psychological, behavioral, and physiological effects (for review see: Besedovsky & Sorkin, 1977; Black, 1994; Miller, 1998; Dunn, 2000; Dantzer, 2001;

Capuron & Dantzer, 2003; Harbuz, 2003; Maier & Watkins, 2003; Raison & Miller, 2003; Straub, 2004). Examples of immune system effects on the nervous system include observed generation of sickness behavior by cytokines (Dantzer, 2001; Larson & Dunn, 2001), cytokine effects on sexual activity (Avitsur & Yirmiya, 1999), changes in circulating hormone levels, metabolic effects of immune activation (Besedovsky et al., 1975; Del Rey & Besedovsky, 1992; Besedovsky & del Rey, 2000), and immune activation induced depression in women with arthritis (Zautra et al., 2004). It is thought that the adaptive effects of this feedback from the immune system to the brain induce the individual to get more rest and stay out of harm’s way to give the immune system the maximal chance for dealing with the wound, infection, or immune challenge at hand.

A body of literature related to sickness behavior (Opp & Imeri, 1999), now shows that changes in immune activation can have profound effects on sleep related parameters and sleep promotion (Krueger et al., 1994; Krueger & Majde, 2003; Opp & Toth, 2003; Toth & Hughes, 2004). Several pathways have been proposed to explain how immune messengers exert effects on the nervous and endocrine systems and on behavior (for review see Watkins, Maier, & Goehler, 1995; Goehler et al., 2000; Dantzer, 2001; Quan & Herkenham, 2002). These include direct CNS effects of cytokines entering the brain through circumventricular organs (Konsman, Kelley, & Dantzer, 1999), effects mediated through the vagus nerve (Laye et al., 1995; Watkins et al., 1995), effects mediated through actions on endothelial cells of the blood brain barrier (Quan, He, & Lai, 2003).

Importantly, it has been shown that aspects of mood disorders like depression may be mediated by CNS actions of cytokines (Miller, 1998; Yirmiya et al., 2000; Capuron et al., 2002; Raison and Miller, 2003) and that anti-depressants may affect cytokine production (Kenis & Maes, 2002) and HPA axis function (Miller, Pariante, & Pearce 1999; Pariante & Miller, 2001). A series of landmark studies has elucidated the deleterious effects of cytokine induced depression during therapeutic interventions involving immunotherapy for diseases like hepatitis C (Raison et al., 2005), malignant melanoma (Capuron et al., 2002; Capuron et al., 2003) and other cancers (Capuron et al., 2001), and alleviated the risk of major depression and depression-induced noncompliance by pre-treatment of patients with anti-depressants (Musselman et al., 2001). These studies illustrate the clinical relevance of the profound reciprocal interactions that can take place between psychophysiological factors and the immune system.

MEASUREMENT OF INNATE AND CELL-MEDIATED IMMUNE PARAMETERS

Table 15.1 shows standard techniques for measuring some of the key immune parameters discussed earlier. (The reader is referred to *Current Protocols in Immunology* (2001) for more detailed descriptions of the protocols used

Table 15.1. Measurement of innate and cell-mediated immunity in human studies

Immune parameter	Analyte/site	Common assay technique
Innate immunity		
Neutrophil	Blood Tissue	Flow cytometry (FC) Myeloperoxidase (MPO) assay
Monocyte	Blood	FC
NK cell	Blood	FC, CD16+CD56+
NK activity	Blood	In vitro lysis of target tumor cells
TNF- α , IL-1a, IL-1b	Plasma/serum In vitro stimulated Intracellular	Immunoassay Immunoassay FC
C-reactive protein	Plasma/serum	Immunoassay
Cell-mediated immunity		
T cell	Blood	FC, CD3+
T helper cell (Th)	Blood	FC, CD3+CD4+
Cytolytic T cell (CTL)	Blood	FC, CD3+CD8+
Naïve T cell	Blood	FC, CD3+CD45RA+CD45RB-
Activated/memory T cell	Blood	FC, CD3+CD45RA-CD45RB+
IFN- γ , IL-2, IL-12	Plasma/serum In vitro stimulated Intracellular	Immunoassay Immunoassay FC
DTH Test	Skin	Intradermal Ag injection Measurement of erythema & induration

to make the measurements shown in Table 15.1.) It is important to carefully evaluate how changes in any measured parameter might reflect the capacity of the subject to mount *vivo* immune responses in the context of the specific experiment or study at hand. In order to achieve this, one has to minimize potential confounding factors that come from the subject on whom the measurements are being made. Such factors, that are similar to potential confounding factors for most studies involving psychophysiology, include smoking, alcohol and caffeine intake, nutritional status, sleep patterns, physical activity (or lack thereof), use of medications, obesity, use of hormonal agents or contraceptives, and overall health status (for review see Kiecolt-Glaser & Glaser, 1988; Uchino et al., 2000) and can have significant effects on immune parameters (Pruett, Ensley, & Crittenden, 1993). The time of day of blood collection is also an important factor to keep constant because endocrine and cellular circadian rhythms can have significant effects on immune function.

Importance of the effects of stress on immune cell distribution. Immune cells or leukocytes circulate continuously from the blood, into various organs, and back into the blood. This circulation is essential for the maintenance of an effective immune defense network (Sprent and Tough,

1994). Because the blood is the most accessible and commonly used compartment for human studies, it is important to carefully evaluate how changes in blood immune parameters might reflect *in vivo* immune function in the context of the specific experiments or study at hand. Moreover, because most blood collection procedures involve a certain amount of stress, because all patients or subjects will have experienced stress in some manner, and because many studies of psychophysiological effects on immune function focus on stress, it is important to keep in mind the effects of stress on blood leukocyte distribution.

The numbers and proportions of leukocytes in the blood provide an important representation of the state of distribution of leukocytes in the body and of the state of activation of the immune system. Stress has been shown to induce a significant decrease in blood leukocyte numbers in fish (Pickford et al., 1971), mice (Jensen, 1969; Schwab et al., 2005), rats (Rinner et al., 1992; Dhabhar et al., 1994; Dhabhar et al., 1995), rabbits (Toft et al., 1993), horses (Snow, Ricketts, & Mason, 1983), nonhuman primates (Morrow-Tesch, McGlone, & Norman, 1993), and humans (Herbert & Cohen, 1993; Schedłowski et al., 1993). In fact, decreases in blood leukocyte numbers were used as an indirect measure for increases in plasma corticosterone before methods were available to directly assay the

hormone (Hoagland, Elmadjian, & Pincus 1946). However, it is commonly assumed that in human studies, stress (especially acute stress) mainly induces an increase in blood leukocyte numbers. Many studies have indeed shown that stress can increase rather than decrease blood leukocyte numbers in humans (Naliboff et al., 1991; Schedlowski et al. 1993; Brosschot et al., 1994; Mills et al., 1995). In fact, stress-induced increases (rather than decreases) in blood leukocyte numbers are more commonly reported in human studies. This apparent contradiction is resolved when three important factors are taken into account. First, stress-induced increases in blood leukocyte numbers are observed following stress conditions that primarily result in the activation of the sympathetic nervous system. These stressors are often of a short duration (a few minutes) or are relatively mild (e.g., public speaking) (Naliboff et al., 1991; Schedlowski et al., 1993; Brosschot et al., 1994; Mills et al., 1995). Second, the increase in leukocyte numbers may be accounted for largely by stress- or catecholamine-induced increases in granulocytes, NK cells, and subpopulations of T cells (Naliboff et al., 1991; Schedlowski et al., 1993; Brosschot et al., 1994; Mills et al., 1995; Benschop, Rodriguez-Feuerhahn, & Schedlowski, 1996; Bosch et al., 2003). Because granulocytes form a large proportion of circulating leukocytes in humans (60–80% granulocytes) an increase in granulocyte numbers is reflected as an increase in total leukocyte numbers in contrast to rats and mice (10–20% granulocytes). Third, stress or pharmacologically-induced increases in glucocorticoid hormones induce a significant decrease in blood lymphocyte and monocyte numbers (Hoagland et al., 1946; Stein, Ronzoni, & Gildea, 1951; Schedlowski et al., 1993; Dhabhar et al., 1995; Dhabhar et al., 1996). Thus, stress conditions that result in a robust activation of the HPA axis will result in a decrease in blood leukocyte numbers. However, such conditions are more difficult to create with acute stressors that are generally used in human studies.

It has been proposed, that acute stress induces an initial increase followed by a decrease in blood leukocyte numbers according to the following pattern (Dhabhar and McEwen, 2001): Stress conditions which result in activation of the sympathetic nervous system, especially conditions which induce high levels of norepinephrine, may induce an increase in circulating leukocyte numbers. These conditions may occur during the very beginning of a stress response, very short duration stress (order of minutes), mild psychological stress, or during exercise. In contrast, stress conditions which result in the activation of the hypothalamic-pituitary-adrenal (HPA) axis induce a decrease in circulating leukocyte numbers. These conditions often occur during the later stages of a stress response, long duration acute stressors (order of hours), or during severe psychological, physical, or physiological stress. An elegant and interesting example in support of this hypothesis comes from Schedlowski et al. who measured changes in blood T cell and NK cell numbers as well as plasma catecholamine and corti-

sol levels in parachutists (Schedlowski et al., 1993). Measurements were made 2 hours before, immediately after, and 1 hour after the jump. Results showed a significant increase in T cell and NK cell numbers immediately (minutes) after the jump which was followed by a significant decrease 1 hour after the jump. An early increase in plasma catecholamines preceded early increases in lymphocyte numbers whereas the more delayed rise in plasma cortisol preceded the late decrease in lymphocyte numbers (Schedlowski et al., 1993). Importantly, changes in NK cell activity and antibody-dependent cell-mediated cytotoxicity (ADCC) closely paralleled changes in blood NK cell numbers, thus suggesting that changes in leukocyte numbers may be an important mediator of apparent changes in leukocyte “activity.” Similarly, Rinner et al. have shown that a short stressor (1 min handling) induced an increase in mitogen-induced proliferation of T and B cells obtained from peripheral blood, whereas a longer stressor (2 h immobilization) induced a decrease in the same proliferative responses (Rinner et al., 1992). In another example, Manuck et al. showed that acute psychological stress induced a significant increase in blood CTL numbers only in those subjects who showed heightened catecholamine and cardiovascular reactions to stress (Manuck et al., 1991).

Therefore, it has been proposed that an acute stress response induces biphasic changes in blood leukocyte numbers (Dhabhar and McEwen, 2001). Soon after the beginning of stress (order of minutes) or during mild acute stress, or exercise, catecholamine hormones and neurotransmitters induce the body's “soldiers” (leukocytes) to exit their “barracks” (spleen, lung, marginated pool, and other organs) and enter the “boulevards” (blood vessels and lymphatics) (Dhabhar, 1998; Dhabhar et al., 2000; Dhabhar and McEwen, 2001). This results in an increase in blood leukocyte numbers, the effect being most prominent for NK cells and granulocytes. As the stress response continues, activation of the HPA axis results in the release of glucocorticoid hormones which induce leukocytes to exit the blood and take position at potential “battle stations” (skin, mucosal lining of gastro-intestinal and urinary-genital tracts, lung, liver, and lymph nodes) in preparation for immune challenges which may be imposed by the actions of the stressor (Dhabhar et al., 1995; Dhabhar & McEwen, 1996). Such a redistribution of leukocytes results in a decrease in blood leukocyte numbers, the effect being most prominent for T and B lymphocytes, NK cells, and monocytes. Thus, acute stress may result in a redistribution of leukocytes from the barracks, through the boulevards, and to potential battle stations within the body (Dhabhar & McEwen, 1999).

It is likely that stress-induced changes in leukocyte distribution are mediated by changes in either the expression, or affinity, of adhesion molecules on leukocytes and/or endothelial cells. It has been suggested that following stress or glucocorticoid-treatment, specific leukocyte subpopulations (being transported by blood and lymph

through different body compartments) may be selectively retained in those compartments in which they encounter a stress- or glucocorticoid-induced “adhesion match” (Dhabhar, 1996; Dhabhar and McEwen, 1999). As a result of this selective retention, the proportion of some leukocyte subpopulations would decrease in the blood whereas it increases in the organ in which the leukocytes are retained (e.g., the skin) (Dhabhar and McEwen, 1996). We propose that adhesion molecules such as the selectins and their ligands, which mediate early adhesion events such as leukocyte rolling (McEver, 1994), are likely mediators of a stress-induced retention of blood leukocytes within the vasculature of target organs such as the skin and lymph nodes.

Support for the “selective retention” hypothesis comes from studies which show that prednisolone induces the retention of circulating lymphocytes within the bone marrow, spleen, and some lymph nodes thus resulting in a decrease in lymphocyte numbers in the thoracic duct and a concomitant decrease in peripheral blood (Spry, 1972; Cox & Ford, 1982). Moreover, glucocorticoid hormones also influence the production of cytokines (Danes & Araneo, 1989; Munck & Guyre, 1989), and lipocortins (Hirata, 1989) which in turn can affect the surface adhesion properties of leukocytes and endothelial cells (Issekutz, 1990). Further investigation of the effects of endogenous glucocorticoids (administered in physiologic doses, and examined under physiologic kinetic conditions) on changes in expression/activity of cell surface adhesion molecules and on leukocyte-endothelial cell adhesion is necessary.

In summary, when measuring immune responses, it is important to recognize the effects of acute and chronic stress on leukocyte distribution within the body. First, stress is an important focus for many studies examining the effects of psychophysiological factors on immune function. Second, even if stress is not the focus of the study per se, many clinical and experimental manipulations can be stressful and are likely to have unintended effects on immune parameters that need to be controlled for and recognized. For example, an adrenergic surge experienced by some individuals upon seeing a physician or nurse approach with a blood collection syringe or even a blood pressure cuff (white coat effect) may stimulate the catecholamine stress response enough to induce a transient leukocytosis. Third, it is important to recognize the difference between transient changes in leukocyte numbers as seen during acute stress and more long-term changes that are likely to be observed during chronic stress. Fourth, because the blood is the most widely sampled compartment for experimental and diagnostic purposes, an understanding of the conditions of blood collection and how they may induce transient unintended changes in endocrine and immune parameters would be useful and beneficial.

Importance of intensity, concentration, and duration. It is also important to keep in mind the effects of intensity (e.g., experimental stressors involving public speaking (Kirschbaum, Pirke, & Hellhammer 1993) are much

milder than those involving sky diving (Schedlowski et al., 1993) and concentration (e.g., amount of pharmacological agent administered) of the experimental manipulation under examination and the duration of manipulation or exposure (for review see Pruett, 2001). For studies that involve administering stress (Rinner et al., 1992; Wood et al., 1993) and pharmacological agents, it is not uncommon to observe bell-shaped or U-shaped relationships between the concentration of agent administered and the degree of change observed in the measured immune parameter. For example, low physiological concentrations of endogenous glucocorticoid hormones have been shown to enhance skin cell mediated immunity whereas high pharmacological concentrations of endogenous glucocorticoids and low concentrations of their synthetic analogs like dexamethasone are potently immunosuppressive (Dhabhar and McEwen, 1999). One might expect to see similar relationships between other psychophysiological parameters and changes in immune function. Cases where such relationships are observed are important to clearly delineate and report just as cases where such relationships are not observed.

FUTURE DIRECTIONS

The past few decades have seen tremendous advances in our understanding of how psychophysiological factors can affect specific immune parameters or aspects of immune function. There is convincing evidence to show that there are connections between psychological and immunological responses that are mediated by physiological factors involving nerves, neurotransmitters, and hormones. Fortunately, each of these fields of research addressing these factors has also seen tremendous advances independently of the others. This presents a golden opportunity for integrational scientists such as those in the field of psychoneuroimmunology, to further the integration between psychophysiology and immune function. Tremendous advances have also been made in the technologies that allow integrational scientists to delve deeper and cast wider as they attempt to understand the biological mechanisms by which mind, physiology, and body work together. Technological advances that allow us to measure more, for longer and more accurately are an amazing asset while conducting multi-dimensional and interdisciplinary studies. For example, advances in flow cytometry allow the simultaneous analyses of multiple immune markers on a single cell and allow the gathering of information on these markers from thousands of representative cells. This greatly increases the amount of information and the accuracy of information that can be obtained about the cellular effects of psychophysiology on the number and relative proportions of immune cells as well as the capacity for adhesion, migration, activation, killing, antigen presentation, antigen specificity, or receptivity to a host of cytokines, hormones, and neurotransmitters. Similarly, advances in gene and protein arrays, that enable

the simultaneous analysis of thousands of molecules from minute quantities of samples, have significantly increased our ability to examine the molecular effects of psychophysiological manipulations.

Future studies need to harness these and other technological advances with insightful collaboration between experts. It is extremely important to recognize that technology makes it relatively easy to perform multiple manipulations and make thousands of measurements but it is only using a well thought-out, carefully designed and collaborative approach involving experienced investigators from all relevant fields, that one is likely to be successful in identifying the most meaningful problems or questions and in obtaining relevant, useful and clinically applicable information.

In summary, the field of psychoneuroimmunology has made many advances in recent decades. Supported by the pioneering work of the founders of the field and studies that are currently combining state of the art techniques to tackle fundamental questions regarding the effects of psychophysiology on immune function, the field has made tremendous progress and been firmly established. Fortunately, there is also tremendous personal interest in this field – people the world over and from different walks of life are interested in understanding how their emotional health might affect their physical health. It behooves us not only to explain how psychophysiology affects immunology and health but to go one step further and understand and explain how an individual can harness their mind and body's natural defenses to maximize the salubrious effects of mind-body interactions. In the case of disease states, the field needs to better understand and explain how these interactions can be harnessed in a therapeutic setting to synergize with conventional medical approaches to rapidly and effectively bring relief to the patient with minimal side effects.
